---

We perform hindcasts Мы делаем ретроспективные прогнозы

Coronal mass ejections (CMEs) and coronal jets are two types of common solar eruptive phenomena, which often independently happen at different spatial scales. Chen+, 2021

---

#### Collection, Collation, and Comparison of 3D Coronal CME Reconstructions

### RESEARCH TOPIC

#### The Magnetic Structures and Their Role in The Evolution of Coronal Mass Ejections

Front. Phys. 2021 <https://www.frontiersin.org/research-topics/17314/the-magnetic-structures-and-their-role-in-the-evolution-of-coronal-mass-ejections#articles>

---

Solar Orbiter First Results (Cruise Phase): many papers on <sup>3</sup>He-rich SEPs, near-relativistic electrons, stealth CME, ICMEs, GCR flux, Forbush

The first spacecraft coronagraph observations of CMEs were made by the OSO-7 coronagraph in the early 1970s (Tousey, [1973](#)). These were followed by better quality and longer periods of CME observations using **Skylab** (1973 – 1974; MacQueen *et al.*, [1980](#)), **P78-1 (Solwind)** (1979 – 1985; Sheeley Jr *et al.*, [1980](#)), and **SMM** (1980; 1984 – 1989; Hundhausen, [1999](#)). In late 1995, **SOHO** was launched and two of its three **LASCO** coronagraphs still operate today (Brueckner *et al.*, [1995](#)). Finally late in 2006, LASCO was joined by the **STEREO CORs** (Howard *et al.*, 2008a).

**CMEs on young, solar-type stars**

Alicia [Aarnio](#):

RHESSI Science Nuggets, No. 214, Dec 2013

[http://sprg.ssl.berkeley.edu/~tohban/wiki/index.php/CMEs\\_on\\_young\\_solar-type\\_stars](http://sprg.ssl.berkeley.edu/~tohban/wiki/index.php/CMEs_on_young_solar-type_stars)

stellar flares and CMEs behave like solar ones.

We find that the relationship between solar flare energy and associated CME mass follows a log-linear relationship over several orders of magnitude in both quantities. Further, we suggest this relationship holds to even higher flare energies and CME masses for young, solar-type stars. We use the relationship to estimate mass loss rates from 10<sup>-12</sup> to 10<sup>-9</sup> MSun yr<sup>-1</sup>. We have also found a set of conditions (frequent eruptions, >10<sup>-10</sup> MSun yr<sup>-1</sup>) in which CMEs can indeed slow stellar rotation toward the end of the TTS phase.

**Solar Flares and Coronal Mass Ejections: A Statistically Determined Flare Flux –CME Mass Correlation**

A.N. [Aarnio](#) · K.G. Stassun · W.J. Hughes · S.L. McGregor

Solar Phys (2011) 268: 195–212, **File**

In an effort to examine the relationship between flare flux and corresponding CME mass, we temporally and spatially correlate all X-ray flares and CMEs in the LASCO and GOES archives from 1996 to 2006. We cross-reference 6733 CMEs having wellmeasured masses against 12 050 X-ray flares having position information as determined from their optical counterparts. For a given flare, we search in time for CMEs which occur 10 – 80 minutes afterward, and we further require the flare and CME to occur within ±45° in position angle on the solar disk. There are 826 CME/flare pairs which fit these criteria. Comparing the flare fluxes with CME masses of these paired events, we find CME mass increases with flare flux, following an approximately log-linear, broken relationship: in the limit of lower flare fluxes,  $\log(\text{CME mass}) \propto 0.68 \log(\text{flare flux})$ , and in the limit of higher flare fluxes,  $\log(\text{CME mass}) \propto 0.33 \log(\text{flare flux})$ . We show that this broken power-law, and in particular the flatter slope at higher flare fluxes, may be due to an observational bias against CMEs associated with the most energetic flares: halo CMEs. Correcting for this bias yields a single power-law relationship of the form  $\log(\text{CME mass}) \propto 0.70 \log(\text{flare flux})$ . This function describes the relationship between CME mass and flare flux over at least 3 dex in flare flux, from  $\approx 10^{-7} - 10^{-4} \text{ Wm}^{-2}$ .

**Serendipitous observation of a coronal mass ejection during the total solar eclipse of 14 December 2020**

[Guillermo Abramson](#)

2021

<https://arxiv.org/pdf/2106.00784.pdf>

We report observations of the total solar eclipse of 14 December 2020, during which a coronal mass ejection can be seen propagating. A comprehensive set of photographs covering a high dynamic range of exposure allow to characterize its dimensions. The displacement of the front can be seen occurring during the few minutes of totality.

**A Small-scale Eruption Leading to a Blowout Macrospicule Jet in an On-disk Coronal Hole**

Mitzi [Adams](#), Alphonse C. Sterling, Ronald L. Moore, and G. Allen Gary

2014 ApJ 783 11

We examine the three-dimensional magnetic structure and dynamics of a solar EUV-macroscopic jet that occurred on **2011 February 27** in an on-disk coronal hole. The observations are from the Solar Dynamics Observatory (SDO) Atmospheric Imaging Assembly (AIA) and the SDO Helioseismic and Magnetic Imager (HMI). The observations reveal that in this event, closed-field-carrying cool absorbing plasma, as in an erupting mini-filament, erupted and opened, forming a blowout jet. Contrary to some jet models, there was no substantial recently emerged, closed, bipolar-magnetic field in the base of the jet. Instead, over several hours, flux convergence and cancellation at the polarity inversion line inside an evolved arcade in the base apparently destabilized the entire arcade, including its cool-plasma-carrying core field, to undergo a blowout eruption in the manner of many standard-sized, arcade-blowout eruptions that produce a flare and coronal mass ejection. Internal reconnection made bright "flare" loops over the polarity inversion line inside the blowing-out arcade field, and external reconnection of the blowing-out arcade field with an ambient open field made longer and dimmer EUV loops on the outside of the blowing-out arcade. That the loops made by the external reconnection were much larger than the loops made by the internal reconnection makes this event a new variety of blowout jet, a variety not recognized in previous observations and models of blowout jets.

## **Effects of Initial Conditions on Magnetic Reconnection in a Solar Transient**

[Satyam Agarwal](#), [Ramit Bhattacharyya](#) & [Thomas Wiegmann](#)

[Solar Physics](#) volume 297, Article number: 91 (2022)

<https://doi.org/10.1007/s11207-022-02016-2>

Coronal magnetic field extrapolations are necessary to understand the magnetic field morphology of the source region in solar coronal transients. The extrapolation models are broadly classified into nonforce-free and force-free, depending on whether the model allows for a Lorentz force or not. Presently, these models are employed to carry out state-of-the-art data-driven and data-constrained magnetohydrodynamics (MHD) simulations to explore magnetic reconnection (MR)—the underlying cause of the transients. It is then imperative to study the influence of different extrapolation models on simulated evolution. For this purpose, the numerical model EULAG-MHD is employed to carry out simulations with different initial magnetic and velocity fields obtained through nonforce-free and force-free extrapolations. The selected active region is NOAA 11977, hosting a C6.6 class eruptive flare. Both extrapolations are found to be in good agreement with the observed line-of-sight and transverse magnetic fields. Further, a morphological comparison on the global scale and particularly for selected topologies, such as a magnetic null point and a hyperbolic flux tube (HFT), suggests that similar magnetic field line structures are reproducible in both models, although the extent of agreement between the two varies. Astoundingly, generation of a three-dimensional null near the HFT is observed in all the simulations, inferring the evolution to be independent of the particular initial field configuration. Moreover, the magnetic field lines (MFLs) undergoing MRs at the null point and HFT evolve similarly, further confirming the near independence of reconnection details on the chosen initial conditions. Consequently, both the extrapolation techniques can be suitable for initiating data-driven and data-constrained simulations.

## **Prediction of Solar Eruptions Using Filament Metadata**

Ashna [Aggarwal](#)<sup>1,2</sup>, Nicole Schanche<sup>2,3</sup>, Katharine K. Reeves<sup>2</sup>, Dustin Kempton<sup>4</sup>, and Rafal Angryk

2018 ApJS 236 15

<https://iopscience.iop.org/article/10.3847/1538-4365/aab77f/pdf>

We perform a statistical analysis of erupting and non-erupting solar filaments to determine the properties related to the eruption potential. In order to perform this study, we correlate filament eruptions documented in the Heliophysics Event Knowledgebase (HEK) with HEK filaments that have been grouped together using a spatiotemporal tracking algorithm. The HEK provides metadata about each filament instance, including values for length, area, tilt, and chirality. We add additional metadata properties such as the distance from the nearest active region and the magnetic field decay index. We compare trends in the metadata from erupting and non-erupting filament tracks to discover which properties present signs of an eruption. We find that a change in filament length over time is the most important factor in discriminating between erupting and non-erupting filament tracks, with erupting tracks being more likely to have decreasing length. We attempt to find an ensemble of predictive filament metadata using a Random Forest Classifier approach, but find the probability of correctly predicting an eruption with the current metadata is only slightly better than chance. **2012/01/09-13**

## **Automatic method for detection of solar coronal width using extreme ultra-violet (EUV) radiation**

Najmeh [Ahmadi](#), [Sherwin Parsi](#)

2019

<https://arxiv.org/pdf/1904.00104.pdf>

Solar corona, the last main layer of the atmosphere of the Sun, is detectable in the EUV and X-ray. The corona is expanding into space up to millions of kilometers and is observable during the eclipse. The temperature is increasing about millions of Kelvin. The investigation of this layer is significant for solar physicists because it is dynamic and features. Active regions (AR) and solar mass ejections (CMEs) are the important features in the solar corona. In this research, the solar limb and coronal width is studied from full-disk images at 284 Å taken by SOHO/EIT during eleven-year period (2000-2010). Next, using image processing methods and by applying region growing function, the corona is segmented and extracted from images in different angles. The radial velocities of CMEs are extracted.

## **Magnetic Interaction of a Super-CME with the Earth's Magnetosphere: Scenario for Young Earth**

Vladimir S. [Airapetian](#), Alex Gloer, William Danchi

Proceedings of 18th Cambridge Workshop on Cool Stars, Stellar Systems, and the Sun  
Proceedings of Lowell Observatory (9-13 June 2014) Edited by G. van Belle & H. Harris  
<http://arxiv.org/pdf/1410.7355v2.pdf>

Solar eruptions, known as Coronal Mass Ejections (CMEs), are frequently observed on our Sun. Recent Kepler observations of superflares on G-type stars have implied that so called super-CMEs, possessing kinetic energies 10 times of the most powerful CME event ever observed on the Sun, could be produced with a frequency of 1 event per 800-2000 yr on solar-like slowly rotating stars. We have performed a 3D time-dependent global magnetohydrodynamic simulation of the magnetic interaction of such a CME cloud with the Earth's magnetosphere. We calculated the global structure of the perturbed magnetosphere and derive the latitude of the open-closed magnetic field boundary. We also estimated energy fluxes penetrating the Earth's ionosphere and discuss the consequences of energetic particle fluxes on biological systems on early Earth.

## **The CME-productivity associated with flares from two active regions**

Adv. Space Res., 39(9), Pages 1469-1472, 2007

S. [Akiyama](#), S. Yashiro and N. Gopalswamy

We report on two flare-productive adjacent active regions (ARs), with different levels of coronal mass ejection (CME) association. AR 10039 and AR 10044 produced strong X-ray flares during their disk passages. We suggest that different pre-eruption evolution and magnetic configuration in the two regions might have contributed to the difference between the two ARs.

## **Evolution of CME Properties in the Inner Heliosphere: Prediction for Solar Orbiter and Parker Solar Probe**

Nada [Al-Haddad](#), [Noe Lugaz](#), [Stefaan Poedts](#), [Charles J. Farrugia](#) and, [Teresa Nieves-Chinchilla](#)  
ApJ **884** 179 **2019**

<https://arxiv.org/pdf/1910.04811.pdf>  
<https://sci-hub.se/10.3847/1538-4357/ab4126>

The evolution of the magnetic field and plasma quantities inside a coronal mass ejection (CME) with distance are known from statistical studies using data from 1 au monitors, planetary missions, Helios, and Ulysses. This does not cover the innermost heliosphere, below 0.29 au, where no data are yet publicly available. Here, we describe the evolution of the properties of simulated CMEs in the inner heliosphere using two different initiation mechanisms. We compare the radial evolution of these properties with that found from statistical studies based on observations in the inner heliosphere by Helios and MESSENGER. We find that the evolution of the radial size and magnetic field strength is nearly indistinguishable for twisted flux rope from that of writhed CMEs. The evolution of these properties is also consistent with past studies, primarily with recent statistical studies using in situ measurements and with studies using remote observations of CMEs.

## **Fitting and Reconstruction of Thirteen Simple Coronal Mass Ejections**

[Nada Al-Haddad](#), [Teresa Nieves-Chinchilla](#), [Neel P. Savani](#), [Noe Lugaz](#), [Ilija I. Roussev](#)  
Solar Phys. May 2018, 293:73

<https://arxiv.org/pdf/1804.02359.pdf>  
<https://link.springer.com/content/pdf/10.1007%2Fs11207-018-1288-3.pdf>

Coronal mass ejections (CMEs) are the main drivers of geomagnetic disturbances, but the effects of their interaction with Earth's magnetic field depend on their magnetic configuration and orientation. Fitting and reconstruction techniques have been developed to determine the important geometrical and physical CME properties. In many instances, there is disagreement between such different methods but also between fitting from in situ measurements and reconstruction based on remote imaging. Here, we compare three methods based on different assumptions for measurements of thirteen CMEs by the Wind spacecraft from 1997 to 2015. These CMEs are selected from the interplanetary coronal mass ejections catalog on [this https URL](#) due to their simplicity in terms of 1) small expansion speed throughout the CME and 2) little asymmetry in the magnetic field profile. This makes these thirteen events ideal candidates to compare codes that do not include expansion nor distortion. We find that, for these simple events, the codes are in relatively good agreement in terms of the CME axis orientation for six out of the 13 events. Using the Grad-Shafranov technique, we can determine the shape of the cross-section, which is assumed to be circular for the other two models, a force-free fitting and a circular-cylindrical non-force-free fitting. Five of the events are found to have a clear circular cross-section, even when this is not a pre-condition of the reconstruction. We make an initial attempt at evaluating the adequacy of the different assumptions for these simple CMEs. The conclusion of this work strongly suggests that attempts at reconciling in situ and remote-sensing views of CMEs must take in consideration the compatibility of the different models with specific CME structures to better reproduce flux ropes. **1997-01-10, 1998-08-**

### **Formation of Radio Type II Bursts During a Multiple Coronal Mass Ejection Event**

Firas [Al-Hamadani](#), Silja Pohjolainen, Eino Valtonen

[Solar Physics](#) December 2017, 292:183

<https://link.springer.com/content/pdf/10.1007%2Fs11207-017-1208-y.pdf>

We study the solar event on **27 September 2001** that consisted of three consecutive coronal mass ejections (CMEs) originating from the same active region, which were associated with several periods of radio type II burst emission at decameter–hectometer (DH) wavelengths. Our analysis shows that the first radio burst originated from a low-density environment, formed in the wake of the first, slow CME. The frequency-drift of the burst suggests a low-speed burst driver, or that the shock was not propagating along the large density gradient. There is also evidence of band-splitting within this emission lane. The origin of the first shock remains unclear, as several alternative scenarios exist. The second shock showed separate periods of enhanced radio emission. This shock could have originated from a CME bow shock, caused by the fast and accelerating second or third CME. However, a shock at CME flanks is also possible, as the density depletion caused by the three CMEs would have affected the emission frequencies and hence the radio source heights could have been lower than usual. The last type II burst period showed enhanced emission in a wider bandwidth, which was most probably due to the CME–CME interaction. Only one shock that could reliably be associated with the investigated CMEs was observed to arrive near Earth.

### **Microwave and EUV Observations of an Erupting Filament and Associated Flare and Coronal Mass Ejections**

C. E. [Alissandrakis](#), A. A. Kochanov, S. Patsourakos, A. T. Altyntsev, S. V. Lesovoi, N. N. Lesovoya  
Publ. Astron. Soc. Japan 65, No SP1, S8 [10 pages] (2013)

<http://pasj.asj.or.jp/v65/sp1/65S008/65S008.pdf>

A filament eruption was observed with the Siberian Solar Radio Telescope (SSRT) on **2012 June 23**, starting at around 06:40 UT, beyond the west limb. The filament could be followed in SSRT images to heights above  $1R_{\odot}$ , and coincided with the core of the CME, seen in LASCO C2 images. We briefly discuss the dynamics of the eruption: the top of the filament showed a smooth acceleration up to an apparent velocity of  $\sim 1100$  km s $^{-1}$ . Images behind the limb from STEREO-A show a two-ribbon flare and the interaction of the main filament, located along the primary neutral line, with an arch-like structure, oriented in the perpendicular direction. The interaction was accompanied by strong emission and twisting motions. The microwave images show a low-temperature component, a high-temperature component associated with the interaction of the two filaments and another high-temperature component apparently associated with the top of flare loops. We computed the differential emission measure from the high-temperature AIA bands and from this the expected microwave brightness temperature; for emission associated with the top of the flare loops, the computed brightness was 35% lower than the observed value.

### **Machine Learning-Based Investigation of the Associations between CMEs and Filaments**

M. [Al-Omari](#) , R. Qahwaji , T. Colak  and S. Ipson 

[Solar Phys.](#) 262(2), 511–539, 2010

In this work we study the association between eruptive filaments/prominences and coronal mass ejections (CMEs) using machine learning-based algorithms that analyse the solar data available between January 1996 and December 2001. The support vector machine (SVM) learning algorithm is used for the purpose of knowledge extraction from the association results. The aim is to identify patterns of associations that can be represented using SVM learning rules for the subsequent use in near real-time and reliable CME prediction systems. Timing and location data in the US National Geophysical Data Center (NGDC) filament catalogue and the Solar and Heliospheric Observatory/Large Angle and Spectrometric Coronagraph (SOHO/LASCO) CME catalogue are processed to associate filaments with CMEs. In the previous studies, which classified CMEs into gradual and impulsive CMEs, the associations were refined based on the CME speed and acceleration. Then the associated pairs were refined manually to increase the accuracy of the training dataset. In the current study, a data-mining system is created to process and associate filament and CME data, which are arranged in numerical training vectors. Then the data are fed to SVMs to extract the embedded knowledge and provide the learning rules that can have the potential, in the future, to provide automated predictions of CMEs. The features representing the event time (average of the start and end times), duration, type, and extent of the filaments are extracted from all the associated and not-associated filaments and converted to a numerical format that is suitable for SVM use. Several validation and verification methods are used on the extracted dataset to determine if CMEs can be predicted solely and efficiently based on the associated filaments. More than 14 000 experiments are carried out to optimise the SVM and determine the input features that provide the best performance.

## **Next-Generation Comprehensive Data-Driven Models of Solar Eruptive Events**

[Joel C. Allred](#), [Graham S. Kerr](#), [Meriem Alaoui](#), [Juan Camilo Buitrago-Casas](#), +++

White paper submitted to the Decadal Survey for Solar and Space Physics (Heliophysics) 2024-2033  
**2023**

<https://arxiv.org/pdf/2307.14946.pdf>

Solar flares and coronal mass ejections are interrelated phenomena that together are known as solar eruptive events. These are the main drivers of space weather and understanding their origins is a primary goal of Heliophysics. In this white paper, we advocate for the allocation of sufficient resources to bring together experts in observations and modeling to construct and test next generation data-driven models of solar eruptive events. We identify the key components necessary for constructing comprehensive end-to-end models including global scale 3D MHD resolving magnetic field evolution and reconnection, small scale simulations of particle acceleration in reconnection exhausts, kinetic scale transport of flare-accelerated particles into the lower solar atmosphere, and the radiative and hydrodynamics responses of the solar atmosphere to flare heating. Using this modeling framework, long-standing questions regarding how solar eruptive events release energy, accelerate particles, and heat plasma can be explored. To address open questions in solar flare physics, we recommend that NASA and NSF provide sufficient research and analysis funds to bring together a large body of researchers and numerical tools to tackle the end-to-end modeling framework that we outline. Current dedicated theory and modeling funding programs are relatively small scale and infrequent; funding agencies must recognize that modern space physics demands the use of both observations and modeling to make rapid progress. **2013-05-13**

## **Prediction of Geoeffective CMEs Using SOHO Images and Deep Learning.**

[Alobaid](#), K.A., Wang, J.T.L., Wang, H. et al.

Sol Phys 299, 159 (2024)

<https://doi.org/10.1007/s11207-024-02385-w>

<https://link.springer.com/content/pdf/10.1007/s11207-024-02385-w.pdf>

The application of machine learning to the study of coronal mass ejections (CMEs) and their impacts on Earth has seen significant growth recently. Understanding and forecasting CME geoeffectiveness are crucial for protecting infrastructure in space and ensuring the resilience of technological systems on Earth. Here we present GeoCME, a deep-learning framework designed to predict, deterministically or probabilistically, whether a CME event that arrives at Earth will cause a geomagnetic storm. A geomagnetic storm is defined as a disturbance of the Earth's magnetosphere during which the minimum Dst index value is less than  $-50$  nT. GeoCME is trained on observations from the instruments including LASCO C2, EIT, and MDI on board the Solar and Heliospheric Observatory (SOHO), focusing on a dataset that includes 136 halo/partial halo CMEs in Solar Cycle 23. Using ensemble and transfer learning techniques, GeoCME is capable of extracting features hidden in the SOHO observations and making predictions based on the learned features. Our experimental results demonstrate the good performance of GeoCME, achieving a Matthew's correlation

coefficient of 0.807 and a true skill statistics score of 0.714 when the tool is used as a deterministic prediction model. When the tool is used as a probabilistic forecasting model, it achieves a Brier score of 0.094 and a Brier skill score of 0.493. These results are promising, showing that the proposed GeoCME can help enhance our understanding of CME-triggered solar-terrestrial interactions. **17 September 2002**

## **Estimating Coronal Mass Ejection Mass and Kinetic Energy by Fusion of Multiple Deep-learning Models**

**2023** ApJL 958 L34

<https://iopscience.iop.org/article/10.3847/2041-8213/ad0c4a/pdf>

<https://arxiv.org/abs/2312.01691>

Coronal mass ejections (CMEs) are massive solar eruptions, which have a significant impact on Earth. In this paper, we propose a new method, called DeepCME, to estimate two properties of CMEs, namely, CME mass and kinetic energy. Being able to estimate these properties helps better understand CME dynamics. Our study is based on the CME catalog maintained at the Coordinated Data Analysis Workshops Data Center, which contains all CMEs manually identified since 1996 using the Large Angle and Spectrometric Coronagraph (LASCO) on board the Solar and Heliospheric Observatory. We use LASCO C2 data in the period between 1996 January and 2020 December to train, validate, and test DeepCME through 10-fold cross validation. The DeepCME method is a fusion of three deep-learning models, namely ResNet, InceptionNet, and InceptionResNet. Our fusion model extracts features from LASCO C2 images, effectively combining the learning capabilities of the three component models to jointly estimate the mass and kinetic energy of CMEs. Experimental results show that the fusion model yields a mean relative error (MRE) of 0.013 (0.009, respectively) compared to the MRE of 0.019 (0.017, respectively) of the best component model InceptionResNet (InceptionNet, respectively) in estimating the CME mass (kinetic energy, respectively). To our knowledge, this is the first time that deep learning has been used for CME mass and kinetic energy estimations.

Coronal mass ejection (CME) is a highly energetic solar phenomenon. It has a significant impact on the space weather in the near-Earth environment. With the accumulation of CME observations, it becomes more challenging to handle them manually. Therefore, we need an automatic method for identifying CMEs. We propose an unsupervised method for classifying and detecting changes in CMEs. The method consists of four main steps: (i) feature extraction: features derived from difference-image and features derived from pretrained convolutional neural networks (CNN), (ii) dimensional reduction using Principal Component Analysis (PCA), (iii) unsupervised classification using K-mean clustering based on PCA components and (iv) morphological post-processing to improve the clustering output. We compare the results with manual catalog (e.g., coordinated data analysis workshops (CDWA) data center) and automatic detection catalogs (e.g., solar eruption detection system (SEEDS), computer-aided CME tracking (CACTus) and coronal image processing (CORIMP)). The comparison is based on CME characteristics (e.g., time of first appearance, position angle, angular width and velocity). We demonstrate the benefit of this unsupervised method, which produces comparable results to classical methods. **2011 November 22, 2014 February 9, 2016 January 8, 2017 September 6**

## **Laboratory study of the torus instability threshold in solar-relevant, line-tied magnetic flux ropes**

<https://doi.org/10.3847/1538-4357/abda4b>

Coronal mass ejections (CME) occur when long-lived magnetic flux ropes (MFR) anchored to the solar surface destabilize and erupt away from the Sun. This destabilization is often described in terms of an ideal magnetohydrodynamic (MHD) instability called the torus instability. It occurs when the external magnetic field decreases sufficiently fast such that its decay index,  $n = -z \partial(\ln B) / \partial z$  is larger than a critical value,  $n > n_{cr}$ , where  $n_{cr} = 1.5$  for a full, large aspect ratio torus. However, when this is applied to solar MFRs, a range of conflicting values for  $n_{cr}$  is found in the literature. To investigate this discrepancy, we have conducted laboratory experiments on arched, line-tied flux ropes and have applied a theoretical model of the torus instability. Our model describes an MFR as a partial torus with footpoints anchored in a conducting surface and numerically calculates various magnetic forces on it. This calculation yields a better prediction of  $n_{cr}$  which takes into account the specific parameters of the MFR. We describe a systematic methodology to properly translate laboratory results to their solar counterparts, provided that the MFRs have sufficiently small edge safety factor, or equivalently, large enough twist. After this translation, our model predicts that  $n_{cr}$  in solar conditions often falls near  $n_{Solcr} \sim 0.9$  and within a larger range of  $n_{Solcr} \sim (0.7, 1.2)$  depending

on the parameters. The methodology of translating laboratory MFRs to their solar counterparts enables quantitative investigations of the initiation of CMEs through laboratory experiments. These experiments allow for new physics insights that are required for better predictions of space weather events but are difficult to obtain otherwise.

Coronal mass ejections (CMEs) are more energetic than any other class of solar phenomena. They arise from the rapid release of up to 10<sup>33</sup> erg of magnetic energy mainly in the form of particle acceleration and bulk plasma motion. Their stellar counterparts, presumably involving much larger energies, are expected to play a fundamental role in shaping the environmental conditions around low-mass stars, in some cases perhaps with catastrophic consequences for planetary systems due to processes such as atmospheric erosion and depletion. Despite their importance, the direct observational evidence for stellar CMEs is almost non-existent. In this way, numerical simulations constitute extremely valuable tools to shed some light on eruptive behavior in the stellar regime. Here we review recent results obtained from realistic modeling of CMEs in active stars, highlighting their key role in the interpretation of currently available observational constraints. We include studies performed on M-dwarf stars, focusing on how emerging signatures in different wavelengths related to these events vary as a function of the magnetic properties of the star. Finally, the implications and relevance of these numerical results are discussed in the context of future characterization of host star-exoplanet systems.

Coronal mass ejections (CMEs) on stars other than the Sun have proven very difficult to detect. One promising pathway lies in the detection of type II radio bursts. Their appearance and distinctive properties are associated with the development of an outward propagating CME-driven shock. However, dedicated radio searches have not been able to identify these transient features in other stars. Large Alfvén speeds and the magnetic suppression of CMEs in active stars have been proposed to render stellar eruptions "radio-quiet". Employing 3D magnetohydrodynamic simulations, we study here the distribution of the coronal Alfvén speed, focusing on two cases representative of a young Sun-like star and a mid-activity M-dwarf (Proxima Centauri). These results are compared with a standard solar simulation and used to characterize the shock-prone regions in the stellar corona and wind. Furthermore, using a flux-rope eruption model, we drive realistic CME events within our M-dwarf simulation. We consider eruptions with different energies to probe the regimes of weak and partial CME magnetic confinement. While these CMEs are able to generate shocks in the corona, those are pushed much farther out compared to their solar counterparts. This drastically reduces the resulting type II radio burst frequencies down to the ionospheric cutoff, which impedes their detection with ground-based instrumentation. **Feb-March 2011 (CR 2107)**

<https://arxiv.org/pdf/1912.12314.pdf>

The stellar magnetic field completely dominates the environment around late-type stars. It is responsible for driving the coronal high-energy radiation (e.g. EUV/X-rays), the development of stellar winds, and the generation of transient events such as flares and coronal mass ejections (CMEs). While progress has been made for the first two processes, our understanding of the eruptive behavior in late-type stars is still very limited. One example of this is the fact that despite the frequent and highly energetic flaring observed in active stars, direct evidence for stellar CMEs is almost non-existent. Here we discuss realistic 3D simulations of stellar CMEs, analyzing their resulting properties in contrast with solar eruptions, and use them to provide a common framework to interpret the available stellar observations. Additionally, we present results from the first 3D CME simulations in M-dwarf stars, with emphasis on possible observable signatures imprinted in the stellar corona.

### **Coronal response to magnetically-suppressed CME events in M-dwarf stars**

ApJL 2019

<https://arxiv.org/pdf/1909.04092.pdf>

We report the results of the first state-of-the-art numerical simulations of Coronal Mass Ejections (CMEs) taking place in realistic magnetic field configurations of moderately active M-dwarf stars. Our analysis indicates that a clear, novel, and observable, coronal response is generated due to the collapse of the eruption and its eventual release into the stellar wind. Escaping CME events, weakly suppressed by the large-scale field, induce a flare-like signature in the emission from coronal material at different temperatures due to compression and associated heating. Such flare-like profiles display a distinctive temporal evolution in their Doppler shift signal (from red to blue), as the eruption first collapses towards the star and then perturbs the ambient magnetized plasma on its way outwards. For stellar fields providing partial confinement, CME fragmentation takes place, leading to rise and fall flow patterns which resemble the solar coronal rain cycle. In strongly suppressed events, the response is better described as a gradual brightening, in which the failed CME is deposited in the form of a coronal rain cloud leading to a much slower rise in the ambient high-energy flux by relatively small factors ( $\sim 2-3$ ). In all the considered cases (escaping/confined) a fractional decrease in the emission from mid-range coronal temperature plasma occurs, similar to the coronal dimming events observed on the Sun. Detection of the observational signatures of these CME-induced features requires a sensitive next generation X-ray space telescope.

## Suppression of **Coronal Mass Ejections in active stars** by an overlying large-scale magnetic field: A numerical study

[Julián D. Alvarado-Gómez](#), [Jeremy J. Drake](#), [Ofar Cohen](#), [Sofia P. Moschou](#), [Cecilia Garraffo](#)

ApJ 862, Issue 2, article id. 93 2018

<https://arxiv.org/pdf/1806.02828.pdf>

We present results from a set of numerical simulations aimed at exploring the mechanism of coronal mass ejection (CME) suppression in active stars by an overlying large-scale magnetic field. We use a state-of-the-art 3D magnetohydrodynamic (MHD) code which considers a self-consistent coupling between an Alfvén wave-driven stellar wind solution, and a first-principles CME model based on the eruption of a flux-rope anchored to a mixed polarity region. By replicating the driving conditions used in simulations of strong solar CMEs, we show that a large-scale dipolar magnetic field of 75 G is able to fully confine eruptions within the stellar corona. Our simulations also consider CMEs exceeding the magnetic energy used in solar studies, which are able to escape the large-scale magnetic field confinement. The analysis includes a qualitative and quantitative description of the simulated CMEs and their dynamics, which reveals a drastic reduction of the radial speed caused by the overlying magnetic field. With the aid of recent observational studies, we place our numerical results in the context of solar and stellar flaring events. In this way, we find that this particular large-scale magnetic field configuration establishes a suppression threshold around  $\sim 3 \times 10^{32}$  erg in the CME kinetic energy. Extending the solar flare-CME relations to other stars, such CME kinetic energies could be typically achieved during erupting flaring events with total energies larger than  $6 \times 10^{32}$  erg (GOES class  $\sim X70$ ). ## Identification of Low Coronal Sources of "Stealth" Coronal Mass Ejections Using New Image Processing Techniques

Nathalia [Alzate](#) and Huw Morgan

2017 ApJ 840 103

<https://sci-hub.ru/10.3847/1538-4357/aa6caa>

Coronal mass ejections (CMEs) are generally associated with low coronal signatures (LCSs), such as flares, filament eruptions, extreme ultraviolet (EUV) waves, or jets. A number of recent studies have reported the existence of stealth CMEs as events without LCSs, possibly due to observational limitations. Our study focuses on a set of **40 stealth CMEs** identified from a study by D'Huys et al. New image processing techniques are applied to high-cadence, multi-instrument sets of images spanning the onset and propagation time of each of these CMEs to search for possible LCSs. Twenty-three of these events are identified as small, low-mass, unstructured blobs or puffs, often occurring in the aftermath of a large CME, but associated with LCSs such as small flares, jets, or filament eruptions. Of the larger CMEs, seven are associated with jets and eight with filament eruptions. Several of these filament eruptions are different from the standard model of an erupting filament/flux tube in that they are eruptions of large, faint flux tubes that seem to exist at large heights for a long time prior to their slow eruption. For two of these events, we see an eruption in Large Angle Spectrometric Coronagraph C2 images and the consequent changes at the bottom edge of the eruption in EUV images. All 40 events in our study are associated with some form of LCS. We conclude that stealth CMEs arise from observational and processing limitations. **2012-01-07, 2012-02-22, 2012-02-29, 2012-04-22, June 02 2012, 2012-07-07, Aug 12 2012, Oct 20 2012, Nov 25 2012**

**Table 1** Description of the 2012 Events

## Low-Coronal Sources of "Stealth" Coronal Mass Ejections

Nathalia [Alzate](#) & Huw Morgan

UKSP Nuggets of 2016 #69

<http://www.uksolphys.org/uksp-nugget/69-low-coronal-sources-of-stealth-coronal-mass-ejections/>

Coronal mass ejections (CMEs) are generally associated with eruptive phenomena in the lower corona such as flares, filament eruptions, EUV waves or jets, collectively known as low-coronal signatures (LCSs). CMEs lacking these

signatures are identified as “stealth” events. In this nugget we report on our application of new image processing techniques [1,2] to events previously classified as stealth CMEs [3]. The processed EUV images reveal LCSs for all the listed “stealth” CMEs ranging from flares and jets to filament eruptions. Many events identified as CMEs are small blobs or puffs [4], often occurring in the aftermath of a large CME. Several of the larger, structured “stealth” CMEs arise from the slow eruption of sizeable, faint flux tubes situated at high latitude and large heights, therefore in regions of low density and weak magnetic field. A “stealth” CME is therefore a misconception arising from observational and processing limitations. **23 February 2012**

## **JETS, CORONAL "PUFFS," AND A SLOW CORONAL MASS EJECTION CAUSED BY AN OPPOSITE-POLARITY REGION WITHIN AN ACTIVE REGION FOOTPOINT**

N. [Alzate](#) and H. Morgan

**2016 ApJ 823 129**

During a period of three days beginning 2013 January 17, twelve recurrent reconnection events occur within a small region of opposing flux embedded within one footpoint of an active region, accompanied by flares and jets observed in EUV and fast and faint structureless "puffs" observed by coronagraphs. During the same period a slow structured CME gradually erupts, with one end anchored close to, or within, the jetting region. Four of the jet events occur in pairs—a narrow, primary jet followed within a few tens of minutes by a wider, more massive, jet. All the jets are slow, with an apparent speed of  $\sim 100 \text{ km s}^{-1}$ . The speed of the wide puffs in the coronagraph data is  $\sim 300 \text{ km s}^{-1}$ , and the timing of their appearance rules out a direct association with the EUV jetting material. The jet material propagates along large-scale closed-field loops and does not escape to the extended corona. The rapid reconfiguration of the closed loops following reconnection causes an outwardly propagating disturbance, or wave front, which manifests as puffs in coronagraph data. Furthermore, the newly expanded closed flux tube forms a pressure imbalance, which can result in a secondary jet. The reconnection events, through recurrent field reconfiguration, also leads to the gradual eruption of the structured flux tube appearing as the slow CME. Faint propagating coronal disturbances resulting from flares/jets may be common, but are usually obscured by associated ejections. Occasionally, the associated material ejections are absent, and coronal puffs may be clearly observed. **17-19 January 2013.**

An eruption loses its moorings among a series of small puffs. **17-19 January 2013.**

## **Magnetic cage and rope as the key for solar eruptions.**

[Amari](#) T, Canou A, Aly JJ, Delyon F, Alauzet F.

**2018 Nature 554, Issue 7691, 211–215. doi: 10.1038/nature24671**

<https://sci-hub.ru/10.1038/nature24671>

<https://www.nature.com/articles/nature24671>

Solar flares are spectacular coronal events that release large amounts of energy. They are classified as either eruptive or confined, depending on whether they are associated with a coronal mass ejection. Two types of model have been developed to identify the mechanism that triggers confined flares, although it has hitherto not been possible to decide between them because the magnetic field at the origin of the flares could not be determined with the required accuracy. In the first type of model, the triggering is related to the topological complexity of the flaring structure, which implies the presence of magnetically singular surfaces. This picture is observationally supported by the fact that radiative emission occurs near these features in many flaring regions. The second type of model attributes a key role to the formation of a twisted flux rope, which becomes unstable. Its plausibility is supported by simulations, by interpretations of some observations and by laboratory experiments. Here we report modelling of a confined event that uses the measured photospheric magnetic field as input. We first use a static model to compute the slowly evolving magnetic state of the corona before the eruption, and then use a dynamical model to determine the evolution during the eruption itself. We find that a magnetic flux rope must be present throughout the entire event to match the field measurements. This rope evolves slowly before saturating and suddenly erupting. Its energy is insufficient to break through the overlying field, whose lines form a confining cage, but its twist is large enough to trigger a kink instability, leading to the confined flare, as previously suggested. Topology is not the main cause of the flare, but it traces out the locations of the X-ray emission. We show that a weaker magnetic cage would have produced a more energetic eruption with a coronal mass ejection, associated with a predicted energy upper bound for a given region.

## **CORONAL MASS EJECTION INITIATION BY CONVERGING PHOTOSPHERIC FLOWS: TOWARD A REALISTIC MODEL**

T. [Amari](#)<sup>1</sup>, J.-J. Aly<sup>2</sup>, J.-F. Luciani<sup>1</sup>, Z. Mikic<sup>3</sup> and J. Linker

**2011 ApJ 742 L27**

In the context of coronal mass ejections triggering, we reconsider the class of models in which the evolution of an active region (AR) is driven by imposed boundary motions converging toward the polarity inversion line (PIL). We introduce a new model problem in which there is a large-scale flow with a diverging structure on the photosphere. This flow is reminiscent of that of the well-known moat flow around each of the two spots of a bipolar AR and transports only part of the magnetic flux toward the PIL. It is thus more compatible with observations than the one used in our previous study, which forced the whole positive and negative polarity parts of the AR approaching each other. We also include a diffusion term associated with small-scale turbulent photospheric motions, but keep the associated diffusivity at a low value in the particular study described here. We show that the evolution of an initial sheared force-free field first leads to the formation of a twisted flux rope which stays in equilibrium for some time. Eventually, however, the configuration suffers a global disruption whose underlying mechanism is found by energetic considerations to be nonequilibrium. It begins indeed when the magnetic energy becomes of the order of the energy of an accessible partially open field. For triggering an eruption by converging flows, it is thus not necessary to advect the whole AR toward the PIL, but only its central part.

## **CORONAL MASS EJECTION INITIATION: ON THE NATURE OF THE FLUX CANCELLATION MODEL**

T. [Amari](#)<sup>1,2,3,4</sup>, J.-J. Aly<sup>2</sup>, Z. Mikic<sup>3</sup>, and J. Linker<sup>3</sup>

Astrophysical Journal Letters, 717:L26–L30, 2010 July, [File](#)

We consider a three-dimensional bipolar force-free magnetic field with a nonzero magnetic helicity, occupying a half-space, and study the problem of its evolution driven by an imposed photospheric flux decrease. For this specific setting of the Flux Cancellation Model describing coronal mass ejections occurring in active regions, we address the issues of the physical meaning of flux decrease, of the influence on field evolution of the size of the domain over which this decrease is imposed, and of the existence of an energetic criterion characterizing the possible onset of disruption of the configuration. We show that (1) the imposed flux disappearance can be interpreted in terms of transport of positive and negative fluxes toward the inversion line, where they get annihilated. (2) For the particular case actually computed, in which the initial state is quite sheared, the formation of a twisted flux rope and the subsequent global disruption of the configuration are obtained when the flux has decreased by only a modest amount over a limited part of the whole active region. (3) The disruption is produced when the magnetic energy becomes of the order of the decreasing energy of a semi-open field, and then before reaching the energy of the associated fully open field. This suggests that the mechanism leading to the disruption is nonequilibrium as in the case where flux is imposed to decrease over the whole region.

## **Magnetic flux ropes: Fundamental structures for eruptive phenomena**

Tahar [Amari](#) and Jean-Jacques Aly<sup>2</sup>

Proceedings of the International Astronomical Union / Volume 4 / Symposium S257, pp 211 - 222 ,

Published online: 16 Mar 2009, [File](#)

<http://journals.cambridge.org/action/displayIssue?iid=4866212>

We consider some general aspects of twisted magnetic flux ropes (TFR), which are thought to play a fundamental role in the structure and dynamics of large scale eruptive events. We first discuss the possibility to show the presence of a TFR in a pre-eruptive configuration by using a model along with observational informations provided by a vector magnetograph. Then we present, in the framework of a generic model in which the coronal field is driven into an evolution by changes imposed at the photospheric level, several mechanisms which may lead to the formation and the disruption of a TFR, including the development of a MHD instability, and we discuss the issues of the energy and helicity contents of an erupting configuration. Finally we report some results of a recent and more ambitious approach to the physics of TFRs in which one tries to describe in a consistent way their rising through the convection zone, their emergence through the photosphere, and their subsequent evolution in the corona. ## **CORONAL MASS EJECTION INITIATION AND COMPLEX TOPOLOGY CONFIGURATIONS IN THE FLUX CANCELLATION AND BREAKOUT MODELS**

T. [Amari](#), J. J. Aly, Z. Mikic and J. Linker

The Astrophysical Journal, 671: L189–L192, 2007

<http://www.journals.uchicago.edu/doi/pdf/10.1086/524942>

We present some new results showing that the flux cancellation model for coronal mass ejections (CMEs) works well also in a complex-topology magnetic field. We consider as a model problem the case of the flux cancellation-driven evolution of a quadrupolar configuration.

## **STABILITY AND DYNAMICS OF A FLUX ROPE FORMED VIA FLUX EMERGENCE INTO THE SOLAR ATMOSPHERE**

J. M. [An](#)<sup>1</sup> and T. Magara

2013 ApJ 773 21

We study the stability and dynamics of a flux rope formed through the emergence of a twisted magnetic flux tube into the solar atmosphere. A three-dimensional magnetohydrodynamic simulation has been performed to investigate several

key factors affecting the dynamics of the flux rope. The stability of the flux rope is examined by deriving the decay index of the coronal magnetic field surrounding the flux rope. We investigate a transition between the quasi-static and dynamic states of the flux rope through an analysis of the curvature and scale height of emerging magnetic field. A practical application of this analysis for global eruptions is also considered.

## **Diagnosis of Magnetic and Electric Fields of Chromospheric Jets through spectropolarimetric Observations of H I Paschen Lines**

Tetsu [Anan](#), Roberto Casini, Kiyoshi Ichimoto

E-print, Feb 2014

Magnetic fields govern the plasma dynamics in the outer layers of the solar atmosphere, and electric fields acting on neutral atoms that move across the magnetic field enable us to study the dynamical coupling between neutrals and ions in the plasma. In order to measure the magnetic and electric fields of chromospheric jets, the full Stokes spectra of the Paschen series of neutral hydrogen in a surge and in some active region jets that took place at the solar limb were observed on **May 5, 2012**, using the spectropolarimeter of the Domeless Solar Telescope at Hida observatory, Japan. First, we inverted the Stokes spectra taking into account only the effect of magnetic fields on the energy structure and polarization of the hydrogen levels. Having found no definitive evidence of the effects of electric fields in the observed Stokes profiles, we then estimated an upper bound for these fields by calculating the polarization degree under the magnetic field configuration derived in the first step, with the additional presence of a perpendicular (Lorentz type) electric field of varying strength. The inferred direction of the magnetic field on the plane of the sky (POS) approximately aligns to the active region jets and the surge, with magnetic field strengths in the range  $10 \text{ G} < B < 640 \text{ G}$  for the surge. Using magnetic field strengths of 70, 200, and 600 G, we obtained upper limits for possible electric fields of 0.04, 0.3, and 0.8 V/cm, respectively. This upper bound is conservative, since in our modeling we neglected the possible contribution of collisional depolarization. Because the velocity of neutral atoms of hydrogen moving across the magnetic field derived from these upper limits of the Lorentz electric field is far below the bulk velocity of the plasma perpendicular to the magnetic field as measured by the Doppler shift, we conclude that the neutral atoms must be highly frozen to the magnetic field in the surge.

## **Predicting Flares and Solar Energetic Particle Events: The FORSPEF Tool**

A. [Anastasiadis](#), A. Papaioannou, I. Sandberg, M. Georgoulis, K. Tziotziou, A. Kouloumvakos, P. Jiggins  
[Solar Physics](#) September 2017, 292:134

A novel integrated prediction system for solar flares (SFs) and solar energetic particle (SEP) events is presented here. The tool called forecasting solar particle events and flares (FORSPEF) provides forecasts of solar eruptive events, such as SFs with a projection to occurrence and velocity of coronal mass ejections (CMEs), and the likelihood of occurrence of an SEP event. In addition, the tool provides nowcasting of SEP events based on actual SF and CME near real-time data, as well as the SEP characteristics (e.g. peak flux, fluence, rise time, and duration) per parent solar event. The prediction of SFs relies on the effective connected magnetic field strength (BeffBeff) metric, which is based on an assessment of potentially flaring active-region (AR) magnetic configurations, and it uses a sophisticated statistical analysis of a large number of AR magnetograms. For the prediction of SEP events, new statistical methods have been developed for the likelihood of the SEP occurrence and the expected SEP characteristics. The prediction window in the forecasting scheme is 24 hours with a refresh rate of 3 hours, while the respective prediction time for the nowcasting scheme depends on the availability of the near real-time data and ranges between 15 – 20 minutes for solar flares and 6 hours for CMEs. We present the modules of the FORSPEF system, their interconnection, and the operational setup. Finally, we demonstrate the validation of the modules of the FORSPEF tool using categorical scores constructed on archived data, and we also discuss independent case studies. **26 Oct-8 Nov 2003, 20 Jan 2005, 7 March 2012, 2014-12-18** <http://tromos.space.noa.gr/forspef/>

## **Internal structure of a coronal mass ejection revealed by Akatsuki radio occultation observations**

H. [Ando](#), D. Shiota, T. Imamura, M. Tokumaru, A. Asai, H. Isobe, M. Pätzold, B. Häusler, M. Nakamura

JGR Volume 120, Issue 7 July 2015 Pages 5318–5328

A coronal mass ejection (CME) was observed at the heliocentric distance of 12.7  $R_{\odot}$  by radio occultation measurements using the Akatsuki spacecraft. The temporal developments of the bulk velocity and the electron column density along the raypath traversing the CME were obtained, and under the assumption that the irregularities are transported across the raypath, the internal structure of the CME covering the region from the core to the tail was retrieved. The suggested internal structure was compared with Large Angle Spectroscopic Coronagraph images, a numerical study and previous radio occultation observations of CMEs to propose a CME model; the bulk velocity and the electron density have relatively large values in the core, decrease behind the core, and increase again in the tail region where the fast plasma flow associated with the magnetic reconnection converges. *This implies that the magnetic reconnection behind the CMEs might continue up to at least the heliocentric distance of  $\sim 13 R_{\odot}$ .* **13 June 2011**

## **A two-Type Classification of Lasco Coronal Mass Ejection,**

**Andrews**, M. D. and R.A. Howard.

*Space Science Reviews*, **95**, Numbers 1-2, p. 147-163 (2001); **File**

The causes and origins of Coronal Mass Ejections (CMEs) remain among the outstanding questions in Space Physics. The observations of CMEs by the LASCO coronagraphs on SOHO suggest that there are two distinct types of CMEs. The two types of events can be most easily distinguished by examining height-time plots. The Type A (Acceleration) events produce curved plots that often indicate a constant acceleration. These events are usually associated with pre-existing helmet-streamers, and are often associated with prominence eruptions or filament disappearance. The Type C (Constant speed) events show a constant speed. These events are usually brighter, larger, and faster than Type A events and may be associated with X-ray flares. While the two types of events can be distinguished in other ways, the height-time plots are a simple and unambiguous way to make this identification.

## **Observations and Simulations of Reconnecting Current Sheets in the Solar Corona**

EGU2020-5597 May 2020

<https://meetingorganizer.copernicus.org/EGU2020/displays/36057>

Jets and mass ejections are ubiquitous features of the Sun's corona. These explosive dynamics are all believed to be driven by magnetic reconnection at two types of current sheets that form in the solar atmosphere: those that form at magnetic null points and separatrix surfaces, and those, such as the heliospheric current sheet, that form as a result of a large expansion of a bipolar magnetic field. In our breakout model, both types of current sheets are essential for the explosive release of magnetic energy. We report on the first direct observations of reconnection and island formation in a null-point current sheet associated with a large coronal jet. The topology and velocities of the islands are in excellent agreement with our numerical simulations of coronal jets. We discuss the implications of the observations and our models for understanding the energetic particles produced by these events and their release into interplanetary space, as well as the implications for observations by Solar Orbiter and the Parker Solar Probe. **20-21 Apr 2019**

## **Reconnection nanojets in the solar corona**

**Antolin, Patrick**; **Pagano, Paolo**; **Testa, Paola**; **Petralia, Antonino**; **Reale, Fabio**

*Nature Astronomy*, Volume 5, p. 54-62, 2021

<https://www.nature.com/articles/s41550-020-1199-8#citeas>

<https://doi.org/10.1038/s41550-020-1199-8>

The solar corona is shaped and mysteriously heated to millions of degrees by the Sun's magnetic field. It has long been hypothesized that the heating results from a myriad of tiny magnetic energy outbursts called nanoflares, driven by the fundamental process of magnetic reconnection. Misaligned magnetic field lines can break and reconnect, producing nanoflares in avalanche-like processes. However, no direct and unique observations of such nanoflares exist to date, and the lack of a smoking gun has cast doubt on the possibility of solving the coronal heating problem. From coordinated multi-band high-resolution observations, we report on the discovery of very fast and bursty nanojets, the telltale signature of reconnection-based nanoflares resulting in coronal heating. Using state-of-the-art numerical simulations, we demonstrate that the nanojet is a consequence of the slingshot effect from the magnetically tensed, curved magnetic field lines reconnecting at small angles. Nanojets are therefore the key signature of reconnection-based coronal heating in action.

## **Hybrid Reconstruction to Derive 3D Height –Time Evolution for Coronal Mass Ejections**

A. **Antunes** · A. Thernisien · A. Yahil

*Solar Phys* (2009) 259: 199–212; **File**

We present a hybrid combination of forward and inverse reconstruction methods using multiple observations of a coronal mass ejection (CME) to derive the three-dimensional (3D) “true” height – time plots for individual CME components. We apply this hybrid method to the components of the **31 December 2007** CME. This CME, observed clearly in both the STEREO A and STEREO B COR2 white-light coronagraphs, evolves asymmetrically across the 15-solar-radius field of view within a span of three hours. The method has two reconstruction steps. We fit a boundary envelope for the potential 3D CME shape using a flux-rope-type model oriented to best match the observations. Using this forward model as a constraining envelope, we then run an inverse reconstruction, solving for the simplest underlying 3D electron density distribution that can, when rendered, reproduce the observed coronagraph data frames. We produce plots for each segment to establish the 3D or “true” height – time plots for each center of mass as well as for the bulk CME motion, and we use these plots along with our derived density profiles to estimate the CME's asymmetric expansion rate.

## **Magnetic Helicity Signs and Flaring Propensity: Comparing Force-free Parameter with the Helicity signs of H $\alpha$ Filaments and X-ray Sigmoids**

V. [Aparna](#), [Manolis K. Georgoulis](#), [Petrus C. Martens](#)

ApJ 967 134 2024

<https://arxiv.org/ftp/arxiv/papers/2403/2403.17075.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ad38c1/pdf>

Sigmoids produce strong eruptive events. Earlier studies have shown that the ICME axial magnetic field  $B_z$  can be predicted with some credibility by observing the corresponding filament or the polarity inversion line in the region of eruption and deriving the magnetic field direction from that. Sigmoids are coronal structures often associated with filaments in the sigmoidal region. In this study, firstly we compare filament chirality with sigmoid handedness to observe their correlation. Secondly, we perform non-linear force-free approximations of the coronal magnetic connectivity using photospheric vector magnetograms underneath sigmoids to obtain a weighted-average value of the force-free parameter and to correlate it with filament chirality and the observed coronal sigmoid handedness. Importantly, we find that the sigmoids and their filament counterparts do not always have the same helicity signs. Production of eruptive events by regions that do not have the same signs of helicities is  $\sim 3.5$  times higher than when they do. A case study of magnetic energy/ helicity evolution in NOAA AR 12473 is also presented. **2011-11-24, 2012-05-05, 2012-06-15, Dec 23, 2015 - Jan 01, 2016.**

## **Solar Filaments and Interplanetary Magnetic Field $B_z$**

V. [Aparna](#) and Petrus C. Martens

2020 ApJ 897 68

<https://doi.org/10.3847/1538-4357/ab908b>

The direction of the axis of an interplanetary coronal mass ejection (ICME) plays an important role in determining if it will cause a geomagnetic disturbance in the Earth's magnetosphere upon impact. Long period southward-pointing ICME fields are known to cause significant space weather impacts and thus geomagnetic storms. We present an extensive analysis of CME-ICME directionality using 86 halo-CMEs observed between 2007 and 2017 to compare the direction of the source filament axial magnetic field on the Sun and the direction of the interplanetary magnetic field near the Earth at the L1 Lagrangian point. Excluding 12 cases that were too ambiguous to determine, for the remaining 74 ICMEs, we find an agreement in terms of the northward/southward orientation of  $B_z$  between ICMEs and their CME source regions in 85% of cases. Some of the previous studies discussed here have obtained an agreement of 77% and 55%. We therefore suggest that our method can be meaningful as a first step in efficiently predicting geoeffective ICMEs by observing and analyzing the source regions of CMEs on the Sun.

## **A HOT FLUX ROPE OBSERVED BY SDO/AIA**

**(A 7~MK hot Flux Rope Observed by SDO/AIA)**

V. [Aparna](#), Durgesh Tripathi

2016 ApJ 819 71

<http://arxiv.org/pdf/1601.01620v1.pdf>

A filament eruption was observed on **October 31, 2010** in the images recorded by the Atmospheric Imaging Assembly (AIA) on board the Solar Dynamic Observatory (SDO) in its Extreme Ultra-Violet (EUV) channels. The filament showed a slow rise phase followed by a fast rise and was classified to be an asymmetric eruption. In addition, multiple localized brightening which was spatially and temporally associated with the slow rise phase were identified leading us to believe that the tether-cutting mechanism to be the cause of the initiation of the eruption. An associated flux rope was detected in high temperature channels of AIA namely 94Å and 131Å corresponding to 7 MK and 11 MK plasma respectively. In addition, these channels are also sensitive to cooler plasma corresponding to  $\sim 1-2$  MK. In this study we have applied the algorithm devised by Warren et al. (2012) to remove cooler emission from the 94Å channel to deduce only the high temperature structure of the flux rope and to study its temporal evolution. We found that the flux rope was very clearly seen in clean 94Å channel image corresponding to Fe XVIII emission which corresponds to a plasma at a temperature of 7 MK. This temperature matched well with that obtained using DEM analysis. This study provides important constraints in the modelling of the thermodynamic structure of the flux ropes in CMEs.

## **SOLARIS: Solar Sail Investigation of the Sun**

Advances in Solar Sailing, pp 259-268, Feb 2014 2017

<https://arxiv.org/ftp/arxiv/papers/1707/1707.08193.pdf>

In this paper, we detail the scientific objectives and outline a strawman payload of the SOLAR sail Investigation of the Sun (SOLARIS). The science objectives are to study the 3D structure of the solar magnetic and velocity field, the variation of total solar irradiance with latitude, and the structure of the corona. We show how we can meet these science objective using solar-sail technologies currently under development. We provide a tentative mission profile considering several trade-off approaches. We also provide a tentative mass budget breakdown and a perspective for a programmatic implementation.

## **Introduction to the physics of solar eruptions and their space weather impact** **Introduction**

Vasilis [Archontis](#), [Loukas Vlahos](#)

Philosophical Transactions of the Royal Society A: Mathematical, Physical and Engineering Sciences v. 377  
[Issue 2148](#) Article ID:20190152 **2019**

<https://royalsocietypublishing.org/doi/pdf/10.1098/rsta.2019.0152>

The physical processes, which drive powerful solar eruptions, play an important role in our understanding of the Sun-Earth connection. In this Special Issue, we firstly discuss how magnetic fields emerge from the solar interior to the solar surface, to build up active regions, which commonly host large-scale coronal disturbances, such as coronal mass ejections (CMEs). Then, we discuss the physical processes associated with the driving and triggering of these eruptions, the propagation of the large-scale magnetic disturbances through interplanetary space and the interaction of CMEs with Earth's magnetic field. The acceleration mechanisms for the solar energetic particles related to explosive phenomena (e.g. flares and/or CMEs) in the solar corona are also discussed. The main aim of this Issue, therefore, is to encapsulate the present state-of-the-art in research related to the genesis of solar eruptions and their space-weather implications. This article is part of the theme issue 'Solar eruptions and their space weather impact'.

## **The emergence of magnetic flux and its role on the onset of solar dynamic events** **Review**

V. [Archontis](#), [P. Syntelis](#)

Philosophical Transactions A v. 377 [Issue 2148](#) Article ID:20180387 **2019**

<https://arxiv.org/pdf/1904.06274.pdf>

<https://royalsocietypublishing.org/doi/pdf/10.1098/rsta.2018.0387>

A plethora of solar dynamic events, such as the formation of active regions, the emission of jets and the occurrence of eruptions is often associated to the emergence of magnetic flux from the interior of the Sun to the surface and above. Here, we present a short review on the onset, driving and/or triggering of such events by magnetic flux emergence. We briefly describe some key observational examples, theoretical aspects and numerical simulations, towards revealing the mechanisms that govern solar dynamics and activity related to flux emergence. We show that the combination of important physical processes like shearing and reconnection of magnetic fieldlines in emerging flux regions or at their vicinity, can power some of the most dynamic phenomena in the Sun on various temporal and spatial scales. Based on previous and recent observational and numerical studies, we highlight that, in most cases, none of these processes alone can drive and also trigger explosive phenomena releasing considerable amount of energy towards the outer solar atmosphere and space, such as flares, jets and large-scale eruptions (e.g. CMEs). In addition, one has to take into account the physical properties of the emerging field (e.g. strength, amount of flux, relative orientation to neighbouring and pre-existing magnetic fields, etc.) in order to better understand the exact role of magnetic flux emergence on the onset of solar dynamic events.

## **Helical Blowout Jets in the Sun**

V. [Archontis](#), A. W. Hood

New UKSP Nugget: 53, Nov **2014**

<http://www.uksolphys.org/uksp-nugget/53-helical-blowout-jets-in-the-sun/>

Numerical simulations demonstrate untwisting and Alfvén wave propagation as a jet erupts

This “blowout” jet is a broad, curtain-like structure, as opposed to the “standard” jets which are more elongated and not commonly associated with the eruption of cool material. In this nugget, we report on the emission of a “blowout” jet in an EFR with a sea-serpent configuration. We show that the “blowout” jet is untwisting during its ejection and, for the first time, we provide direct evidence of propagating torsional Alfvén waves during the emission of the “blowout” jets.

## **Recurrent Explosive Eruptions and the "Sigmoid-to-arcade" Transformation in the Sun Driven by Dynamical Magnetic Flux Emergence**

V. [Archontis](#)<sup>1,2</sup>, A. W. Hood<sup>2</sup>, and K. Tsinganos

**2014** ApJ 786 L21

<http://arxiv.org/pdf/1405.6955v1.pdf>

We report on three-dimensional MHD simulations of recurrent mini coronal mass ejection (CME)-like eruptions in a small active region (AR), which is formed by the dynamical emergence of a twisted (not kink unstable) flux tube from the solar interior. The eruptions develop as a result of the repeated formation and expulsion of new flux ropes due to continuous emergence and reconnection of sheared field lines along the polarity inversion line of the AR. The acceleration of the eruptions is triggered by tether-cutting reconnection at the current sheet underneath the erupting field. We find that each explosive eruption is followed by reformation of a sigmoidal structure and a subsequent "sigmoid-to-flare arcade" transformation in the AR. These results might have implications for recurrent CMEs and eruptive sigmoids/flares observations and theoretical studies.

## **The Emergence of Weakly Twisted Magnetic Fields in the Sun**

V. [Archontis](#)<sup>1,2</sup>, A. W. Hood<sup>2</sup>, and K. Tsinganos

2013 ApJ 778 42

We have studied the emergence of a weakly twisted magnetic flux tube from the upper convection zone into the solar atmosphere. It is found that the rising magnetized plasma does not undergo the classical, single  $\Omega$ -shaped loop emergence, but it becomes unstable in two places, forming two magnetic lobes that are anchored in small-scale bipolar structures at the photosphere, between the two main flux concentrations. The two magnetic lobes rise and expand into the corona, forming an overall undulating magnetic flux system. The dynamical interaction of the lobes results in the triggering of high-speed and hot jets and the formation of successive cool and hot loops that coexist in the emerging flux region. Although the initial emerging field is weakly twisted, a highly twisted magnetic flux rope is formed at the low atmosphere, due to shearing and reconnection. The new flux rope (hereafter post-emergence flux rope) does not erupt. It remains confined by the overlying field. Although there is no ejective eruption of the post-emergence rope, it is found that a considerable amount of axial and azimuthal flux is transferred into the solar atmosphere during the emergence of the magnetic field.

## A NUMERICAL MODEL OF STANDARD TO BLOWOUT JETS

V. [Archontis](#) and A. W. Hood

2013 ApJ 769 L21

We report on three-dimensional (3D) MHD simulations of the formation of jets produced during the emergence and eruption of solar magnetic fields. The interaction between an emerging and an ambient magnetic field in the solar atmosphere leads to (external) reconnection and the formation of "standard" jets with an inverse Y-shaped configuration. Eventually, low-atmosphere (internal) reconnection of sheared fieldlines in the emerging flux region produces an erupting magnetic flux rope and a reconnection jet underneath it. The erupting plasma blows out the ambient field and, moreover, it unwinds as it is ejected into the outer solar atmosphere. The fast emission of the cool material that erupts together with the hot outflows due to external/internal reconnection form a wider "blowout" jet. We show the transition from "standard" to "blowout" jets and report on their 3D structure. The physical plasma properties of the jets are consistent with observational studies.

## Magnetic flux emergence: a precursor of solar plasma expulsion

V. [Archontis](#) and A. W. Hood

A&A 537, A62 (2012)

**Aims.** We model the emergence of magnetized plasma from the top of the convection zone to the lower corona. We investigate the eruption of coronal flux ropes above emerging flux regions.

**Methods.** We performed three-dimensional numerical experiments in which the time-dependent and resistive equations of MHD are solved self-consistently, using the Lare3D code.

**Results.** A subphotospheric magnetic flux tube rises from the convectively unstable layer into the solar surface, followed by the formation and eruption of a new flux rope into the corona. Firstly, we examined the case where the corona is field-free. The expansion of the emerging field forms an envelope sheath that surrounds the newly formed flux rope. The erupting ropes are confined by the envelope field. The eruptions are driven by the gradient of the gas pressure and the tension of fieldlines that reconnect within the emerging flux region. The amount of the initial twist of the emerging field and the dense plasma that is lifted up, determine the height-time profile of the erupting ropes. Secondly, we examined the case of emergence into a pre-existing magnetic field in the upper solar atmosphere. A variety of different ambient field configurations was used in the experiments. External reconnection between the emerging and the pre-existing field may result in the removal of sufficient flux from the interacting fields and the full ejection of the flux ropes.

**Conclusions.** The results indicate that the relative contact angle of the interacting flux systems and their field strengths are crucial parameters that ultimately affect the evolution of the eruption of the rope into the higher solar atmosphere. One important result is that for any contact angle that favors reconnection, ejective eruptions occur earlier when the ambient field is relatively strong. In many cases, the erupting plasma adopts an S-like configuration. The sigmoidal structure accelerates during the fast eruption of the rope. The acceleration is enhanced by the external and internal reconnection of fieldlines during the rising motion of the rope. A key result is that in the reconnection-favored cases, the flux ropes experience ejective eruptions when the envelope flux is reduced (owing to removal by external reconnection) below that of the erupting flux rope. If the envelope flux stays higher than the erupting flux, the magnetic flux rope remains confined by the envelope field.

## Flux emergence and coronal eruption

V. [Archontis](#) and A. W. Hood

A&A 514, A56 (2010)

**Aims.** Our aim is to study the photospheric flux distribution of a twisted flux tube that emerges from the solar interior. We also report on the eruption of a new flux rope when the emerging tube rises into a pre-existing magnetic field in the corona.

Methods. To study the evolution, we use 3D numerical simulations by solving the time-dependent and resistive MHD equations. We qualitatively compare our numerical results with MDI magnetograms of emerging flux at the solar surface.

Results. We find that the photospheric magnetic flux distribution consists of two regions of opposite polarities and elongated magnetic tails on the two sides of the polarity inversion line (PIL), depending on the azimuthal nature of the emerging field lines and the initial field strength of the rising tube. Their shape is progressively deformed due to plasma motions towards the PIL. Our results are in qualitative agreement with observational studies of magnetic flux emergence in active regions (ARs). Moreover, if the initial twist of the emerging tube is small, the photospheric magnetic field develops an undulating shape and does not possess tails. In all cases, we find that a new flux rope is formed above the original axis of the emerging tube that may erupt into the corona, depending on the strength of the ambient field.

### **A stellar flare-coronal mass ejection event revealed by X-ray plasma motions**

C. [Argiroffi](#) (1 and 2), [F. Reale](#) (1 and 2), [J. J. Drake](#) (3), [A. Ciaravella](#) (2), [P. Testa](#) (3), [R. Bonito](#) (2), [M. Miceli](#) (1 and 2), [S. Orlando](#) (2), [G. Peres](#) (1 and 2)

Nature Astronomy **2019** See <https://rdcu.be/bEAta>

<https://arxiv.org/pdf/1905.11325.pdf>

Coronal mass ejections (CMEs), often associated with flares, are the most powerful magnetic phenomena occurring on the Sun. Stars show magnetic activity levels up to  $10^4$  times higher, and CME effects on stellar physics and circumstellar environments are predicted to be significant. However, stellar CMEs remain observationally unexplored. Using time-resolved high-resolution X-ray spectroscopy of a stellar flare on the active star HR 9024 observed with Chandra/HETGS, we distinctly detected Doppler shifts in S XVI, Si XIV, and Mg XII lines that indicate upward and downward motions of hot plasmas ( $\sim 10$ –25 MK) within the flaring loop, with velocity  $v \sim 100$ –400 km/s, in agreement with a model of flaring magnetic tube. Most notably, we also detected a later blueshift in the O VIII line which reveals an upward motion, with  $v = 90 \pm 30$  km/s, of cool plasma ( $\sim 4$  MK), that we ascribe to a CME coupled to the flare. From this evidence we were able to derive a CME mass of  $1 \times 10^{21}$  g and a CME kinetic energy of  $5 \times 10^{34}$  erg. These values provide clues in the extrapolation of the solar case to higher activity levels, suggesting that CMEs could indeed be a major cause of mass and angular momentum loss.

### **Global energetics of solar flares. XIII. The Neupert effect and acceleration of coronal mass ejections**

[Markus J. Aschwanden](#)

ApJ **2021**

<https://arxiv.org/pdf/2112.07759.pdf> **File**

Our major aim is a height-time model  $r(t)$  of the propagation of  $\{ \text{Coronal Mass Ejections (CMEs)} \}$ , where the lower corona is self-consistently connected to the heliospheric path. We accomplish this task by using the Neupert effect to derive the peak time, duration, and rate of the CME acceleration phase, as obtained from the time derivative of the  $\{ \text{soft X-ray (SXR)} \}$  light curve. This novel approach offers the advantage to obtain the kinematics of the CME height-time profile  $r(t)$ , the CME velocity profile  $v(t) = dr(t)/dt$ , and the CME acceleration profile  $a(t) = dv(t)/dt$  from  $\{ \text{Geostationary Orbiting Earth Satellite (GOES)} \}$  and white-light data, without the need of  $\{ \text{hard X-ray (HXR)} \}$  data. We apply this technique to a data set of 576 (GOES X and M-class) flare events observed with GOES and the  $\{ \text{Large Angle Solar Coronagraph (LASCO)} \}$ . Our analysis yields acceleration rates in the range of  $a_A = 0.1$ –13  $\text{km s}^{-2}$ , acceleration durations of  $\tau_A = 1.2$ –45 min, and acceleration distances in the range of  $d_A = 3$ –1063 Mm, with a median of  $d_A = 39$  Mm, which corresponds to the hydrostatic scale height of a corona with a temperature of  $T_e \approx 0.8$  MK. The results are consistent with standard flare/CME models that predict magnetic reconnection and synchronized (primary) acceleration of CMEs in the low corona (at a height of  $\sim 0.1 R_{\text{sun}}$ ), while secondary (weaker) acceleration may occur further out at heliospheric distances. **2011-03-09, 2011-03-12, 2011-08-09, 2011-09-05, 2011-11-15, 2011-12-30, 2012-01-23, 2012-03-06, 2012-03-07, 2012-07-06, 2012-07-09, 2012-07-14, 2013-05-14, 2013-05-31, 2013-10-15, 2013-11-05, 2014-02-02, 2014-02-13, 2014-02-25, 2014-05-06, 2014-10-20**

### **Correlation of the sunspot number and the waiting time distribution of solar flares, coronal mass ejections, and solar wind switchback events observed with the Parker Solar Probe**

[Markus J. Aschwanden](#), [Thierry Dudok de Wit](#)

ApJ **912** 94 **2021**

<https://arxiv.org/pdf/2102.02305.pdf>

<https://doi.org/10.3847/1538-4357/abef69>

Waiting time distributions of solar flares and coronal mass ejections (CMEs) exhibit power law-like distribution functions with slopes in the range of  $\alpha\tau \approx 1.4-3.2$ , as observed in annual data sets during 4 solar cycles (1974-2012). We find a close correlation between the waiting time power law slope  $\alpha\tau$  and the sunspot number (SN), i.e.,  $\alpha\tau = 1.38 + 0.01 \times \text{SN}$ . The waiting time distribution can be fitted with a Pareto-type function of the form  $N(\tau) = N_0 (\tau_0 + \tau)^{-\alpha\tau}$ , where the offset  $\tau_0$  depends on the instrumental sensitivity, the detection threshold of events, and pulse pile-up effects. The time-dependent power law slope  $\alpha\tau(t)$  of waiting time distributions depends only on the global solar magnetic flux (quantified by the sunspot number) or flaring rate, independent of other physical parameters of self-organized criticality (SOC) or magneto-hydrodynamic (MHD) turbulence models. Power law slopes of  $\alpha\tau \approx 1.2-1.6$  were also found in solar wind switchback events, as observed with the Parker Solar Probe (PSP). We conclude that the annual variability of switchback events in the heliospheric solar wind is modulated by flare and CME rates originating in the photosphere and lower corona.

## Global Energetics of Solar Flares. VII. Aerodynamic Drag in Coronal Mass Ejections

Markus J. [Aschwanden](#)<sup>1</sup> and Nat Gopalswamy

2019 ApJ 877 149

<https://sci-hub.ru/10.3847/1538-4357/ab1b39>

The free energy that is dissipated in a magnetic reconnection process of a solar flare, generally accompanied by a coronal mass ejection (CME), has been considered as the ultimate energy source of the global energy budget of solar flares in previous statistical studies. Here we explore the effects of the aerodynamic drag force on CMEs, which supplies additional energy from the slow solar wind to a CME event, besides the magnetic energy supply. For this purpose, we fit the analytical aerodynamic drag model of Cargill and Vršnak et al. to the height-time profiles  $r(t)$  of LASCO/SOHO data in 14,316 CME events observed during the first 8 yr (2010–2017) of the Solar Dynamics Observatory era (ensuring EUV coverage with AIA). Our main findings are (1) a mean solar wind speed of  $w = 472 \pm 414 \text{ km s}^{-1}$ , (2) a maximum drag-accelerated CME energy of  $E_{\text{drag}} \lesssim 2 \times 10^{32} \text{ erg}$ , (3) a maximum flare-accelerated CME energy of  $E_{\text{flare}} \lesssim 1.5 \times 10^{33} \text{ erg}$ , (4) the ratio of the summed kinetic energies of all flare-accelerated CMEs to the drag-accelerated CMEs amounts to a factor of 4, (5) the inclusion of the drag force slightly lowers the overall energy budget of CME kinetic energies in flares from  $\approx 7\%$  to  $\approx 4\%$ , and (6) the arrival times of CMEs at Earth can be predicted with an accuracy of  $\approx 23\%$ .

**Table 1** Statistics of CME Parameters for 14,316 Eruptive CME Events Detected with LASCO/SOHO during 2010–2017

## Global Energetics of Solar Flares: VI. Refined Energetics of Coronal Mass Ejections

Markus J. [Aschwanden](#)

ApJ 847 27 2017

<https://arxiv.org/pdf/1704.01993.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/aa8952/pdf>

In this study we refine a CME model presented in an earlier study on the global energetics of solar flares and associated CMEs, and apply it to all (860) GOES M- and X-class flare events observed during the first 7 years (2010-2016) of the Solar Dynamics Observatory (SDO) mission, which doubles the statistics of the earlier study. The model refinements include: (1) the CME geometry in terms of a 3D sphere undergoing self-similar adiabatic expansion; (2) the inclusion of solar gravitational deceleration during the acceleration and propagation of the CME, which discriminates eruptive and confined CMEs; (4) a self-consistent relationship between the CME center-of-mass motion detected during EUV dimming and the leading-edge motion observed in white-light coronagraphs; (5) the equi-partition of the CME kinetic and thermal energy; and (6) the Rosner-Tucker-Vaiana (RTV) scaling law. The refined CME model is entirely based on EUV dimming observations (using AIA/SDO data) and complements the traditional white-light scattering model (using LASCO/SOHO data), and both models are independently capable to determine fundamental CME parameters such as the CME mass, speed, and energy. Comparing the two methods we find that: (1) LASCO is less sensitive than AIA in detecting CMEs (in 24% of the cases); (2) CME masses below  $m_{\text{CME}} \sim 10^{14} \text{ g}$  are under-estimated by LASCO; (3) AIA and LASCO masses, speeds, and energy agree closely in the statistical mean after elimination of outliers; (4) the CMEs parameters of the speed  $v$ , emission measure-weighted flare peak temperature  $T_e$ , and length scale  $L$  are consistent with the following scaling laws (derived from first principles):  $v \propto T_e^{1/2}$ ,  $v \propto (m_{\text{CME}})^{1/4}$ , and  $m_{\text{CME}} \propto L^2$ .

## Global Energetics of Solar Flares: V. Energy Closure in Flares and Coronal Mass Ejections

Markus J. [Aschwanden](#), Amir Campi, Christina M.S. Cohen, [Gordon Holman](#), [Ju Jing](#), [Matthieu Kretzschmar](#), [Eduard P. Kontar](#), [James McTiernan](#), [Richard A. Mewaldt](#), [Aidan O'Flanagan](#), [Ian G. Richardson](#), [Daniel Ryan](#), [Harry P. Warren](#), [Yan Xu](#)

ApJ 836 17 2017

<https://arxiv.org/pdf/1701.01176v1.pdf>

In this study we synthesize the results of four previous studies on the global energetics of solar flares and associated coronal mass ejections (CMEs), which include magnetic, thermal, nonthermal, and CME energies in 399 solar M and X-class flare events observed during the first 3.5 years of the Solar Dynamics Observatory (SDO) mission. Our findings are: (1) The sum of the mean nonthermal energy of flare-accelerated particles ( $E_{\text{nt}}$ ), the energy of direct heating ( $E_{\text{dir}}$ ), and the energy in coronal mass ejections (ECME), which are the primary energy dissipation processes in a flare, is found to have a ratio of  $(E_{\text{nt}} + E_{\text{dir}} + E_{\text{CME}}) / E_{\text{mag}} = 0.87 \pm 0.18$ , compared with the dissipated magnetic free

energy  $E_{\text{mag}}$ , which confirms energy closure within the measurement uncertainties and corroborates the magnetic origin of flares and CMEs; (2) The energy partition of the dissipated magnetic free energy is:  $0.51 \pm 0.17$  in nonthermal energy of  $\geq 6$  keV electrons,  $0.17 \pm 0.17$  in nonthermal  $\geq 1$  MeV ions,  $0.07 \pm 0.14$  in CMEs, and  $0.07 \pm 0.17$  in direct heating; (3) The thermal energy is almost always less than the nonthermal energy, which is consistent with the thick-target model; (4) The bolometric luminosity in white-light flares is comparable with the thermal energy in soft X-rays (SXR); (5) Solar Energetic Particle (SEP) events carry a fraction  $\approx 0.03$  of the CME energy, which is consistent with CME-driven shock acceleration; and (6) The warm-target model predicts a lower limit of the low-energy cutoff at  $e \approx 6$  keV, based on the mean differential emission measure (DEM) peak temperature of  $T_e = 8.6$  MK during flares. This work represents the first statistical study that establishes energy closure in solar flare/CME events.

## Global Energetics of Solar Flares: IV. Coronal Mass Ejection Energetics

Markus J. [Aschwanden](#)

ApJ 831 105 2016

<http://arxiv.org/pdf/1605.04952v1.pdf> File

[http://www.lmsal.com/~aschwand/eprints/2016\\_global4.pdf](http://www.lmsal.com/~aschwand/eprints/2016_global4.pdf)

This study entails the fourth part of a global flare energetics project, in which the mass  $m_{\text{CME}}$ , kinetic energy  $E_{\text{kin}}$ , and the gravitational potential energy  $E_{\text{grav}}$  of coronal mass ejections (CMEs) is measured in 399 M and X-class flare events observed during the first 3.5 yrs of the Solar Dynamics Observatory (SDO) mission, *using a new method based on the EUV dimming effect*. The EUV dimming is modeled in terms of a radial adiabatic expansion process, which is fitted to the observed evolution of the total emission measure of the CME source region. The model derives the evolution of the mean electron density, the emission measure, the bulk plasma expansion velocity, the mass, and the energy in the CME source region. The EUV dimming method is truly complementary to the Thomson scattering method in white light, which probes the CME evolution in the heliosphere at  $r > 2R_{\odot}$ , while the EUV dimming method tracks the CME launch in the corona. We compare the CME parameters obtained in white light with the LASCO/C2 coronagraph with those obtained from EUV dimming with the Atmospheric Imaging Assembly (AIA) onboard SDO for all identical events in both data sets. We investigate correlations between CME parameters, the relative timing with flare parameters, frequency occurrence distributions, and the energy partition between magnetic, thermal, nonthermal, and CME energies. CME energies are found to be systematically lower than the dissipated magnetic energies, which is consistent with a magnetic origin of CMEs. **2010-10-16, 2010-06-12, 2011-05-29, 2011-08-02, 2011-09-24, 2011-09-28, 2011-11-09, 2012-01-27, 2012-03-10, 2012-03-13, 2012-06-06, 2012-07-05, 2012-07-19, 2012-08-11, 2012-09-09, 2012-11-13, 2013-05-22, 2013-08-17, 2013-10-24, 2013-11-01, 2013-11-03, 2013-11-06, 2013-11-19, 2014-01-07**

## 3D Reconstruction of Active Regions with STEREO (Invited **Review**)

Markus J. [Aschwanden](#) and Jean-Pierre Wuelser

E-print, Feb 2010, J. Atmos. Solar-Terr. Physics,

We review data analysis and physical modeling related to the 3D reconstruction of active regions in the solar corona, using stereoscopic image pairs from the STEREO/EUVI instrument. This includes the 3D geometry of coronal loops (with measurements of the loop inclination plane, coplanarity, circularity, and hydrostaticity), the 3D electron density and temperature distribution (which enables diagnostics of hydrostatic, hydrodynamic, and heating processes), the 3D magnetic field (independent of any theoretical model based on photospheric extrapolations), as well as the 3D reconstruction of CME phenomena, such as EUV dimming, CME acceleration, CME bubble expansion, and associated Lorentz forces that excite MHD kink-mode oscillations in the surroundings of a CME launch site. The mass of CMEs, usually measured from white-light coronagraphs, can be determined independently from the EUV dimming in the CME source region. The full 3D density and temperature structure of an active region can be reconstructed in unprecedented detail with instant stereoscopic tomography.

## 4D-Modeling of CME Expansion and EUV Dimming with Fitting to STEREO/EUVI Observations

Markus J. [Aschwanden](#)

E-print, June 2009; *Annales Geophysicae*, 27, 3275-3286, 2009, [File](#)

This is the first attempt to model the kinematics of a CME launch and the resulting EUV dimming quantitatively with a self-consistent model. Our 4D-model assumes self-similar expansion of a spherical CME geometry that consists of a CME front with density compression and a cavity with density rarefaction, satisfying mass conservation of the total CME and swept-up corona. The model contains 12 free parameters and is fitted to the **2008 March 25**, 18:30 UT, CME event observed with STEREO/A and B. Our model is able reproduce the observed CME expansion and related EUV dimming during the initial phase from 18:30 UT to 19:00 UT. The CME kinematics can be characterized by a constant acceleration (i.e., a constant magnetic driving force). While the observations of EUVI/A are consistent with a spherical bubble geometry, we detect significant asymmetries and density inhomogeneities with EUVI/B. This new forward-modeling method demonstrates how the observed EUV dimming can be used to model physical parameters of the CME source region, the CME geometry, and CME kinematics.

### **First Measurements of the Mass of Coronal Mass Ejections from the EUV Dimming Observed with STEREO EUVI A+B Spacecraft**

Markus J. [Aschwanden](#), Nariaki V. Nitta, Jean-Pierre Wuelser, James R. Lemen, Anne Sandman, Angelos Vourlidas, Robin C. Colaninno

E-print, April 2009, *ApJ*, 706:376–392, 2009 November, [File](#),

The masses of Coronal Mass Ejections (CMEs) have traditionally been determined from whitelight coronagraphs, based on the Thomson scattering of electrons, which depends on the (generally unknown) angle of the CME propagation direction. Here we develop a new method of measuring CME masses from the EUV dimming seen with EUV imaging telescopes in multiple temperature filters. As a test we investigate 8 CME events with previous mass determinations from STEREO/COR2, of which 5 cases are fully detected with EUVI, 2 partially, and 1 not, using an automated multi-wavelength detection code. We find CME masses in the range of  $m_{\text{CME}} = (2 - 7) \times 10^{15} \text{ g}$ . The agreement between the two EUVI/A and B spacecraft is  $m_{\text{A}}/m_{\text{B}} = 1.3 \pm 0.6$  and the consistency with white-light measurements by COR2 is  $m_{\text{EUV}}/m_{\text{COR2}} = 1.1 \pm 0.3$ . The consistency between EUVI and COR2 implies no significant mass backflows (or inflows) at  $r < 4R_{\odot}$  and adequate temperature coverage for the bulk of the CME mass in the range of  $T \approx 0.5 - 3.0 \text{ MK}$ . The temporal evolution of the EUV dimming allows us also to model the evolution of the CME density  $n_e(t)$ , volume  $V(t)$ , height-time  $h(t)$ , and propagation speed  $v(t)$  in terms of an adiabatically expanding self-similar geometry. We determine e-folding EUV dimming times of  $\tau_{\text{dim}} = 1.3 \pm 1.4 \text{ hr}$ . We test the adiabatic expansion model in terms of the predicted detection delay ( $\tau_{\text{t}} \approx 0.7 \text{ hr}$ ) between EUVI and COR2 for the fastest CME event (2008-Mar-25) and find good agreement with the observed delay ( $\tau_{\text{t}} \approx 0.8 \text{ hr}$ ).

### **Solar Flare and CME Observations with STEREO/EUVI**

M.J. [Aschwanden](#), · J.P. Wuelser, N.V. Nitta, · J.R. Lemen

E-print, Dec 2008; *Solar Phys.* (2009) **256**: 3-40 DOI 10.1007/s11207-009-9347-4, 2009, [File](#)

STEREO/EUVI observed 185 flare events (detected above the GOES class C1 level or at  $>25 \text{ keV}$  with RHESSI) during the first two years of the mission (Dec 2006 - Nov 2008), while coronal mass ejections (CME) were reported in about a third of these events. We compile a **comprehensive catalog of these EUVI-observed events**, containing the peak fluxes in soft X-rays, hard X-rays, and EUV, as well as a classification and statistics of prominent EUV features: 79% show impulsive EUV emission (coincident with hard X-rays), 73% show delayed EUV emission from postflare loops and arcades, 24% represent occulted flares, 17% exhibit EUV dimming, 5% show loop oscillations or propagating waves, and at least 3% show erupting filaments. We analyze an example of each EUV feature by stereoscopic modeling of their 3D geometry. We find that impulsive EUV emission indicates compression of cold coronal plasma during the flare energy release, in contrast to the delayed postflare EUV emission that results from cooling of the soft X-ray emitting flare loops. Occulted flares allow us to determine CME-related coronal dimming uncontaminated from flare-related EUV emission. From modeling the time evolution of EUV dimming we can accurately quantify the initial expansion of CMEs and determine their masses. Further we find evidence that coronal loop oscillations are excited by the rapid initial expansion of CMEs. These examples demonstrate that stereoscopic EUV data provide powerful new methods to model the 3D aspects in the hydrodynamics of flares and kinematics of CMEs.

### **Photospheric signatures of CME onset**

O P M [Aslam](#), D MacTaggart, T Williams, L Fletcher, P Romano

*MNRAS*, Volume 534, Issue 1, October 2024, Pages 444–454,

<https://doi.org/10.1093/mnras/stae2110>

<https://watermark.silverchair.com/stae2110.pdf>

Coronal mass ejections (CMEs) are solar eruptions that involve large-scale changes to the magnetic topology of an active region. There exists a range of models for CME onset which are based on twisted or sheared magnetic field above a polarity inversion line (PIL). We present observational evidence that topological changes at PILs, in the photosphere, form a key part of CME onset, as implied by many models. In particular, we study the onset of 30 CMEs

and investigate topological changes in the photosphere by calculating the magnetic winding flux, using the artop code. By matching the times and locations of winding signatures with CME observations produced by the almanac code, we confirm that these signatures are indeed associated with CMEs. Therefore, as well as presenting evidence that changes in magnetic topology at the photosphere are a common signature of CME onset, our approach also allows for the finding of the source location of a CME within an active region. **2011.02.15, 2011.10.15**

Advances in Space Research Volume 56, Issue 12, 15 December **2015**, Pages 2833–2838  
<http://www.sciencedirect.com/science/article/pii/S0273117715001854>

The most powerful coronal mass ejection of the 24th solar cycle took place on the opposite side of the Sun on **July 23, 2012** and had no geomagnetic consequences. Nevertheless, as a result of passing of the ejection through the heliosphere, variations of galactic cosmic rays flux were observed on the Earth. These variations were registered by the muon hodoscope URAGAN (MEPhI, Moscow). Muon flux angular distributions on the Earth's surface are reported and analyzed.

### **The spheromak tilting and how it affects modelling coronal mass ejections**

Eleanna [Asvestari](#), [Tobias Rindlisbacher](#), [Jens Pomoell](#), [Emilia Kilpua](#)

ApJ **926** 87 **2022**

<https://arxiv.org/pdf/2111.08770.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac3a73/pdf>

Spheromak type flux ropes are increasingly used for modelling coronal mass ejections (CMEs). Many models aim in accurately reconstructing the magnetic field topology of CMEs, considering its importance in assessing their impact on modern technology and human activities in space and on ground. However, so far there is little discussion about how the details of the magnetic structure of a spheromak affect its evolution through the ambient field in the modelling domain, and what impact this has on the accuracy of magnetic field topology predictions. If the spheromak has its axis of symmetry (geometric axis) at an angle with respect to the direction of the ambient field, then the spheromak starts rotating so that its symmetry axis finally aligns with the ambient field. When using the spheromak in space weather forecasting models this tilting can happen already during insertion and significantly affects the results. In this paper we highlight this issue previously not examined in the field of space weather and we estimate the angle by which the spheromak rotates under different conditions. To do this we generated simple purely radial ambient magnetic field topologies (weak/strong positive/negative) and inserted spheromaks with varying initial speed and tilt, and magnetic helicity sign. We employ different physical and geometric criteria to locate the magnetic centre of mass and axis of symmetry of the spheromak. We confirm that spheromaks rotate in all investigated conditions and their direction and angle of rotation depend on the spheromak's initial properties and ambient magnetic field strength and orientation.

### **Modelling a multi-spacecraft coronal mass ejection encounter with EUHFORIA**

A&A **652**, A27 **2021**

<https://arxiv.org/pdf/2105.11831.pdf>

<https://www.aanda.org/articles/aa/pdf/2021/08/aa40315-21.pdf>

<https://doi.org/10.1051/0004-6361/202140315>

Coronal mass ejections (CMEs) are a manifestation of the Sun's eruptive nature. They can have a great impact on Earth, but also on human activity in space and on the ground. Therefore, modelling their evolution as they propagate through interplanetary space is essential. EUropean Heliospheric FOrecasting Information Asset (EUHFORIA) is a data-driven, physics-based model, tracing the evolution of CMEs through background solar wind conditions. It employs a spheromak flux rope, which provides it with the advantage of reconstructing the internal magnetic field configuration of CMEs. This is something that is not included in the simpler cone CME model used so far for space weather forecasting. This work aims at assessing the spheromak CME model included in EUHFORIA. We employed the spheromak CME model to reconstruct a well observed CME and compare model output to in situ observations. We focus on an eruption from **6 January 2013** encountered by two radially aligned spacecraft, Venus Express and STEREO-A. We first analysed the observed properties of the source of this CME eruption and we extracted the CME properties as it lifted off from the Sun. Using this information, we set up EUHFORIA runs to model the event. The model predicts arrival times from half to a full day ahead of the in situ observed ones, but within errors established from similar studies. In the modelling domain, the CME appears to be propagating primarily southward, which is in accordance with white-light images of the CME eruption close to the Sun. In order to get the observed magnetic field topology, we aimed at selecting a spheromak rotation angle for which the axis of symmetry of the spheromak is perpendicular to the direction of the polarity inversion line (PIL). The modelled magnetic field profiles, their amplitude, arrival times, and sheath region length are all affected by the choice of radius of the modelled spheromak.

## **FESTIVAL: A Multiscale Visualization Tool for Solar Imaging Data**

F. [Auchère](#) · E. Soubrié · K. Bocchialini · F. LeGall

Solar Phys (2008) 248: 213–224

<http://www.springerlink.com/content/g42h84170449n7mq/fulltext.pdf>

**Abstract** Since 4 December 2006, the SECCHI instrument suites onboard the two STEREO A and B probes have been imaging the solar corona and the heliosphere on a wide range of angular scales. The EUVI telescopes have a plate scale of 1.7 arcseconds pixel<sup>-1</sup>, while that of the HI2 wide-angle cameras is 2.15 arcminutes pixel<sup>-1</sup>, *i.e.* 75 times larger, with the COR1 and COR2 coronagraphs having intermediate plate scales. These very different instruments, aimed at studying Coronal Mass Ejections and their propagation in the heliosphere, create a data visualization challenge. This paper presents FESTIVAL, a SolarSoftware package originally developed to be able to map the SECCHI data into dynamic composite images of the sky as seen by the STEREO and SOHO probes. Data from other imaging instruments can also be displayed. Using the mouse, the user can quickly and easily zoom in and out and pan through these composite images to explore all spatial scales from EUVI to HI2 while keeping the native resolution of the original data. A large variety of numerical filters can be applied, and additional data (*i.e.* coordinate grids, stars catalogs, *etc.*) can be overlaid on the images. The architecture of FESTIVAL is such that it is easy to add support for other instruments and these new data immediately benefit from the already existing capabilities. Also, because its mapping engine is fully 3D, FESTIVAL provides a convenient environment to display images from future out-of-the-Ecliptic solar missions, such as *Solar Orbiter* or *Solar Probe*.

## **The return of the jet**

[Guillaume Aulanier](#)

[Nature Astronomy](#) (2021)

<https://doi.org/10.1038/s41550-021-01416-x>

Turmoil has engulfed the solar community for decades about which physical mechanisms are sufficient to trigger and drive solar eruptions. New high-resolution numerical magnetohydrodynamic simulations bring an old idea back into the light: the reconnection jet from the tether-cutting model.

## **Drifting of the line-tied footpoints of CME flux-ropes**

Guillaume [Aulanier](#), [Jaroslav Dudik](#)

A&A 621, A72 (2019)

<https://arxiv.org/pdf/1811.04253.pdf>

[http://www.lesia.obspm.fr/perso/guillaume-aulanier/Aulanier\\_Dudik\\_2018\\_AeA.pdf](http://www.lesia.obspm.fr/perso/guillaume-aulanier/Aulanier_Dudik_2018_AeA.pdf)

<https://sci-hub.ru/10.1051/0004-6361/201834221>

**Context.** Bridging the gap between heliospheric and solar observations of eruptions requires to map ICME footpoints down to the Sun's surface. But this not straightforward. Improving the understanding of the spatio-temporal evolutions of eruptive flares requires a comprehensive standard model. But the current one is two-dimensional only and it cannot address the question of CME footpoints.

**Aims.** Existing 3D extensions to the standard model show that flux-rope footpoints are surrounded by curved-shaped QSL-footprints that can be related with hook-shaped flare-ribbons. We build upon this finding and further address the joint questions of their timeevolution, and of the formation of flare loops at the ends of flaring PILs of the erupting bipole, which are both relevant for flare understanding in general and for ICME studies in particular.

**Methods.** We calculate QSLs and relevant field lines in an MHD simulation of a torus-unstable flux-rope. The evolving QSL footprints are used to define the outer edge of the flux rope at different times, and to identify and characterize new 3D reconnection geometries and sequences that occur above the ends of the flaring PIL. We also analyse flare-ribbons as observed in EUV by SDO/AIA and IRIS during two X-class flares.

**Results.** The flux-rope footpoints are drifting during the eruption, which is unexpected due to line-tying. This drifting is due to a series of coronal reconnections that erode the flux rope on one side and enlarge it on the other side. Other changes in the flux-rope footpoint-area are due to multiple reconnections of individual field lines whose topology can evolve sequentially from arcade to flux rope and finally to flare loop. These are associated with deformations and displacements of QSL footprints, which resemble those of the studied flare ribbons.

**Conclusions.** Our model predicts continuous deformations and a drifting of ICME flux-rope footpoints whose areas are surrounded by equally-evolving hooked-shaped flare-ribbons, as well as the formation of flare loops at the ends of flaring PILs which originate from the flux-rope itself, both of which being due to purely three-dimensional reconnection geometries. The observed evolution of flare-ribbons in two events supports the model, but more observations are required to test all its predictions. **July 12, 2012, September 10, 2014**

## **The physical mechanisms that initiate and drive solar eruptions**

**Review**

[G. Aulanier](#)

E-print, Sept 2013; 2014, IAU Symposium, 300, 184

[http://www.lesia.obspm.fr/perso/guillaume-aulanier/Review\\_2014\\_InitiatingDriving\\_Eruptions.pdf](http://www.lesia.obspm.fr/perso/guillaume-aulanier/Review_2014_InitiatingDriving_Eruptions.pdf)

Solar eruptions are due to a sudden destabilization of force-free coronal magnetic fields. But the detailed mechanisms which can bring the corona towards an eruptive stage, then trigger and drive the eruption, and finally make it explosive, are not fully understood. A large variety of storage-and-release models have been developed and opposed to each other since 40 years. For example, photospheric flux emergence vs. flux cancellation, localized coronal reconnection vs. large-scale ideal instabilities and loss of equilibria, tether-cutting vs. breakout reconnection, and so on. The competition

between all these approaches has led to a tremendous drive in developing and testing all these concepts, by coupling state-of-the-art models and observations. Thanks to these developments, it now becomes possible to compare all these models with one another, and to revisit their interpretation in light of their common and their different behaviors. This approach leads me to argue that no more than two distinct physical mechanisms can actually initiate and drive prominence eruptions: the magnetic breakout and the torus instability. In this view, all other processes (including flux emergence, flux cancellation, flare reconnection and long-range couplings) should be considered as various ways that lead to, or than strengthen, one of the aforementioned driving mechanisms.

## **The standard flare model in three dimensions**

### **I. Strong-to-weak shear transition in post-flare loops**

G. [Aulanier](#), M. Janvier, and B. Schmieder

E-print, 20 May, 2012, **File**; A&A

The standard CSHKP model for eruptive flares is two-dimensional. Yet observational interpretations of photospheric currents in pre-eruptive sigmoids, shear in post-flare loops, and relative positioning and shapes flare ribbons, all together require three-dimensional extensions to the model. The paper focuses on the strong-to-weak shear transition in post-flare loop, and on the time-evolution of the geometry of photospheric electric currents, which occur during the development of eruptive flares. The objective is to understand the three-dimensional physical processes which cause them, and to know how much the post-flare and the pre-eruptive distributions of shear depend on each other. The strong-to-weak shear transition in post-flare loops is identified and quantified in a flare observed by STEREO, as well as in a magnetohydrodynamic simulation of CME initiation performed with the OHM code. In both approaches, the magnetic shear is evaluated with field line footpoints. In the simulation, the shear is also estimated from ratios between magnetic field components. The modeled strong-to-weak shear transition in post-flare loops comes from two effects. Firstly, a reconnection-driven transfer of the differential magnetic shear, from the pre- to the post-eruptive configuration. Secondly, a vertical straightening of the inner legs of the CME, which induces an outer shear weakening. The model also predicts the occurrence of narrow electric current layers inside J-shaped flare ribbons, which are dominated by direct currents. Finally, the simulation naturally accounts for energetics and time-scales for weak and strong flares, when typical scalings for young and decaying solar active regions are applied. The results provide three-dimensional extensions to the standard flare model. These extensions involve MHD processes that should be tested with observations. **May 9, 2011**

## **FORMATION OF TORUS-UNSTABLE FLUX ROPES AND ELECTRIC CURRENTS IN ERUPTING SIGMOIDS**

G. [Aulanier](#), T. Török, P. Démoulin, E. E. DeLuca

ApJ, 708:314–333, 2010 January, **File**

We analyze the physical mechanisms that form a three-dimensional coronal flux rope and later cause its eruption. This is achieved by a zero- $\beta$  MHD simulation of an initially potential, asymmetric bipolar field, which evolves by means of simultaneous slow magnetic field diffusion and sub-Alfvénic, line-tied shearing motions in the photosphere. As in similar models, flux-cancellation driven photospheric reconnection in a bald-patch separatrix transforms the sheared arcades into a slowly rising and stable flux rope. A bifurcation from a bald-patch to a quasi-separatrix layer (QSL) topology occurs later on in the evolution, while the flux rope keeps growing and slowly rising, now due to shear-driven coronal slip-running reconnection, which is of tether-cutting type and takes place in the QSL. As the flux rope reaches the altitude at which the decay index  $-\partial \ln B / \partial \ln z$  of the potential field exceeds  $\sim 3/2$ , it rapidly accelerates upward while the overlying arcade eventually develops an inverse tear-drop shape, as observed in coronal mass ejections (CMEs). This transition to eruption is in accordance with the onset criterion of the torus instability. Thus we find that photospheric flux-cancellation and tether-cutting coronal reconnection do not trigger CMEs in bipolar magnetic fields, but are key pre-eruptive mechanisms for flux ropes to build up and to rise to the critical height above the photosphere at which the torus instability causes the eruption. In order to interpret recent Hinode X-Ray Telescope observations of an erupting sigmoid, we produce simplified synthetic soft X-ray images from the distribution of the electric currents in the simulation. We find that a bright sigmoidal envelope is formed by pairs of J-shaped field lines in the pre-eruptive stage. These field lines form through the bald-patch reconnection, and merge later on into S-shaped loops through the tethercutting reconnection. During the eruption, the central part of the sigmoid brightens due to the formation of a vertical current layer in the wake of the erupting flux rope. Slip-running reconnection in this layer yields the formation of flare loops. A rapid decrease of currents due to field line expansion, together with the increase of narrow currents in the reconnecting QSL, yields the sigmoid hooks to thin in the early stages of the eruption. Finally, a slightly rotating erupting loop-like feature (ELLF) detaches from the center of the sigmoid. Most of this ELLF is not associated with the erupting flux rope, but with a current shell which develops within expanding field lines above the rope. Only the short, curved end of the ELLF corresponds to a part of the flux rope. We argue that the features found in the simulation are generic for the formation and eruption of soft X-ray sigmoids.

## Radio evidence for breakout reconnection in solar eruptive events

H. Aurass, G. Holman, S. Braune, G. Mann, P. Zlobec

E-print, May 2013, File; A&A

Magnetic reconnection is understood to be fundamental to energy release in solar eruptive events (SEEs). In these events reconnection produces a magnetic flux rope above an arcade of hot flare loops. Breakout reconnection, a secondary reconnection high in the corona between this flux rope and the overlying magnetic field, has been hypothesized. Direct observational evidence for breakout reconnection has been elusive, however. The aim of this study is to establish a plausible interpretation of the combined radio and hard X-ray (HXR) emissions observed during the impulsive phase of the near-limb X3.9-class SEE on **2003 November 03**. We study radio spectra (AIP), simultaneous radio images (Nancay Multi-frequency Radio Heliograph, NRH), and single-frequency polarimeter data (OAT). The radio emission is nonthermal plasma radiation with a complex structure in frequency and time. Emphasis is on the time interval when the HXR flare loop height was observed by the Ramaty High Energy Solar Spectroscopic Imager (RHESSI) to be at its minimum and an X-ray source was observed above the top of the arcade loops. Two stationary, meter-wavelength sources are observed radially aligned at 0.18 and 0.41Rs above the active region and hard X-ray sources. The lower source is apparently associated with the upper reconnection jet of the flare current sheet (CS), and the upper source is apparently associated with breakout reconnection. Sources observed at lower radio frequencies surround the upper source at the expected locations of the breakout reconnection jets. We believe the upper radio source is the most compelling evidence to date for the onset of breakout reconnection during a SEE. The height stationarity of the breakout sources and their dynamic radio spectrum discriminate them from propagating disturbances. Timing and location arguments reveal for the first time that both the earlier described "above the flare loop top" HXR source and the lower radio source are emission from the upper reconnection jet above the vertical flare CS.

## RADIO EVIDENCE OF BREAK-OUT RECONNECTION?

H. Aurass<sup>1</sup>, G. Mann<sup>1</sup>, P. Zlobec<sup>2</sup> and M. Karlický<sup>3</sup>

2011 ApJ 730 57, File

We reconsider the **2003 October 28** X17 flare/coronal mass ejection (CME), studying the five minutes immediately before the impulsive flare phase (not discussed in previous work). To this aim we examine complementary dynamic radio spectrograms, single frequency polarimeter records, radio images, space-based longitudinal field magnetograms, and ultraviolet images. We find widely distributed faint and narrowband meter wave radio sources located outside active regions but associated with the boundaries of magnetic flux connectivity cells, inferred from the potential extrapolation of the observed photospheric longitudinal field as a model for coronal magnetic field structures. The meter wave radio sources occur during the initial decimeter wave effects, which are well known to be associated with filament destabilization in the flaring active region (here NOAA 10486). Antiochos et al. predict in their break-out model for CME initiation that "... huge phenomena ... may be controlled by detailed plasma processes that occur in relatively tiny regions." They suggest that the expected faint energy release "... on long field lines far away from any neutral line ... may be detectable in radio/microwave emission from nonthermal particles..." In this paper, we describe meter wave sources whose properties correctly coincide with the quoted predictions of the break-out reconnection model of the CME initiation.

## Observational evidence for breakout reconnection

## Coronal current sheet signatures during the 17 May 2002 CME-flare

H. Aurass<sup>1</sup>, F. Landini<sup>2</sup>, G. Poletto

E-print, Aug 2009, File; A&A

Context. The relation between current sheets (CSs) associated with flares, revealed by characteristic radio signatures, and current sheets associated with coronal mass ejections (CMEs), detected in coronal ultraviolet (UV) and white light data, has not been analyzed, yet.

Aims. We aim at establishing the relationship between CSs associated with a limb flare and CSs associated with the CME that apparently develops after the flare. We use a unique data set, acquired on May 17, 2002, which includes radio and extreme ultraviolet (XUV) observations.

Methods. Spectral radio diagnostics, UV spectroscopic techniques, white light coronagraph imaging, and (partly) radio imaging are used to illustrate the relation between the CSs and to infer the physical parameters of the radially aligned features that develop in the aftermath of the CME.

Results. During the flare, several phenomena are interpreted in accordance with earlier work and with reference to the common eruptive flare scenario as evidence of flare CSs in the low corona. These are drifting pulsating structures in dynamic radio spectra, an erupting filament, expanding coronal loops morphologically recalling the later white light CME, and associated with earlier reported hard X-ray source sites. In the aftermath of the CME, UV spectra allowed us to estimate the CS temperature and density, over the 1.5 - 2.1  $R_{\odot}$  interval of heliocentric altitudes. The UV detected CS, however, appears to be only one of many current sheets that exist underneath the erupting flux rope. A type II burst following the CME radio continuum in time at lower frequencies is considered as the radio signature of a coronal shock excited at the flank of the CME.

Conclusions. *The results show that we can build an overall scenario where the CME is interpreted in terms of an erupting arcade crossing the limb of the Sun and connected to underlying structures via multiple CSs. Eventually, the observed limb flare seems to be a consequence of the ongoing CME.*

## **Electric Current Neutralization in Solar Active Regions and Its Relation to Eruptive Activity**

Ellis A. [Avallone](#), [Xudong Sun](#)

ApJ **893** 123 **2020**

<https://arxiv.org/pdf/2003.02814.pdf>

<https://doi.org/10.3847/1538-4357/ab7afa>

It is well established that magnetic free energy associated with electric currents powers solar flares and coronal mass ejections (CMEs) from solar active regions (ARs). However, the conditions that determine whether an AR will produce an eruption are not well understood. Previous work suggests that the degree to which the driving electric currents, or the sum of all currents within a single magnetic polarity, are neutralized may serve as a good proxy for assessing the ability of ARs to produce eruptions. Here, we investigate the relationship between current neutralization and flare/CME production using a sample of 15 flare-active and 15 flare-quiet ARs. All flare-quiet and 4 flare-active ARs are also CME-quiet. We additionally test the relation of current neutralization to the degree of shear along polarity inversion lines (PILs) in an AR. We find that flare-productive ARs are more likely to exhibit non-neutralized currents, specifically those that also produce a CME. We find that flare/CME-active ARs also exhibit higher degrees of PIL shear than flare/CME-quiet ARs. We additionally observe that currents become more neutralized during magnetic flux emergence in flare-quiet ARs. Our investigation suggests that current neutralization in ARs is indicative of their eruptive potential. **2011.02.15, 2013.06.19-20, 2017.09.4-7**

## **Mass motion in a prominence bubble revealing a kinked flux rope configuration**

Arun Kumar [Awasthi](#), [Rui Liu](#)

Frontiers in Physics - Stellar and Solar Physics

**2019**

<https://arxiv.org/pdf/1911.12100.pdf>

Prominence bubbles are cavities rising into quiescent prominences from below. The bubble-prominence interface is often the active location for the formation of plumes, which flow turbulently into quiescent prominences. Not only the origin of prominence bubbles is poorly understood, but most of their physical characteristics are still largely unknown. Here, we investigate the dynamical properties of a bubble, which is observed since its early emergence beneath the spine of a quiescent prominence on **20 October 2017** in the  $H\alpha$  line-center and in  $\pm 0.4$  angstrom line-wing wavelengths by the 1-m New Vacuum Solar Telescope. We report the prominence bubble to be exhibiting a disparate morphology in the  $H\alpha$  line-center compared to its line-wings' images, indicating a complex pattern of mass motion along the line-of-sight. Combining Doppler maps with flow maps in the plane of sky derived from a Nonlinear Affine Velocity Estimator, we obtained a comprehensive picture of mass motions revealing a counter-clockwise rotation inside the bubble; with blue-shifted material flowing upward and red-shifted material flowing downward. This sequence of mass motions is interpreted to be either outlining a kinked flux rope configuration of the prominence bubble or providing observational evidence of the internal kink instability in the prominence plasma.

## **Pre-Eruptive Magnetic Reconnection within a Multi-Flux-Rope System in the Solar Corona**

Arun Kumar [Awasthi](#), [Rui Liu](#), [Haimin Wang](#), [Yuming Wang](#), [Chenglong Shen](#)

ApJ **857** 124 **2018**

<https://arxiv.org/pdf/1803.04088.pdf>

[sci-hub.se/10.3847/1538-4357/aab7fb](https://doi.org/10.3847/1538-4357/aab7fb)

The solar corona is frequently disrupted by coronal mass ejections (CMEs), whose core structure is believed to be a flux rope made of helical magnetic field. This has become a "standard" picture although it remains elusive how the flux rope forms and evolves toward eruption. While 1/3 of the ejecta passing through spacecrafts demonstrate a flux-rope structure, the rest have complex magnetic fields. Are they originating from a coherent flux rope, too? Here we investigate the source region of a complex ejecta, focusing on a flare precursor with definitive signatures of magnetic reconnection, i.e., nonthermal electrons, flaring plasma, and bi-directional outflowing blobs. Aided by nonlinear force-free field modeling, we conclude that the reconnection occurs within a system of

multiple braided flux ropes with different degree of coherency. The observation signifies the importance of internal structure and dynamics in understanding CMEs and in predicting their impacts on Earth. **22 June 2015**

## **Coronal Mass Ejections from the Sun - Propagation and Near Earth Effects**

Arun **Babu**

THESIS, 2014

<http://arxiv.org/pdf/1407.4258v1.pdf>

Owing to our dependence on spaceborne technology, an awareness of disturbances in the near-Earth space environment is proving to be increasingly crucial. Earth-directed Coronal mass ejections (CMEs) emanating from the Sun are the primary drivers of space weather disturbances. Studies of CMEs, their kinematics, and their near-Earth effects are therefore gaining in importance.

The effect of CMEs near the Earth is often manifested as transient decreases in galactic cosmic ray intensity, which are called **Forbush decreases (FDs)**. In this thesis we probe the structure of CMEs and their associated shocks using FD observations by the GRAPES-3 muon telescope at Ooty. We have established that the cumulative diffusion of galactic cosmic rays into the CME is the dominant mechanism for causing FDs (Chapter 3).

This diffusion takes place through a turbulent sheath region between the CME and the shock. One of our main results concerns the turbulence level in this region. We have quantitatively established that cross-field diffusion aided by magnetic field turbulence accounts for the observed lag between the FD and the magnetic field enhancement of the sheath region (Chapter 4).

We have also investigated the nature of the driving forces acting on CMEs in this thesis. Using CME data from the SECCHI coronagraphs aboard STEREO spacecraft, we have found evidence for the non-force-free nature of the magnetic field configuration inside these CMEs, which is the basis for the (often-invoked) Lorentz self-force driving (Chapter 5).

Taken together the work presented in this thesis is a comprehensive attempt to characterise CME propagation from typical coronagraph fields of view to the Earth.

## **Plasma Physical Parameters along CME-driven Shocks. II. Observation–Simulation Comparison**

F. **Bacchini**<sup>1</sup>, R. Susino<sup>2</sup>, A. Bemporad<sup>2</sup>, and G. Lapenta<sup>1</sup>

2015 ApJ 809 58

In this work, we compare the spatial distribution of the plasma parameters along the **1999 June 11** coronal mass ejection (CME)-driven shock front with the results obtained from a CME-like event simulated with the FLIPMHD3D code, based on the FLIP-MHD particle-in-cell method. The observational data are retrieved from the combination of white-light coronagraphic data (for the upstream values) and the application of the Rankine–Hugoniot equations (for the downstream values). The comparison shows a higher compression ratio  $X$  and Alfvénic Mach number  $MA$  at the shock nose, and a stronger magnetic field deflection  $d$  toward the flanks, in agreement with observations. Then, we compare the spatial distribution of  $MA$  with the profiles obtained from the solutions of the shock adiabatic equation relating  $MA$ ,  $X$ , and  $\theta_{Bn}$  (the angle between the upstream magnetic field and the shock front normal) for the special cases of parallel and perpendicular shock, and with a semi-empirical expression for a generically oblique shock. The semi-empirical curve approximates the actual values of  $MA$  very well, if the effects of a non-negligible shock thickness  $\delta_{sh}$  and plasma-to magnetic pressure ratio  $\beta_u$  are taken into account throughout the computation. Moreover, the simulated shock turns out to be supercritical at the nose and sub-critical at the flanks. Finally, we develop a new one-dimensional Lagrangian ideal MHD method based on the GrAALe code, to simulate the ion-electron temperature decoupling due to the shock transit. Two models are used, a simple solar wind model and a variable- $\gamma$  model. Both produce results in agreement with observations, the second one being capable of introducing the physics responsible for the additional electron heating due to secondary effects (collisions, Alfvén waves, etc.).

## **Evidence for precursors of the coronal hole jets in solar bright points**

Salome R. **Bagashvili**, **Bidzina M. Shergelashvili**, **Darejan R. Japaridze**, **Vasil Kukhianidze**, **Stefaan Poedts**, **Teimuraz V. Zaqarashvili**, **Maxim L. Khodachenko**, **Patrick De Causmaecker**

ApJL 2018

<https://arxiv.org/pdf/1803.00551.pdf>

A set of 23 observations of coronal jet events that occurred in coronal bright points has been analyzed. The focus was on the temporal evolution of the mean brightness before and during coronal jet events. In the absolute majority of the cases either single or recurrent coronal jets were preceded by slight precursor disturbances observed in the mean intensity curves. The key conclusion is that we were able to detect quasi-periodical oscillations with characteristic periods from sub-minute up to 3-4 min values in the bright point brightness which precede the jets. Our basic claim is that along with the conventionally accepted scenario of bright point evolution through new magnetic flux emergence and its reconnection with the initial structure of the bright point and the coronal hole, certain MHD oscillatory and wave-like motions can be excited and these can take an important place in the observed dynamics. These quasi-oscillatory phenomena might play the role of links between different epochs of the coronal jet ignition and evolution. They can be an indication of the MHD wave excitation processes due to the system entropy variations, density

variations or shear flows. It is very likely a sharp outflow velocity transverse gradients at the edges between the open and closed field line regions. We suppose that magnetic reconnections can be the source of MHD waves due to impulsive generation or rapid temperature variations, and shear flow driven nonmodel MHD wave evolution (self-heating and/or overreflection mechanisms). **9 Dec 2015 Table 23 events (2015-2016)**

## **Shock and Discontinuity Formation in the Front of an Expanding Coronal Magnetic Arcade in Two-fluid Simulations**

T. E. **Bagwell** and Z. W. Ma

2020 ApJ 898 167

<https://doi.org/10.3847/1538-4357/aba2d4>

The dynamic evolution of a magnetic arcade associated with footpoint shearing motions is investigated by an ideal two-fluid (electron-ion) code. The two-fluid numerical simulations produce conspicuous differences compared to earlier MHD simulations beyond the inner arcade region. The decoupling motion between electrons and heavier ions during the arcade expansion induces a growing charge separation and strong electric field in the front of the expanding arcade. The presence of this electric field provides an additional force, along with the magnetic and thermal pressures, that drives the growth of an outwardly expanding wave that steepens into a propagating discontinuity in the plasma and magnetic field. The propagation speed of the discontinuity eventually exceeds the local phase velocity of the MHD fast mode and becomes a perpendicular fast-like shock. There is significant heating at the shock due to adiabatic compression, with preferential heating of the ion fluid also being observed. In addition, parameter tests indicate that (1) the propagation speed of the shock before exiting the inner arcade is independent of the maximum shear speed; (2) slower shearing speeds produce weaker shocks with weaker adiabatic heating; (3) the ion-to-electron mass ratio,  $m_i/m_e$ , impacts the strength of the charge separation linearly but has a moderate effect on the propagation speed; and (4) the normalized value of the ion inertial length does not affect the formation and speed of the shock as a whole.

<http://iopscience.iop.org/article/10.3847/1538-4357/aaf1d1/pdf>

Dynamical jets are generally found on light bridges (LBs), which are key to studying sunspot decay. So far, their formation mechanism is not fully understood. In this paper, we used state-of-the-art observations from the Goode Solar Telescope, the Interface Region Imaging Spectrograph, the Spectro-polarimeter on board Hinode, and the Atmospheric Imaging Assembly (AIA) on board the Solar Dynamics Observatory to analyze the fan-shaped jets on LBs in detail. A continuous upward motion of the jets in the ascending phase is found from the H $\alpha$  velocity that lasts for 12 minutes and is associated with the H $\alpha$  line wing enhancements. Two mini jets appear on the bright fronts of the fan-shaped jets visible in the AIA 171 and 193 Å channels, with a time interval as short as 1 minute. Two kinds of small-scale convective motions are identified in the photospheric images, along with the H $\alpha$  line wing enhancements. One seems to be associated with the formation of a new convection cell, and the other manifests as the motion of a dark lane passing through the convection cell. The finding of three-lobe Stokes V profiles and their inversion with the NICOLE code indicate that there are magnetic field lines with opposite polarities in LBs. From the H $\alpha$  -0.8 Å images, we found ribbon-like brightenings propagating along the LBs, possibly indicating slipping reconnection. Our observation supports the idea that the fan-shaped jets under study are caused by magnetic reconnection, and photospheric convective motions play an important role in triggering the magnetic reconnection. **2014 August 1**

## **Further Evidence for the Minifilament-Eruption Scenario for Solar Polar Coronal Jets**

[Tomi K. Baikie](#), [Alphonse C. Sterling](#), [Ronald L. Moore](#), [Amanda M. Alexander](#), [David A. Falconer](#), [Antonia Savcheva](#), [Sabrina L. Savage](#)

ApJ 927 79 2022

<https://arxiv.org/pdf/2201.08882.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac473e/pdf>

We examine a sampling of 23 polar-coronal-hole jets. We first identified the jets in soft X-ray (SXR) images from the X-ray telescope (XRT) on the Hinode spacecraft, over 2014-2016. During this period, frequently the polar holes were small or largely obscured by foreground coronal haze, often making jets difficult to see. We selected 23 jets among those adequately visible during this period, and examined them further using Solar Dynamics Observatory (SDO) Atmospheric Imaging Assembly (AIA) 171, 193, 211, and 304 Å images. In SXRs we track the lateral drift of the jet spire relative to the jet base's jet bright point (JBP). In 22 of 23 jets the spire either moves away from (18 cases) or is stationary relative to (4 cases) the JBP. The one exception where the spire moved toward the JBP may be a consequence of line-of-sight projection effects at the limb. From the AIA images, we clearly identify an erupting minifilament in 20 of the 23 jets, while the remainder are consistent with such an eruption having taken place. We also confirm that some jets can trigger onset of nearby "sympathetic" jets, likely because eruption of the minifilament field of the first jet

removes magnetic constraints on the base-field region of the second jet. The propensity for spire drift away from the JBP, the identification of the erupting minifilament in the majority of jets, and the magnetic-field topological changes that lead to sympathetic jets, all support or are consistent with the minifilament-eruption model for jets. **13 Aug 2014, 27 Feb 2015, 2015 March 19, 8 Apr 2015, 2015 June 5, 2016 March 17, 2016 March 23, 2016 April 01**

### **RADIO IMAGING OF SHOCK-ACCELERATED ELECTRONS ASSOCIATED WITH AN ERUPTING PLASMOID ON 2010 NOVEMBER 3**

H. M. [Bain](#), Säm Krucker<sup>1</sup>, L. Glesener, and R. P. Lin  
**2012 ApJ 750 44**

We present observations of a metric type II solar radio burst that occurred on the **3rd of November 2010** in association with an erupting plasmoid. The eruption was well observed by the Atmospheric Imaging Assembly (AIA) on board the Solar Dynamics Observatory and the Reuven Ramaty High Energy Solar Spectroscopic Imager, while the burst occurred in the frequency range of the Nançay Radioheliograph (NRH). Such events, where the type II emission occurs in the NRH frequency range, allowing us to image the burst, are infrequent. Combining these data sets, we find that the type II is located ahead of the hot ( $\sim 11$  MK) core of the plasmoid, which is surrounded by a well-defined envelope of cool (few MK) plasma. Using two methods, we determine the propagation velocity of the shock: (1) fitting the type II emission observed in PHOENIX and HUMAIN radio spectrogram data; (2) direct imaging of the type II source location using NRH observations. We use LASCO C2 polarized brightness images to normalize our coronal density model. However, we find that information from imaging is required in order to fine-tune this normalization. We determine a shock propagation velocity between  $1900 \text{ km s}^{-1}$  and  $2000 \text{ km s}^{-1}$ . This is faster than the plasmoid observed at extreme-ultraviolet wavelengths by AIA ( $v = 670\text{-}1440 \text{ km s}^{-1}$ , where the cooler plasma propagates faster than the hot core). The positioning of the type II, ahead of the plasmoid, suggests that the electrons are accelerated in a piston-driven shock.

### **Coronal Mass Ejections Associated with Slow Long Duration Flares**

U. [Bağ-Steślicka](#), S. Kołomański, T. Mrozek  
**Solar Phys. 2013, File**

It is well known that there is a temporal relationship between coronal mass ejections (CMEs) and associated flares. The duration of the acceleration phase is related to the duration of the rise phase of a flare. We investigate CMEs associated with slow long duration events (LDEs), i.e. flares with the long rising phase. We determined the relationships between flares and CMEs and analyzed the CME kinematics in detail. The parameters of the flares (GOES flux, duration of the rising phase) show strong correlations with the CME parameters (velocity, acceleration during main acceleration phase, and duration of the CME acceleration phase). These correlations confirm the strong relation between slow LDEs and CMEs. We also analyzed the relation between the parameters of the CMEs, i.e. a velocity, an acceleration during the main acceleration phase, a duration of the acceleration phase, and a height of a CME at the end of the acceleration phase. The CMEs associated with the slow LDEs are characterized by high velocity during the propagation phase, with the median equal to  $1423 \text{ km s}^{-1}$ . In half of the analyzed cases, the main acceleration was low ( $a < 300 \text{ m s}^{-2}$ ), which suggests that the high velocity is caused by the prolonged acceleration phase (the median for the duration of the acceleration phase is equal 90 minutes). The CMEs were accelerated up to several solar radii (with the median  $\approx 7 R_{\odot}$ ), which is much higher than in typical impulsive CMEs. Therefore, slow LDEs may potentially precede extremely strong geomagnetic storms. The analysis of slow LDEs and associated CMEs may give important information for developing more accurate space-weather forecasts, especially for extreme events.

**ApJ 924:17 2022**

<https://arxiv.org/pdf/2110.11714.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac32d2/pdf>

Magnetic flux ropes are bundles of twisted magnetic field enveloping a central axis. They harbor free magnetic energy and can be progenitors of coronal mass ejections (CMEs), but identifying flux ropes on the Sun can be challenging. One of the key coronal observables that has been shown to indicate the presence of a flux rope is a peculiar bright coronal structure called a sigmoid. In this work, we show Hinode EUV Imaging Spectrometer (EIS) observations of sigmoidal active region 10977. We analyze the coronal plasma composition in the active region and its evolution as the sigmoid (flux rope) forms and erupts as a CME. Plasma with photospheric composition was observed in coronal loops close to the main polarity inversion line during episodes of significant flux cancellation, suggestive of the injection of photospheric plasma into these loops driven by photospheric flux cancellation. Concurrently, the increasingly sheared core field contained plasma with coronal composition. As flux cancellation decreased and the sigmoid/flux rope formed, the plasma evolved to an intermediate composition in between photospheric and typical active region coronal compositions. Finally, the flux rope contained predominantly photospheric plasma during and after a failed eruption preceding the CME. Hence, plasma composition observations of active region 10977 strongly support models of

flux rope formation by photospheric flux cancellation forcing magnetic reconnection first at the photospheric level then at the coronal level. **2007 December 4–7**

### **Plasma Upflows Induced by Magnetic Reconnection Above an Eruptive Flux Rope**

*Solar Physics* volume 296, Article number: 103 (2021)

<https://link.springer.com/content/pdf/10.1007/s11207-021-01849-7.pdf>

<https://doi.org/10.1007/s11207-021-01849-7>

One of the major discoveries of Hinode's Extreme-ultraviolet Imaging Spectrometer (EIS) is the presence of upflows at the edges of active regions. As active regions are magnetically connected to the large-scale field of the corona, these upflows are a likely contributor to the global mass cycle in the corona. Here we examine the driving mechanism(s) of the very strong upflows with velocities in excess of  $70 \text{ km s}^{-1}$ , known as blue-wing asymmetries, observed during the eruption of a flux rope in AR 10977 (eruptive flare SOL2007-12-07T04:50). We use Hinode/EIS spectroscopic observations combined with magnetic-field modeling to investigate the possible link between the magnetic topology of the active region and the strong upflows. A Potential Field Source Surface (PFSS) extrapolation of the large-scale field shows a quadrupolar configuration with a separator lying above the flux rope. Field lines formed by induced reconnection along the separator before and during the flux-rope eruption are spatially linked to the strongest blue-wing asymmetries in the upflow regions. The flows are driven by the pressure gradient created when the dense and hot arcade loops of the active region reconnect with the extended and tenuous loops overlying it. In view of the fact that separator reconnection is a specific form of the more general quasi-separatrix (QSL) reconnection, we conclude that the mechanism driving the strongest upflows is, in fact, the same as the one driving the persistent upflows of  $\approx 10 - 20 \text{ km s}^{-1}$  observed in all active regions.

*Solar Physics*, Volume 276, Numbers 1-2, 219-239, 2012, [File](#)

Multi-temperature plasma flows resulting from the interaction between a mature active region (AR) inside an equatorial coronal hole (CH) are investigated. Outflow velocities observed by Hinode EIS ranged from a few to  $13 \text{ km s}^{-1}$  for three days at the AR's eastern and western edges. However, on the fourth day, velocities intensified up to  $20 \text{ km s}^{-1}$  at the AR's western footpoint about six hours prior to a CME. 3D MHD numerical simulations of the observed magnetic configuration of the AR-CH complex showed that the expansion of the mature AR's loops drives persistent outflows along the neighboring CH field (Murray et al. in *Solar Phys.* 261, 253, 2010). Based on these simulations, intensification of outflows observed pre-eruption on the AR's western side where same-polarity AR and CH field interface, is interpreted to be the result of the expansion of a sigmoidal AR, in particular, a flux rope containing a filament that provides stronger compression of the neighboring CH field on this side of the AR. Intensification of outflows in the AR is proposed as a new type of CME precursor.

Coronal mass ejections are eruptions of plasma and magnetic field from low in the Sun's atmosphere. They act as a valve to release magnetic energy from the Sun's atmosphere and are the major driver of space weather events. Theoretical and observational developments since their discovery in the early 1970's have shown that coronal mass ejections are driven by changes in the magnetic field which occur over a wide range of time scales from hours to weeks. Since it is not currently possible to directly observe the magnetic field in this region of the Sun to understand these changes, other observational signatures must be used as a proxy for the magnetic field evolution. In the past this has included the slow rise of filaments or coronal loops which indicate an overall rise or expansion of the magnetic structure which can in many cases be interpreted as being that of a twisted rope of magnetic field. This nugget discusses how plasma outflows from an active region which erupts to produce a coronal mass ejection can be used to understand when important changes in the magnetic field start to occur.

[Abstract](#) [Full Article](#) (PDF, 4868 KB)

Combining STEREO, ACE and Hinode observations has presented an opportunity to follow a filament eruption and coronal mass ejection (CME) on the **17th of October 2007** from an active region (AR) inside a coronal hole (CH) into the heliosphere. This particular combination of 'open' and closed magnetic topologies provides an ideal scenario for interchange reconnection to take place. With Hinode and STEREO data we were able to identify the emergence time and type of structure seen in the in-situ data four days later. On the 21st, ACE observed in-situ the passage of an ICME with 'open' magnetic topology. The magnetic field configuration of the source, a mature AR located inside an equatorial CH, has important implications for the solar and interplanetary signatures of the eruption. We interpret the formation of an 'anemone' structure of the erupting AR and the passage in-situ of the ICME being disconnected at one leg, as manifested by uni-directional suprathermal electron flux in the ICME, to be a direct result of interchange reconnection between closed loops of the CME originating from the AR and 'open' field lines of the surrounding CH.

## Coronal Mass Ejections Associated with Slow Long Duration Flares

U. Bak-Steslicka, S. Kolomanski, T. Mrozek

E-print, Feb **2013**; Solar Phys., April **2013**, Volume 283, Issue 2, pp 505-517, **File**

It is well known that there is temporal relationship between coronal mass ejections (CMEs) and associated flares. The duration of the acceleration phase is related to the duration of the rise phase of a flare. We investigate CMEs associated with slow long duration events (LDEs), i.e. flares with the long rising phase. We determined the relationships between flares and CMEs and analyzed the CME kinematics in detail. The parameters of the flares (GOES flux, duration of the rising phase) show strong correlations with the CME parameters (velocity, acceleration during main acceleration phase and duration of the CME acceleration phase). These correlations confirm the strong relation between slow LDEs and CMEs. We also analyzed the relation between the parameters of the CMEs, i.e. a velocity, an acceleration during the main acceleration phase, a duration of the acceleration phase, and a height of a CME at the end of the acceleration phase. The CMEs associated with the slow LDEs are characterized by high velocity during the propagation phase, with the median equal 1423 km/s. In half of the analyzed cases, the main acceleration was low ( $a < 300 \text{ m/s}^2$ ), which suggests that the high velocity is caused by the prolonged acceleration phase (the median for the duration of the acceleration phase is equal 90 minutes). The CMEs were accelerated up to several solar radii (with the median 7  $R_{\text{sun}}$ ), which is much higher than in typical impulsive CMEs. Therefore, slow LDEs may potentially precede extremely strong geomagnetic storms. The analysis of slow LDEs and associated CMEs may give important information for developing more accurate space weather forecasts, especially for extreme events.

## Investigation of Slow Rising LDE Flares and Associated CMEs

Bak-Steslicka, U.; Kolomanski, S.; Jakimiec, J

Freiburg ESP Meeting **2008**, **Poster**

We investigated limb long duration flares with slow rising phases (slow LDE) accompanied with CMEs.

It was shown by other authors that acceleration phase of CME lasts as long as the rising phase of associated flare. Thus, slow evolution of slow rising flares allows to study earliest stages of CME evolution in details.

Using LASCO data we examined statistical properties of these CME while SXT, EIT and TRACE data were utilized to analyse structure and evolution of associated slow LDE flares. The SXT, EIT and TRACE data allow us to identify CME related structures visible in EUV and SXR.

## The Hyper-inflation Stage in the Coronal Mass Ejection Formation: A Missing Link That Connects Flares, Coronal Mass Ejections, and Shocks in the Low Corona

Laura A. Balmaceda<sup>1,2</sup>, Angelos Vourlidis<sup>3</sup>, Guillermo Stenborg<sup>3</sup>, and Ryun-Young Kwon<sup>4</sup>

**2022** ApJ 931 141

<https://iopscience.iop.org/article/10.3847/1538-4357/ac695c/pdf>

We analyze the formation and three-dimensional (3D) evolution of two coronal mass ejections (CMEs) and their associated waves in the low corona via a detailed multi-viewpoint analysis of extreme-ultraviolet observations. We analyze the kinematics in the radial and lateral directions and identify three stages in the early evolution of the CME: (1) a hyper-inflation stage, when the CME laterally expands at speeds of  $\sim 1000 \text{ km s}^{-1}$ , followed by (2) a shorter and slower expansion stage of a few minutes and ending with (3) a self-similar phase that carries the CME into the middle corona. The first two stages coincide with the impulsive phase of the accompanying flare, the formation and separation of an EUV wave from the CME, and the start of the metric type II radio burst. Our 3D analysis suggests that the hyper-

inflation phase may be a crucial stage in the CME formation with wide-ranging implications for solar eruption research. It likely represents the formation stage of the magnetic structure that is eventually ejected into the corona, as the white-light CME. It appears to be driven by the injection of poloidal flux into the ejecting magnetic structure, which leads to the lateral (primarily) growth of the magnetic flux rope. The rapid growth results in the creation of EUV waves and eventually shocks at the CME flanks that are detected as metric type II radio bursts. In other words, the hyper-inflation stage in the early CME evolution may be the "missing" link between CMEs, flares, and coronal shocks. **2011 March 7, 2011 June 7**

### **On the Expansion Speed of Coronal Mass Ejections: Implications for Self-Similar Evolution**

[L. A. Balmaceda](#), [A. Vourlidas](#), [G. Stenborg](#) & [O. C. St. Cyr](#)

[Solar Physics](#) volume 295, Article number: 107 (2020)

<https://link.springer.com/content/pdf/10.1007/s11207-020-01672-6.pdf>

A proper characterization of the kinematics of coronal mass ejections (CMEs) is important not only for practical purposes, i.e. space weather forecasting, but also to improve our current understanding of the physics behind their evolution in the middle corona and into the heliosphere. The first and core step toward this goal is the estimation of the three main components of the CME speeds, namely the expansion speed relative to the center of motion in both, the radial and lateral directions, and the propagation speed (i.e.  $V_{\text{front}}$ ,  $V_{\text{lat}}$ ,  $V_{\text{bulk}}$ , respectively). To this aim, we exploit the observations obtained with COR2 onboard the Solar Terrestrial Relations Observatory (STEREO) from 2007 to 2014 to investigate the relationships among the different components as a function of the heliocentric distance of the CME events. Here, we analyze a sample of 475 CMEs. The selected events exhibit clear flux rope signatures as seen either edge on (i.e. F-CMEs: three-part structure, presence of a cavity) or face on (i.e. L- or loop CMEs) in white light images. Our main findings are: i) L-CMEs show almost twice as large expansion speeds compared to F-CMEs ( $V_{\text{front,L}}=367 \text{ kms}^{-1}$ ,  $V_{\text{lat,L}}=365 \text{ kms}^{-1}$  vs.  $V_{\text{front,F}}=215 \text{ kms}^{-1}$ ,  $V_{\text{lat,F}}=182 \text{ kms}^{-1}$ ); ii) the relationship between the two components of the expansion speeds is linear and does not change with height; iii) the ratio of the propagation speed to the lateral expansion speed is a function of the angular width that describes the self-similarity evolution of a CME; and iv) 65% of the CMEs exhibit a self-similar evolution at 10 solar radii, reaching 70% at 15 solar radii. **2008-02-23**

### **How Reliable Are the Properties of Coronal Mass Ejections Measured from a Single Viewpoint?**

Laura A. [Balmaceda](#)<sup>1,5</sup>, Angelos [Vourlidas](#)<sup>2,6</sup>, Guillermo [Stenborg](#)<sup>3</sup>, and Alisson Dal Lago<sup>4</sup>

**2018 ApJ 863 57**

<https://sci-hub.ru/10.3847/1538-4357/aacff8>

We present an analysis of widths and kinematic properties of coronal mass ejections (CMEs) obtained via a supervised image segmentation algorithm, the CORonal SEGmentation Technique (CORSET), on simultaneous observations from the two COR2 telescopes on the Solar Terrestrial Relations Observatory (STEREO) mission, from 2007 May to 2014 September. The sample of 460 events with measurements from two vantage points offers the opportunity to test the accuracy and constraints of single-viewpoint properties that underlie the bulk of CME research to date. In addition, we examine the dependence of the properties on the morphology of the events. The main findings are as follows. (1) The radial speeds derived from different perspectives are in good agreement with a relatively low intrinsic uncertainty of 39%. (2) Projection effects are more important for determination of CME width rather than for speed. (3) The expansion speeds depend on CME morphology, with loop-type CMEs expanding twice as fast as flux-rope CMEs, possibly underpinning the more explosive nature. (4) Triangulations of CME speed and propagation direction are optimal from viewpoints separated by  $60^\circ$ – $90^\circ$ ; e.g., between the Lagrangian points L1 and L5 (or L4). (5) The projected speeds are underestimated, on average, by at least 20% when compared to their deprojected (triangulated) values. We also discuss in detail the lessons learned from the application of the CORSET algorithm to event tracking. Our findings should hopefully be a useful guide in the use of (semi)automated algorithms for extraction of CME physical parameters and in the interpretation of single-viewpoint observations (likely to be the norm after the end of the STEREO mission).

### **The Role of a Tiny Brightening in a Huge Geo-effective Solar Eruption Leading to the St Patrick's Day Storm**

Yumi [Bamba](#), [Satoshi Inoue](#), [Keiji Hayashi](#)

**ApJ 2019**

<https://arxiv.org/pdf/1902.04871.pdf>

The largest magnetic storm in solar cycle 24 was caused by a fast coronal mass ejection (CME) that was related to a small C9.1 flare that occurred on **15 March 2015** in solar active region (AR) NOAA 12297. The purpose of this study is to understand the onset mechanism of the geo-effective huge solar eruption. We focused on the C2.4 flare that occurred prior to the C9.1 flare of the filament eruption. The magnetic field structure in the AR was complicated: there were several filaments including the one that erupted and caused the CME. We hence carefully investigated the photospheric magnetic field, brightenings observed in the solar atmosphere, and the three-dimensional coronal magnetic field extrapolated from nonlinear force-free field modeling, using data from Hinode and Solar Dynamics Observatory. We found three intriguing points: (1) There was a compact but noticeably highly twisted magnetic field structure that is represented by a small filament in the C2.4 flaring region, where a tiny precursor brightening was observed before the

C2.4 flare. (2) The C2.4 flaring region is located in the vicinity of a foot point of the closed field that prohibits the filament from erupting. (3) The filament shows a sudden eruption after the C2.4 flare and accompanying small filament eruption. From our analysis, we suggest that a small magnetic disturbance that was represented by the tiny precursor brightening at the time of the C2.4 flare is related to the trigger of the huge filament eruption.

## **Transverse Oscillation of Coronal Loops Induced by Eruptions of a Magnetic Flux Tube and a Plasmoid**

[K. Safna Banu](#), [Ram Ajor Maurya](#) & [P. T. Jain Jacob](#)

[Solar Physics](#) volume 297, Article number: 134 (2022)

<https://doi.org/10.1007/s11207-022-02065-7>

We studied transverse oscillations in hot coronal loops of active region NOAA 12673 located at the west limb. Loop oscillations were associated with a plasmoid ejection from the same location. During the rising phase of the plasmoid, a magnetic flux tube was seen to be rising and bending towards the loop system that erupted before the plasmoid ejection. In addition to the plasmoid ejection, a large coronal mass ejection (CME) and an X8.2 flare were observed in the same active region for several hours ( $\approx 7$  hours). After the plasmoid ejection, a follow-up shock wave from the flare site was triggered by a sudden momentum transfer towards the solar disk. It was found to be propagating across the entire solar disk with an average speed of  $\approx 1290$  km s<sup>-1</sup>. By analyzing the time sequence of these events, we found that a plasmoid ejection perturbed the loops from their equilibrium and set them in oscillation. We found different oscillations of the fundamental mode in two loops, fast decaying (with a period of 7.93 minutes and an average damping time of  $\approx 19$  minutes) and slow decaying (with a period of 6.31 minutes and an average damping time of  $\approx 34$  minutes). The two different oscillations could be due to their lengths, magnetic fields, and plasma densities. Using the methods of coronal seismology, we estimated the average magnetic field in the coronal loops to be 29 G and 36 G, which is consistent with the order of the coronal magnetic fields found in other studies. **10 Sep 2017**

## **Evolution of coronal mass ejections in the early stage**

Xingming [Bao](#), Hongqi Zhang, Jun Lin, Yunchun Jiang and Leping Li

*Adv. Space Res.*, 39(12), p. 1847-1852, 2007, *File*

This work reports the investigation of two coronal mass ejections (CME) observed in white light, Ha, EUV and X-ray by various

instruments both in space and on ground on **February 18, 2003 and January 19, 2005**, respectively. The white light coronal images show that the first CME began with the rarefaction of a region above the solar limb and was followed by the formation of its leading edge at the boundary of the rarefying region at altitude of 0.46 Rx from the solar surface. The rarefaction coincided the slow rising phase of the filament eruption, and the CME leading edge was observed to form as the filament eruption started to accelerate apparently. In the early stage of the second CME, a bright loop was first observed above the solar limb with height of 0.37 Rx in EUV images. We found that the more gradual CMEs initial process, the larger the timing difference between CMEs and their associated flares. The lower part of the filament brightened in Ha images as the filament rose to a certain height. These brightenings imply that the filament may be heated by magnetic reconnection below the filament in the early stage of the eruption. We suggest that the possible mechanism which led to the formation of the CME leading edge and cavity is magnetic reconnection which occurred under the filament when it reached a certain height.

## **Coronal mass ejections and the associated activities on the solar disk observed on October 26, 2003**

X. [Bao](#), H. Zhang<sup>1</sup>, J. Lin<sup>2,3</sup>, and G. A. Stenborg<sup>4</sup>

*A&A* 463, 321-331 (2007)

We analyzed four CMEs that happen to take off near the west limb of the Sun on October 26, 2003.

We have explored more explicitly than in previous studies the relationship between different types of CMEs and the associated on-disk activities.

## **Improving CME evolution and arrival predictions with AMR and grid stretching in Icarus**

T. [Baratashvili](#)<sup>1</sup>, C. Verbeke<sup>1,2</sup>, N. Wijsen<sup>1</sup> and S. Poedts<sup>1,3</sup>

*A&A* 667, A133 (2022)

<https://www.aanda.org/articles/aa/pdf/2022/11/aa44111-22.pdf>

Context. Coronal mass ejections (CMEs) are one of the main drivers of disturbances in interplanetary space. Strong CMEs, when directed towards the Earth, cause geomagnetic storms upon interacting with the Earth's magnetic field, and can cause significant damage to our planet and affect everyday life. As such, efficient space weather prediction tools are necessary to forecast the arrival and impact of CME eruptions. Recently, a new heliospheric model called Icarus was developed based on MPI-AMRVAC, which is a 3D ideal magnetohydrodynamics model for the solar wind and CME propagation, and it introduces advanced numerical techniques to make the simulations more efficient. In this model the reference frame is chosen to be co-rotating with the Sun, and radial grid stretching together with adaptive mesh refinement (AMR) can be applied to the numerical domain.

Aims. Grid stretching and AMR speed up simulation results and performance. Our aim is to combine the advanced techniques available in the Icarus model in order to obtain better results with fewer computational resources than with the equidistant grid. Different AMR strategies are suggested, depending on the purpose of the simulation.

Methods. In this study, we model the CME event that occurred on July 12, 2012. A cone model was used to study the CME's evolution through the background solar wind, and its arrival at and impact with the Earth. Grid stretching and AMR were combined in the simulations by using multiple refinement criteria, to assess its influence on the simulations' accuracy and the required computational resources. We compare simulation results to the EUHFORIA model. Results. We applied different refinement criteria to investigate the potential of solution AMR for different applications. As a result, the simulations were sped up by a factor of  $\sim 17$  for the most optimal configuration in Icarus. For the cone CME model, we found that limiting the AMR to the region around the CME-driven shock yields the best results. The results modelled by the simulations with radial grid stretching and AMR level 4 are similar to the results provided by the original EUHFORIA and Icarus simulations with the 'standard' resolution and equidistant grids. The simulations with 5 AMR levels yielded better results than the simulations with an equidistant grid and standard resolution. Conclusions. Solution AMR is flexible and provides the user the freedom to modify and locally increase the grid resolution according to the purpose of the simulation. We find that simulations with a combination of grid stretching and AMR can reproduce the simulations performed on equidistant grids significantly faster. The advanced techniques implemented in Icarus can be further used to improve the forecasting procedures, since the reduced simulation time is essential to make physics-based forecasts less computationally expensive. **July 12-15, 2012**

### **Spectro-imagery of an active tornado-like prominence: formation and evolution**

[Krzysztof Barczynski](#), [Brigitte Schmieder](#), [Aaron W. Peat](#), [Nicolas Labrosse](#), [Pierre Mein](#), [Nicole Mein](#)  
A&A 653, A94 2021

<https://arxiv.org/pdf/2106.04259.pdf>

<https://www.aanda.org/articles/aa/pdf/2021/09/aa40976-21.pdf>

The nature of flows in tornado-prominences is an open issue. While the AIA imager aboard the Solar Dynamics Observatory (SDO) allowed us to follow the global structure of a tornado-like prominence during five hours, the Interface Region Imaging Spectrograph (IRIS), and the Multi subtractive Double pass spectrograph (MSDP) permitted to obtain plasma diagnostics of its fine structures. We aim to address two questions. Is the observed plasma rotation conceptually acceptable in a flux rope magnetic support configuration with dips? How is the plasma density distributed in the tornado-like prominence? We calculated line-of-sight velocities and non-thermal line widths using Gaussian fitting for Mg II lines and bisector method for H-alpha line. We determined the electron density from Mg II line integrated intensities and profile fitting methods using 1D NLTE radiative transfer theory models. The global structure of the prominence observed in H-alpha, and Mg II h and k lines fits with a magnetic field structure configuration with dips. Coherent Dopplershifts in red- and blue-shifted areas observed in both lines were detected along rapidly-changing vertical and horizontal structures. However, the tornado at the top of the prominence consists of multiple-fine threads with opposite flows suggesting counter streaming flows rather than rotation. Surprisingly we found that the electron density at the top of the prominence could be larger ( $10^{11} \text{ cm}^{-3}$ ) than in the inner part of the prominence. We suggest that the tornado is in a formation state with cooling of hot plasma in a first phase, and following that, a phase of leakage of the formed blobs with large transverse flows of material along long loops extended away of the UV prominence top. The existence of such long magnetic field lines on both sides of the prominence would avoid the tornado-like prominence to really turn around its axis. **2018 April 19**

### **Electric current evolution at the footpoints of solar eruptions**

Krzysztof [Barczynski](#), [Guillaume Aulanier](#), [Miho Janvier](#), [Brigitte Schmieder](#), [Sophie Masson](#)

ApJ 2020

<https://arxiv.org/pdf/2004.07990.pdf>

Electric currents play a critical role in the triggering of solar flares and their evolution. The aim of the present paper is to test whether the surface electric current has a surface or subsurface fixed source as predicts the circuit approach of flare physics, or is the response of the surface magnetic field to the evolution of the coronal magnetic field as the MHD approach proposes. Out of all 19 X-class flares as observed by SDO from 2011 to 2016 near the disk center, we analyzed the only 9 eruptive flares for which clear ribbon-hooks were identifiable. Flare ribbons with hooks are considered to be the footprints of eruptive flux ropes in MHD flare models. For the first time, fine measurements of time-evolution of electric currents inside the hooks in the observations as well as in the OHM 3D MHD simulation are performed. Our analysis shows a decrease of the electric current in the area surrounded by the ribbon hooks during and after the eruption. We interpret the decrease of the electric currents as due to the expansion of the flux rope in the corona during the eruption. Our analysis brings a new contribution to the standard flare model in 3D. **15 February 2011, 7 September 2011, 29th March 2014, 10th September 2014, 7 November 2014, 11 March 2015**

Table 1. Properties of flares, ribbon and ribbon hooks visibility for 19 flares (2011-2015).

### **Periodic behaviour of coronal mass ejections, eruptive events, and solar activity proxies during solar cycles 23 and 24**

Tatiana [Barlyaeva](#) [JulienWojakabPhilippeLamyabBriceBocletabImreToth](#)

[Journal of Atmospheric and Solar-Terrestrial Physics](#)

Volume 177, October 2018, Pages 12-28

[sci-hub.ru/10.1016/j.jastp.2018.05.012](https://doi.org/10.1016/j.jastp.2018.05.012)

<https://arxiv.org/pdf/1704.02336.pdf> File

We report on the parallel analysis of the periodic behaviour of [coronal mass ejections](#) (CMEs) based on 21 years [1996–2016] of observations with the SOHO/LASCO–C2 coronagraph, [solar flares](#), prominences, and several proxies of [solar activity](#). We consider values of the rates globally and whenever possible, distinguish solar hemispheres and [solar cycles](#) 23 and 24. Periodicities are investigated using both frequency (periodogram) and time-frequency (wavelet) analysis. We find that these different processes, in addition to following the  $\approx 11$ -year Solar Cycle, exhibit diverse statistically significant oscillations with [properties common](#) to all solar, coronal, and heliospheric processes: variable periodicity, intermittence, asymmetric development in the northern and southern solar hemispheres, and largest amplitudes during the maximum phase of solar cycles, being more pronounced during solar cycle 23 than the weaker cycle 24. However, our analysis reveals an extremely complex and diverse situation. For instance, there exists very limited commonality for periods of less than one year. The few exceptions are the periods of 3.1–3.2 months found in the global occurrence rates of CMEs and in the [sunspot](#) area (SSA) and those of 5.9–6.1 months found in the northern hemisphere. Mid-range periods of  $\approx 1$  and  $\approx 2$  years are more wide spread among the studied processes, but exhibit a very distinct behaviour with the first one being present only in the northern hemisphere and the second one only in the [southern hemisphere](#). These periodic behaviours likely results from the complexity of the underlying physical processes, prominently the emergence of [magnetic flux](#).

### **The State of the Corona During the Weak Solar Cycle 24: the View from LASCO Images**

[Barlyaeva](#), T.; Lamy, P.; Llebaria, A.; Boclet, B.

Ground-based Solar Observations in the Space Instrumentation Era

ASP Conference Series, Vol. 504, p. 287, 2016

<http://aspbooks.org/publications/504/287.pdf>

The LASCO-C2 coronagraph onboard SOHO continues its white-light imaging of the corona from 1.5 to 6.0 solar radii, thus allowing investigating the consequences of the weak Solar Cycle 24 on the corona and comparing it to the previous cycle (23). Temporal variations of the global radiance of the corona are presented. We pay particular attention to the mid-term variations which are distinctly different between the two cycles and highlight the similarities and differences. Finally, we rely on our ARTEMIS II catalog of coronal mass ejections (CMEs) to compare their global rates during these two cycles.

### **The Solar Stormwatch CME catalogue: Results from the first space weather citizen science project,**

[Barnard](#), L., et al.

(2014), *Space Weather*, 12, 657–674, doi:10.1002/2014SW001119. **File (2015)**

<http://onlinelibrary.wiley.com/doi/10.1002/2014SW001119/pdf>

Solar Stormwatch was the first space weather citizen science project, the aim of which is to identify and track coronal mass ejections (CMEs) observed by the Heliospheric Imagers aboard the STEREO satellites. The project has now been running for approximately 4 years, with input from >16,000 citizen scientists, resulting in a data set of >38,000 time-elongation profiles of CME trajectories, observed over 18 preselected position angles. We present our method for reducing this data set into a CME catalogue. The resulting catalogue consists of 144 CMEs over the period January 2007 to February 2010, of which 110 were observed by STEREO-A and 77 were observed by STEREO-B. For each CME, the time-elongation profiles generated by the citizen scientists are averaged into a consensus profile along each position angle that the event was tracked. We consider this catalogue to be unique, being at present the only citizen science-generated CME catalogue, tracking CMEs over an elongation range of  $4^\circ$  out to a maximum of approximately  $70^\circ$ . Using single spacecraft fitting techniques, we estimate the speed, direction, solar source region, and latitudinal width of each CME. This shows that at present, the Solar Stormwatch catalogue (which covers only solar minimum years) contains almost exclusively slow CMEs, with a mean speed of approximately 350 km s<sup>-1</sup>. The full catalogue is available for public access at [www.met.reading.ac.uk/~spate/solarstormwatch](http://www.met.reading.ac.uk/~spate/solarstormwatch). This includes, for each event, the unprocessed time-elongation profiles generated by Solar Stormwatch, the consensus time-elongation profiles, and a set of summary plots, as well as the estimated CME properties.

### **The Coronal Mass Ejection of 1998 April 20: Direct Imaging at Radio Wavelengths**

T. S. [Bastian](#)<sup>1</sup>, M. Pick<sup>2</sup>, A. Kerdraon<sup>2</sup>, D. Maia<sup>2,4</sup>, and A. Vourlidas<sup>3</sup>

2001 ApJ 558 L65

<https://iopscience.iop.org/article/10.1086/323421/pdf>

Spectroscopic data were obtained between 40 and 800 MHz by the spectrometer at Trensdorf, Germany, and between 20 kHz and 14 MHz with the WAVES instrument on board the Wind spacecraft. Energetic particle data were obtained from the Wind 3D Plasma and Energetic Particle experiment. The CME was observed in white light by the Large-Angle Spectrometric COronagraph experiment on board the Solar and Heliospheric Observatory spacecraft. For the first time, the expanding CME loops are imaged directly at radio wavelengths. We show that the radio-emitting CME loops are the result of nonthermal synchrotron emission from electrons with energies of  $\sim 0.5$ –5 MeV interacting with magnetic fields of  $\sim 0.1$  to a few gauss. They appear nearly simultaneously with the onset of an associated type II radio burst, shock-accelerated type III radio bursts, and the initiation of a solar energetic particle event. We suggest possible sources of the energetic electrons responsible for this "radio CME" and point out diagnostic uses for synchrotron emission from CME loops. **20 Apr 1998**

## Identifying the energy release site in a Solar microflare with a jet

[Andrea Francesco Battaglia](#), [Wen Wang](#), [Jonas Saqri](#), [Tatiana Podladchikova](#), [Astrid M. Veronig](#), [Hannah Collier](#), [Ewan C. M. Dickson](#), [Olena Podladchikova](#), [Christian Monstein](#), [Alexander Warmuth](#), [Frédéric Schuller](#), [Louise Harra](#), [Säm Krucker](#)

A&A 2022

<https://arxiv.org/pdf/2212.11098.pdf>

One of the main science questions of the Solar Orbiter and Parker Solar Probe missions deals with understanding how electrons in the lower solar corona are accelerated and how they subsequently access interplanetary space. We aim to investigate the electron acceleration and energy release sites as well as the manner in which accelerated electrons access the interplanetary space in the case of the **SOL2021-02-18T18:05** event, a GOES A8 class microflare associated with a coronal jet. This study takes advantage of three different vantage points, Solar Orbiter, STEREO-A, and Earth, with observations ranging from radio to X-ray. Multi-wavelength timing analysis combined with UV/EUV imagery and X-ray spectroscopy by Solar Orbiter/STIX (Spectrometer/Telescope for Imaging X-rays) is used to investigate the origin of the observed emission during different flare phases. The event under investigation satisfies the classical picture of the onset time of the acceleration of electrons coinciding with the jet and the radio type III bursts. This microflare features prominent hard X-ray nonthermal emission down to at least 10 keV and a spectrum that is much harder than usual for a microflare with a spectral index of 2.9. From Earth's vantage point, the microflare is seen near the limb, revealing the coronal energy release site above the flare loop in EUV, which, from STIX spectroscopic analysis, turns out to be hot (at roughly the same temperature of the flare). Moreover, this region is moving toward higher altitudes over time (about 30 km/s). During the flare, the same region spatially coincides with the origin of the coronal jet. We conclude that the energy release site observed above-the-loop corresponds to the electron acceleration site, corroborating that interchange reconnection is a viable candidate for particle acceleration in the low corona on field lines open to interplanetary space.

## The LASCO Coronal Brightness Index

Karl [Battams](#), [Russell A. Howard](#), [Hillary A. Dennison](#), [Robert S. Weigel](#), [Judith L. Lean](#)

Solar Phys. 2020

<https://arxiv.org/pdf/2001.07596.pdf>

We present the construction of a new white-light coronal brightness index (CBI) from the entire archive of observations recorded by the Large Angle Spectrometric Coronagraph (LASCO) C2 camera between 1996 and 2017, comprising two full solar cycles. We reduce all fully calibrated daily C2 observations of the white light corona into a single daily coronal brightness observation for every day of observation recorded by the instrument, with mean daily brightness values binned into 0.1 R<sub>sun</sub> radial x 1 degree angular regions from 2.4 -- 6.2 R<sub>sun</sub> for a full 360-degrees. As a demonstration of the utility of the CBI, we construct a new solar irradiance proxy that correlates well with a variety of direct solar irradiance observations, with correlations shown to be in the range of 0.77-0.89. We also present a correlation mapping technique to show how irradiance correlations depend on, and relate to, coronal structure/locations, and to demonstrate how the LASCO CBI can be used to perform long-term "spatial correlation" studies to investigate relationships between the solar corona and any arbitrary concurrent geophysical index. Using this technique we find possible relationships between coronal brightness and plasma temperature, interplanetary magnetic field magnitude and (very weakly) proton density.

## FINMHD: An Adaptive Finite-element Code for Magnetic Reconnection and Formation of Plasmoid Chains in Magnetohydrodynamics

Hubert [Baty](#)

2019 ApJS 243 23

<https://sci-hub.ru/10.3847/1538-4365/ab2cd2>

Solving the problem of fast eruptive events in magnetically dominated astrophysical plasmas requires the use of particularly well adapted numerical tools. Indeed, the central mechanism based on magnetic reconnection is determined by a complex behavior with quasi-singular forming current layers enriched by their associated small-scale magnetic islands called plasmoids. A new code is thus presented for the solution of two-dimensional dissipative magnetohydrodynamics (MHD) equations in cartesian geometry specifically developed to this end. A current-vorticity formulation representative of an incompressible model is chosen in order to follow the formation of the current sheets and the ensuing magnetic reconnection process. A finite-element discretization using triangles with quadratic basis functions on an unstructured grid is employed, and implemented via a highly adaptive characteristic-Galerkin scheme. The adaptivity of the code is illustrated on simplified test equations and finally for magnetic reconnection associated with the nonlinear development of the tilt instability between two repelling current channels. Varying the Lundquist number  $S$  has allowed us to study the transition between the steady-state Sweet-Parker reconnection regime (for  $S \lesssim 104$ ) and the plasmoid-dominated reconnection regime (for  $S \gtrsim 105$ ). The implications for the understanding of the mechanism explaining the fast conversion of free magnetic energy in astrophysical environments such as the solar corona are briefly discussed.

## On the factors determining the eruptive character of solar flares

Christian [Baumgartner](#), [Julia K. Thalmann](#), [Astrid M. Veronig](#)

ApJ 853 105 2017

<https://arxiv.org/pdf/1712.05106.pdf>

We investigated how the magnetic field in solar active regions (ARs) controls flare activity, i.e., whether a confined or eruptive flare occurs. We analyzed 44 flares of GOES class M5.0 and larger that occurred during 2011–2015. We used 3D potential magnetic field models to study their location (using the flare distance from **the flux-weighted AR center** dFC) and the strength of the magnetic field in the corona above (via decay index  $n$  and flux ratio). We also present a first systematic study of the orientation of the coronal magnetic field, using the orientation  $\phi$  of the flare-relevant polarity inversion line as a measure. We analyzed all quantities with respect to the size of the underlying dipole field, characterized by the distance between the opposite-polarity centers, dPC. Flares originating from underneath the AR dipole (dFC/dPC < 0.5) tend to be eruptive if launched from compact ARs (dPC  $\leq$  60 Mm) and confined if launched from extended ARs. Flares ejected from the periphery of ARs (dFC/dPC > 0.5) are predominantly eruptive. In confined events the flare-relevant field adjusts its orientation quickly to that of the underlying dipole with height ( $\Delta\phi$  & 40° until the apex of the dipole field), in contrast to eruptive events where it changes more slowly with height. The critical height for torus instability,  $h_{crit} = h(n = 1.5)$ , discriminates best between confined ( $h_{crit}$  & 40 Mm) and eruptive flares ( $h_{crit}$  . 40 Mm). It discriminates better than  $\Delta\phi$ , implying that the decay of the confining field plays a stronger role than its orientation at different heights. **2014-10-25**

**Table 1.** Event list (**Flares  $\geq$ M5.0** that occurred between January 2011 and December 2015.)

## **A Precursor to Solar Prominence Eruptions: Detection and Analysis of EUV Prominence Oscillations**

William **Beckwith-Chandler**<sup>3</sup>, Claire Foullon, and Erwin Verwichte

**2024** ApJ 977 253

<https://iopscience.iop.org/article/10.3847/1538-4357/ad8e3c/pdf>

The eruption of prominences can have a significant influence on the solar–terrestrial environment. However, accurately predicting these eruptions remains a challenge. We apply automated detection methods for extreme ultraviolet (EUV) prominences observed by the twin spacecraft from the Solar Terrestrial Relations Observatory (STEREO) mission and the Solar Dynamics Observatory near Earth. We study an event, during 2011 March, when each STEREO spacecraft is in quadrature with respect to the Earth. For two time ranges, we obtain longitudinal height profiles as a function of time. We also track the corresponding EUV filaments across the solar disk, which reveal the emergence of ultra-long-period oscillations in the EUV filament channels. Our analysis shows a correlation between the prominence's increasing height and the oscillation periods, suggesting a potential link to the subsequent eruption observed by the STEREO spacecraft off-limb. These findings offer new insights into prominence dynamics and may pave the way for improved eruption prediction. **2011.03.18-22-26**

## **THE HEIGHT EVOLUTION OF THE "TRUE" CORONAL MASS EJECTION MASS DERIVED FROM STEREO COR1 AND COR2 OBSERVATIONS**

B. M. **Bein**<sup>1</sup>, M. Temmer<sup>1</sup>, A. Vourlidas<sup>2</sup>, A. M. Veronig<sup>1</sup>, and D. Utz

**2013** ApJ 768 31; **File**

<http://arxiv.org/pdf/1303.3372v1.pdf>

Using combined STEREO-A and STEREO-B EUVI, COR1, and COR2 data, we derive deprojected coronal mass ejection (CME) kinematics and CME "true" mass evolutions for a sample of 25 events that occurred during 2007 December to 2011 April. We develop a fitting function to describe the CME mass evolution with height. The function considers both the effect of the coronagraph occulter, at the beginning of the CME evolution, and an actual mass increase. The latter becomes important at about 10-15  $R_{\odot}$  and is assumed to mostly contribute up to 20  $R_{\odot}$ . The mass increase ranges from 2% to 6% per  $R_{\odot}$  and is positively correlated to the total CME mass. Due to the combination of COR1 and COR2 mass measurements, we are able to estimate the "true" mass value for very low coronal heights (<3  $R_{\odot}$ ). Based on the deprojected CME kinematics and initial ejected masses, we derive the kinetic energies and propelling forces acting on the CME in the low corona (<3  $R_{\odot}$ ). The derived CME kinetic energies range between  $1.0\text{--}66 \times 10^{23}$  J, and the forces range between  $2.2\text{--}510 \times 10^{14}$  N.

## **IMPULSIVE ACCELERATION OF CORONAL MASS EJECTIONS. II. RELATION TO SOFT X-RAY FLARES AND FILAMENT ERUPTIONS**

B. M. **Bein**<sup>1</sup>, S. Berkebile-Stoiser<sup>1</sup>, A. M. Veronig<sup>1</sup>, M. Temmer<sup>1</sup>, and B. Vršnak

**2012** ApJ 755 44, **File**

<http://arxiv.org/pdf/1206.2144v1.pdf>

Using high time cadence images from the STEREO EUVI, COR1, and COR2 instruments, we derived detailed kinematics of the main acceleration stage for a sample of 95 coronal mass ejections (CMEs) in comparison with associated flares and filament eruptions. We found that CMEs associated with flares reveal on average significantly higher peak accelerations and lower acceleration phase durations, initiation heights, and heights, at which they reach their peak velocities and peak accelerations. This means that CMEs that are associated with flares are characterized by higher and more impulsive accelerations and originate from lower in the corona where the magnetic field is stronger. For CMEs that are associated with filament eruptions we found only for the CME peak acceleration significantly lower

values than for events that were not associated with filament eruptions. The flare rise time was found to be positively correlated with the CME acceleration duration and negatively correlated with the CME peak acceleration. For the majority of the events the CME acceleration starts before the flare onset (for 75% of the events) and the CME acceleration ends after the soft X-ray (SXR) peak time (for 77% of the events). In ~60% of the events, the time difference between the peak time of the flare SXR flux derivative and the peak time of the CME acceleration is smaller than  $\pm 5$  minutes, which hints at a feedback relationship between the CME acceleration and the energy release in the associated flare due to magnetic reconnection.

### **Impulsive acceleration of coronal mass ejections: I. Statistics and CME source region characteristics**

B. M. [Bein](#), S. Berkebile-Stoiser, A. M. Veronig, M. Temmer, N. Muhr, I. Kienreich, D. Utz  
E-print, 5 Aug, 2011, [File](#); 2011 ApJ 738 191, [File](#)?

We use high time cadence images acquired by the STEREO EUVI and COR instruments to study the evolution of coronal mass ejections (CMEs), from their initiation, through the impulsive acceleration to the propagation phase. For a set of 95 CMEs we derived detailed height, velocity and acceleration profiles and statistically analysed characteristic CME parameters: peak acceleration, peak velocity, acceleration duration, initiation height, height at peak velocity, height at peak acceleration and size of the CME source region. The CME peak accelerations derived range from 20 to 6800  $\text{m s}^{-2}$  and are inversely correlated to the acceleration duration and to the height at peak acceleration. 74% of the events reach their peak acceleration at heights below 0.5  $R_{\text{sun}}$ . CMEs which originate from compact sources low in the corona are more impulsive and reach higher peak accelerations at smaller heights. These findings can be explained by the Lorentz force, which drives the CME accelerations and decreases with height and CME size.

### **Caltech Lab Experiments and the Insights They Provide Into Solar Corona Phenomena**

[Paul M. Bellan](#)

JGR [Volume 125, Issue 8](#) August 2020 e2020JA028139

<https://agupubs.onlinelibrary.wiley.com/doi/10.1029/2020JA028139>

A comprehensive overview of two decades of Caltech experiments relevant to solar corona physics is presented. The extent to which the experiments scale to the solar corona, the basic configurations and operation, and the importance of the magnetic force  $\mathbf{J} \times \mathbf{B}$  common to all the experiments is discussed. Summaries are given of the various configurations used, the main observations, and interpretations of these observations, including new models developed to provide these interpretations. Topics include observations and explanations for flux rope self-collimation, axial flows along flux ropes, eruption of arched flux ropes, strapping magnetic fields that inhibit eruption, the torus instability, and effects such as X-ray emission of a kink-driven secondary Rayleigh-Taylor instability.

### **First Determination in the Extended Corona of the 2D Thermal Evolution of a Current Sheet after a Solar Eruption**

Alessandro [Bemporad](#)<sup>1,2</sup>, Guanglu Shi<sup>2,3</sup>, Shuting Li<sup>2,3</sup>, Beili Ying<sup>2,3</sup>, Li Feng<sup>2,3</sup>, Jun Lin<sup>4</sup>, Lucia Abbo<sup>1</sup>, Vincenzo Andretta<sup>5</sup>, Aleksandr Burtovoi<sup>6</sup>, Vania Da Deppo<sup>7</sup>Show full author list  
2024 ApJ 964 92

<https://iopscience.iop.org/article/10.3847/1538-4357/ad2516/pdf>

For the first time the evolution of the coronal reconfiguration after a coronal mass ejection (CME) was observed by the multichannel Metis Coronagraph on board the ESA–Solar Orbiter mission. The images acquired in visible light (VL) between 3.0 and 5.4  $R_{\text{e}}$  show the formation after a CME of a bright elongated radial feature interpreted as a post-CME current sheet (CS). The unique combination of VL and UV images allowed the time evolution of multiple plasma physical parameters inside and outside the CS region to be mapped in 2D for the first time. The CS electron temperature reached peak values higher than 1 MK, more than twice as high as the surrounding corona. An elongated vertical diffusion region, characterized as a region of much higher thermal pressure and lower magnetic pressure, is observed to slowly propagate outward during 13 hr of observations. Inside this region the Alfvénic Mach number is of the order of  $MA \approx 0.02\text{--}0.11$ , the plasma  $\beta$  is close to unity, and the level of turbulence is higher than in the surrounding corona, but decreases slowly with time. All these results provide one of the most complete pictures of these features, and support the idea of a magnetic reconnection coupled with turbulence, thus allowing significant heating of the local plasma, despite the weakness of involved coronal magnetic fields in the considered altitude range. **2021 February 12–13**

### **Analysis of the first coronagraphic multi-band observations of a sungrazing comet**

A. [Bemporad](#)<sup>1</sup>, S. Pennella<sup>2</sup>, K. Battams<sup>3</sup>, S. Giordano<sup>1</sup>, B. Gray<sup>4</sup>, M. M. Knight, + + +  
A&A 680, A90 (2023)

<https://www.aanda.org/articles/aa/pdf/2023/12/aa46881-23.pdf>

Context. Between **24 and 25 December 2021** a sungrazing comet (SOHO-4341) approached the Sun, being observed by “classical” visible light (VL) coronagraphs on board the SOHO and STEREO missions, and also by the innovative Metis coronagraph on board the ESA-NASA Solar Orbiter mission in the VL and ultraviolet (UV H I Lyman- $\alpha$ ) band.

**Aims.** We show how VL data acquired by the Metis coronagraph can be combined with those provided by other space-based coronagraphs to reconstruct the comet orbit, but also to provide information on the dust composition from the polarized VL emission. Moreover, we show how the UV emission can be employed to measure local plasma parameters of the ambient solar wind.

**Methods.** By using the comet positions tracked with VL Metis images (with spatial resolution that is four times better than UV), the UV images (with a time cadence that is five times faster than VL) have been coaligned to maximize the signal-to-noise ratio in the UV band. The local electron density  $n_e$  was measured from the observed exponential decay of the UV Lyman- $\alpha$  intensity along the tail, while the solar wind speed  $v_{\text{wind}}$  was measured from the UV Lyman- $\alpha$  tail inclination with respect to the cometary orbital path deprojected in 3D. Moreover, the proton kinetic temperature  $T_k$  was also obtained by the aperture angle of the UV Lyman- $\alpha$  tail.

**Results.** When the comet was at an average heliocentric distance of  $14.3 R_{\odot}$ , the comet had a radial speed of  $155 \text{ km s}^{-1}$  and a tangential speed of  $59 \text{ km s}^{-1}$ . The comet had a UV Lyman- $\alpha$  tail extending in the anti-solar direction over more than  $1.5 R_{\odot}$ . From the analysis of the tail shape in UV we obtained the local solar wind speed ( $v_{\text{wind}} = 190 \text{ km s}^{-1}$ ), electron density ( $n_e = 1.5 \times 10^4 \text{ cm}^{-3}$ ), and proton temperature ( $T_k = 1.2 \times 10^6 \text{ K}$ ). Moreover, theoretical analysis of the measured UV Lyman- $\alpha$  intensity allowed us to estimate the radius of the cometary nucleus ( $R_{\text{com}} = 65 \text{ m}$ ) and the water outgassing rate ( $\text{QH}_2\text{O} = 4.8 \times 10^{28} \text{ molec s}^{-1}$ ).

**Conclusions.** These results show that sungrazing comets are unique “local probes” for the ambient coronal plasma, providing measurements that are not as affected by the line-of-sight integration effects as those provided by remote sensing instruments, in regions of the Heliosphere that are not explored in situ by the ongoing space missions.

## **A Coronal Mass Ejection followed by a prominence eruption and a plasma blob as observed by Solar Orbiter**

[A. Bemporad](#), [V. Andretta](#), [R. Susino](#), [S. Mancuso](#), [D. Spadaro](#), [M. Mierla](#), [D. Berghmans](#), [E. D’Huys](#), [A. N. Zhukov](#), [D.-C. Talpeanu](#), [R. Colaninno](#), [P. Nicolini](#), [M. Pancrazzi](#), [M. Romoli](#), [C. Sasso](#), [A. Slemer](#), [M. Stangalini](#), [L. Teriaca](#)

A&A 665, A7 2022

<https://arxiv.org/pdf/2202.10294.pdf>

<https://www.aanda.org/articles/aa/pdf/2022/09/aa43162-22.pdf>

On **February 12, 2021** two subsequent eruptions occurred above the West limb, as seen along the Sun-Earth line. The first event was a typical slow Coronal Mass Ejection (CME), followed  $\sim 7$  hours later by a smaller and collimated prominence eruption, originating Southward with respect to the CME, followed by a plasma blob. These events were observed not only by SOHO and STEREO-A missions, but also by the suite of remote sensing instruments on-board Solar Orbiter (SolO). This work shows how data acquired by the Full Sun Imager (FSI), Metis coronagraph, and Heliospheric Imager (SoloHI) from the SolO perspective can be combined to study the eruptions and the different source regions. Moreover, we show how Metis data can be analyzed to provide new information about solar eruptions. Different 3D reconstruction methods were applied to the data acquired by different spacecraft including remote sensing instruments on-board SolO. Images acquired by both Metis channels in the Visible Light (VL) and H I Lyman- $\alpha$  line (UV) were combined to derive physical information on the expanding plasma. The polarization ratio technique was also applied for the first time to the Metis images acquired in the VL channel. The two eruptions were followed in 3D from their source region to their expansion in the intermediate corona. Thanks to the combination of VL and UV Metis data, the formation of a post-CME Current Sheet (CS) was followed for the first time in the intermediate corona. The plasma temperature gradient across a post-CME blob propagating along the CS was also measured for the first time. Application of the polarization ratio technique to Metis data shows that, thanks to the combination of four different polarization measurements, the errors are reduced by  $\sim 5\text{--}7\%$ , thus better constraining the 3D distribution of plasma.

## **Measuring the electron temperatures of coronal mass ejections with future space-based multi-channel coronagraphs: a numerical test**

A. [Bemporad](#)<sup>1</sup>, P. Pagano<sup>2</sup> and S. Giordano

A&A 619, A25 (2018)

<https://sci-hub.ru/10.1051/0004-6361/201833058>

**Context.** The determination from coronagraphic observations of physical parameters of the plasma embedded in coronal mass ejections (CMEs) is of crucial importance for our understanding of the origin and evolution of these phenomena. **Aims.** The aim of this work is to perform the first ever numerical simulations of a CME as it will be observed by future two-channel (visible light VL and UV Ly- $\alpha$ ) coronagraphs, such as the Metis instrument on-board ESA-Solar Orbiter mission, or any other future coronagraphs with the same spectral band-passes. These simulations are then used to test and optimize the plasma diagnostic techniques to be applied to future observations of CMEs.

**Methods.** The CME diagnostic techniques are tested here by analyzing synthetic coronagraphic observations. First, a numerical three-dimensional (3D) magnetohydrodynamic (MHD) simulation of a CME is performed, and the plasma parameters in the simulation are used to generate synthetic visible light (VL) and ultraviolet (UV) coronagraphic two-dimensional (2D) images of the eruption (i.e., integrated along the line-of-sight). Second, synthetic data are analyzed with different assumptions (as will be done with real data), to infer the kinematic properties of the CME (such as the extension along the line-of-sight of the emitting region, the expansion speed, and the CME propagation direction), as

well as physical parameters of the CME plasma (the plasma electron density and temperature). A comparison between input parameters from the simulation and output parameters from the synthetic data analysis is then performed. Results. The inversion of VL polarized data allows to successfully determine the CME speed and 3D propagation direction (with the polarization ratio technique), as well as to derive information on the extension along the line-of-sight of the emitting plasma, a crucial parameter needed to convert the plasma electron column densities into number densities. These parameters are used to analyze UV Ly- $\alpha$  images and to estimate the CME plasma temperature, also taking into account Doppler dimming effect. Output plasma temperatures are in general underestimated, both in the CME body and core regions. By neglecting the UV Ly- $\alpha$  radiative excitation of H atoms, reliable temperatures can be more easily derived in the CME core (within  $\sim 60\%$ ). On the other hand, we show that a determination of temperatures (within  $\sim 20\text{--}30\%$ ) in the CME body requires 2D maps of CME radial speeds and Doppler dimming coefficients to be derived.

## Measuring coronal magnetic fields with remote sensing observations of shock waves **Review**

Alessandro **Bemporad**, Roberto Susino, Federica Frassati, Silvano Fineschi

Frontiers in Astronomy and Space Sciences, Volume 3, id.17 2016

<https://arxiv.org/ftp/arxiv/papers/1608/1608.05536.pdf>

Recent works demonstrated that remote sensing observations of shock waves propagating into the corona and associated with major solar eruptions can be used to derive the strength of coronal magnetic fields met by the shock over a very large interval of heliocentric distances and latitudes. This opinion article will summarize most recent results obtained on this topic and will discuss the weaknesses and strengths of these techniques to open a constructive discussion with the scientific community.

## Physical Conditions of Coronal Plasma at the transit of a Shock driven by a Coronal Mass Ejection

A. **Bemporad**, R. Susino, S. Mancuso

ApJ 2015

<http://arxiv.org/pdf/1509.09131v1.pdf>

We report here on the determination of plasma physical parameters across a shock driven by a Coronal Mass Ejection using White Light (WL) coronagraphic images and Radio Dynamic Spectra (RDS). The event analyzed here is the spectacular eruption that occurred on **June 7th 2011**, a fast CME followed by the ejection of columns of chromospheric plasma, part of them falling back to the solar surface, associated with a M2.5 flare and a type-II radio burst. Images acquired by the SOHO/LASCO coronagraphs (C2 and C3) were employed to track the CME-driven shock in the corona between  $2\text{--}12 R_{\odot}$  in an angular interval of about  $110^{\circ}$ . In these intervals we derived 2-Dimensional (2D) maps of electron density, shock velocity and shock compression ratio, and we measured the shock inclination angle with respect to the radial direction. Under plausible assumptions, these quantities were used to infer 2D maps of shock Mach number MA and strength of coronal magnetic fields at the shock's heights. We found that in the early phases ( $2\text{--}4 R_{\odot}$ ) the whole shock surface is super-Alfvénic, while later on (i.e. higher up) it becomes super-Alfvénic only at the nose. This is in agreement with the location for the source of the observed type-II burst, as inferred from RDS combined with the shock kinematic and coronal densities derived from WL. For the first time, a coronal shock is used to derive a 2D map of the coronal magnetic field strength over a  $10 R_{\odot}$  altitude and  $\sim 110^{\circ}$  latitude intervals.

## Uncertainties in polarimetric 3D reconstructions of coronal mass ejections

Alessandro **Bemporad**, Paolo Pagano

A&A 576, A93 2015

<http://arxiv.org/pdf/1503.00314v1.pdf>

This work is aimed at quantifying the uncertainties in the 3D reconstruction of the location of coronal mass ejections (CMEs) obtained with the polarization ratio technique. The method takes advantage of the different distributions along the line of sight (LOS) of total (tB) and polarized (pB) brightnesses to estimate the average location of the emitting plasma. To this end, we assumed two simple electron density distributions along the LOS (a constant density and Gaussian density profiles) for a plasma blob and synthesized the expected tB and pB for different distances  $z$  of the blob from the plane of the sky (POS) and different projected altitudes  $\rho$ . Reconstructed locations of the blob along the LOS were thus compared with the real ones, allowing a precise determination of uncertainties in the method. Independently of the analytical density profile, when the blob is centered at a small distance from the POS (i.e. for limb CMEs) the distance from the POS starts to be significantly overestimated. Polarization ratio technique provides the LOS position of the center of mass of what we call folded density distribution, given by reflecting and summing in front of the POS the fraction of density profile located behind that plane. On the other hand, when the blob is far from the POS, but with very small projected altitudes (i.e. for halo CMEs,  $\rho < 1.4 R_{\odot}$ ), the inferred distance from that plane is significantly underestimated. Better determination of the real blob position along the LOS is given for intermediate locations, and in particular when the blob is centered at an angle of  $20^{\circ}$  from the POS. These results have important consequences not only for future 3D reconstruction of CMEs with polarization ratio technique, but also for the design of future coronagraphs aimed at providing a continuous monitoring of halo-CMEs for space weather prediction purposes.

## Plasma Physical Parameters along Coronal-mass-ejection-driven Shocks. I. Ultraviolet and White-light Observations

A. [Bemporad](#)<sup>1</sup>, R. Susino<sup>1</sup>, and G. Lapenta

2014 ApJ 784 102

<http://arxiv.org/pdf/1403.0870v1.pdf>

In this work, UV and white-light (WL) coronagraphic data are combined to derive the full set of plasma physical parameters along the front of a shock driven by a coronal mass ejection. Pre-shock plasma density, shock compression ratio, speed, and inclination angle are estimated from WL data, while pre-shock plasma temperature and outflow velocity are derived from UV data. The Rankine-Hugoniot (RH) equations for the general case of an oblique shock are then applied at three points along the front located between 2.2 and 2.6  $R_{\odot}$  at the shock nose and at the two flanks. Stronger field deflection (by  $\sim 46^{\circ}$ ), plasma compression (factor  $\sim 2.7$ ), and heating (factor  $\sim 12$ ) occur at the nose, while heating at the flanks is more moderate (factor 1.5-3.0). Starting from a pre-shock corona where protons and electrons have about the same temperature ( $T_p \sim T_e \sim 1.5 \times 10^6$  K), temperature increases derived with RH equations could better represent the proton heating (by dissipation across the shock), while the temperature increase implied by adiabatic compression (factor  $\sim 2$  at the nose,  $\sim 1.2$ -1.5 at the flanks) could be more representative of electron heating: the transit of the shock causes a decoupling between electron and proton temperatures. Derived magnetic field vector rotations imply a draping of field lines around the expanding flux rope. The shock turns out to be super-critical (sub-critical) at the nose (at the flanks), where derived post-shock plasma parameters can be very well approximated with those derived by assuming a parallel (perpendicular) shock.

## Super- and sub-critical regions in shocks driven by radio-loud and radio-quiet CMEs.

## Study of Multiple Coronal Mass Ejections at Solar Minimum Conditions

A. [Bemporad](#), F. P. Zuccarello, C. Jacobs, M. Mierla and S. Poedts

Solar Physics, 2012, DOI: 10.1007/s11207-012-9999-3

The aim of this work is to provide a physical explanation for the genesis of multiple coronal mass ejections (CMEs) in an asymmetric coronal field configuration. We analyze STEREO observations of a multiple eruption and compare the results from the data analysis with predictions provided by magnetohydrodynamic (MHD) simulations. To this end, the multiple CMEs (MCMEs) observed on **21 – 22 September 2009** were selected. Both eruptions originated from the same source region and showed approximately the same latitudinal deflection, by more than 15 degrees, toward the heliospheric current sheet (HCS) during their propagation in the COR1 field of view. Numerical MHD simulations of the MCMEs have been performed, starting from an asymmetric coronal field configuration that mimics the potential field source surface extrapolation for 21 September 2009. The results demonstrate that, by shearing the footpoints at the base of the southern arcade, we were able to reproduce the observed dynamics of the MCMEs. Both CMEs are deflected toward the HCS due to an imbalance in the magnetic pressure and tension forces; the global field strength turns out to be a crucial parameter in order to release two subsequent eruptions, and hence to reproduce the observed evolution.

## IDENTIFICATION OF SUPER- AND SUBCRITICAL REGIONS IN SHOCKS DRIVEN BY CORONAL MASS EJECTIONS

A. [Bemporad](#) and S. Mancuso

2011 ApJ 739 L64, [File](#)

In this work, we focus on the analysis of a coronal mass ejection (CME) driven shock observed by the Solar and Heliospheric Observatory/Large Angle and Spectrometric Coronagraph Experiment. We show that white-light coronagraphic images can be employed to estimate the compression ratio  $X = \rho_d / \rho_u$  all along the front of CME-driven shocks.  $X$  increases from the shock flanks (where  $X \sim 1.2$ ) to the shock center (where  $X \sim 3.0$  is maximum). From the estimated  $X$  values, we infer the Alfvén Mach number for the general case of an oblique shock. It turns out that only a small region around the shock center is supercritical at earlier times, while higher up in the corona the whole shock becomes subcritical. This suggests that CME-driven shocks could be efficient particle accelerators at the initiation phases of the event, while at later times they progressively lose energy, also losing their capability to accelerate high-energy particles. This result has important implications on the localization of particle acceleration sites and in the context of predictive space weather studies.

## FIRST COMPLETE DETERMINATION OF PLASMA PHYSICAL PARAMETERS ACROSS A CORONAL MASS EJECTION-DRIVEN SHOCK

A. [Bemporad](#) and S. Mancuso

Astrophysical Journal, 720:130–143, 2010

We report on the study of a fast coronal mass ejection (CME)-driven shock associated with the solar eruption of **2002 March 22**. This event was observed in the intermediate corona both in white light and the extreme ultraviolet (EUV) by the LASCO and UVCS instruments on board the *Solar and Heliospheric Observatory*, as well as in metric and decametric wavelengths through space- and ground-based radio observatories. Clear signatures of shock transit are (1) strong type II emission lanes observed after the CME initiation, (2) strong Ovi  $\lambda\lambda 1032, 1037$  line profile broadenings (up to  $\sim 2 \times 10^7$  K) associated with the shock transit across the UVCS slit field of view, and (3) a density enhancement located in LASCO images above the CME front. Since the UVCS slit was centered at  $4.1R_{\odot}$ , in correspondence with the flank of the expanding CME, this observation represents the highest UV detection of a shock obtained so far with the UVCS instrument. White-light and EUV data have been combined in order to estimate not only the shock compression ratio and the plasma temperature, but also the strength of the involved coronal magnetic fields, by applying the Rankine–Hugoniot equations for the general case of oblique shocks.

Results show that, for a compression ratio  $X = 2.06$  as derived from LASCO data, the coronal plasma is heated across the shock from an initial temperature of  $2.3 \times 10^5$  K up to  $1.9 \times 10^6$  K, while at the same time the magnetic field undergoes a compression from a pre-shock value of  $\sim 0.02$  G up to a post-shock field of  $\sim 0.04$  G. Magnetic and kinetic energy density increases at the shock are comparable (in agreement with the idea of equipartition of energy), and both are more than two times larger than the thermal energy density increase. This is the first time that a complete characterization of pre- and post-shock plasma physical parameters has been derived in the solar corona.

## **SIDE MAGNETIC RECONNECTIONS INDUCED BY CORONAL MASS EJECTIONS: OBSERVATIONS AND SIMULATIONS**

A. [Bemporad](#)<sup>1</sup>, A. Soenen<sup>2</sup>, C. Jacobs<sup>2</sup>, F. Landini<sup>3</sup>, and S. Poedts<sup>2</sup>

Astrophysical Journal, 718:251–265, 2010 July; **File**

Over the last few years coronagraphic and spectroscopic observations have demonstrated that small-scale eruptions, such as “jets,” “narrow coronal mass ejections (CMEs),” “mini CMEs,” “streamer puffs,” “streamer detachments,” and others, occur ubiquitously on the Sun. Nevertheless, the origin of small-scale eruptive events and how these are interrelated with larger scale CMEs have been poorly investigated so far. In this work, we study a series of small-scale side eruptions that occurred during and after a large-scale CME. Observations show that a CME can be associated not only with a single reconnection process, leading to the large-scale phenomenon, but also with many other side reconnections occurring at different locations and times around the main flux rope, possibly induced by the CME expansion in the surrounding corona. White light and EUV observations of a slow CME acquired by the *SOHO/LASCO* and *SOHO/UVCS* instruments are analyzed here to characterize the locations of side reconnections induced by the CME. The magnetic reconnection rate  $M$  has been estimated from the UVCS data from the ratio between the inflows and outflows observed around the reconnection region, and from the LASCO data from the observed aperture angles between the slow mode shocks (SMSs) associated with the reconnection. It turns out that  $M \sim 0.05$  at the heliocentric distance of  $1.8R_{\odot}$ , while between  $\sim 2.5$  and  $5.5R_{\odot}$ ,

$M$  values progressively decrease with time/altitude from  $M \sim 1$  down to  $M \sim 0.3$ . Such large values of  $M$  are theoretically acceptable only if flux pile-up reconnection is envisaged. The observed occurrence of multiple reconnections associated with a CME is verified by numerical simulations of an eruption occurring within multiple helmet streamers. The simulations confirm that small side reconnections are a consequence of CME expansion against the surrounding coronal streamers. The simulated and observed evolution of aperture angles between the SMSs are in good agreement as well. These results demonstrate the effect of the global coronal magnetic field in the occurrence of small-scale eruptions due to lateral reconnection in a preceding CME event.

## **STEREOSCOPIC RECONSTRUCTION FROM STEREO/EUV IMAGERS DATA OF THE THREE-DIMENSIONAL SHAPE AND EXPANSION OF AN ERUPTING PROMINENCE**

A. [Bemporad](#)

Astrophysical Journal, 701:298–305, 2009; **File**

On **2007 May 9**, a prominence eruption was observed in the He II  $\lambda 304$  filter by the two EUV Imagers (EUVI) telescopes aboard the *STEREO A* and *B* spacecrafts. The high spatial resolution ( $\sim 1.5$  pixel<sup>-1</sup>) EUVI images have been used to infer via triangulation the three-dimensional (3D) shape and orientation of the prominence  $\sim 12$  minutes after the beginning (13:40 UT) of the eruption. At this time, the prominence has the shape of a “hook” with the base anchored at the Sun. The “hook” prominence is highly inclined southward with

respect to the radial direction, has an average thickness of  $0.061R_{\odot}$ , a length of  $0.43R_{\odot}$ , and lies in first approximation on a plane inclined by  $\sim 54.5^{\circ}$  with respect to the line of sight. Thanks to the very high temporal cadence ( $\sim 37$  s) of EUVI observations it has been possible also to infer the 3D early eruption trajectory. In the following  $\sim 20$  minutes the prominence rotates westward, undergoing a strong latitudinal acceleration,  $\sim 3$  times larger than the radial acceleration. In this time interval, the prominence expands in a direction mainly parallel to the plane of the sky; the total volume occupied by the plasma increases by a factor of  $\sim 8$ , while the prominence thickness increases only by  $\sim 12\%$ . This is related to the fact that the early prominence expansion is anisotropic and occurs mainly on a plane parallel to the plane of the sky. Even if the small-scale spatial distribution of the erupting material observed in the He II EUVI images is quite complex, both the approximately planar shape and the successive planar expansion suggest that on larger spatial scales the prominence can be globally approximated as a two-dimensional “ribbon-like” feature, instead of a 3D twisted flux tube.

## **SPECTROSCOPIC DETECTION OF TURBULENCE IN *POST-CME CURRENT SHEETS***

A. [Bemporad](#)

*Astrophysical Journal*, 689:572Y584, 2008, [File](#)

Plasma in **post-CME current sheets** (CSs) is expected to be highly turbulent because of the tearing and coalescence instability and/or local microscopic instabilities. For this reason, in the last decade the inconsistency between the observed ( $\sim 10^4$ – $10^5$  km) and the expected ( $\sim 10$  m) CS thickness has been tentatively explained in many MHD models as a consequence of plasma turbulence that should be able to significantly broaden the CS. However, from the observational point of view, little is known about this subject. A few post-CME CSs have been observed in UVCS spectra as a strong emission in the high-temperature [Fe XVIII] line, usually unobservable in the solar corona. In this work, published data on post-CME CSs observed by UVCS are reanalyzed, concentrating for the first time on the evolution of turbulence derived from the nonthermal broadening of the [Fe XVIII] line profiles. Derived turbulent speeds are on the order of  $\sim 60$  km s $^{-1}$  a few hours after the CME and slowly decay down to  $\sim 30$  km s $^{-1}$  in the following 2 days. From this evolution the anomalous diffusivity due to microinstabilities has been estimated, and the scenario of multiple small-scale reconnections is tested. Results show that the existence of many ( $\sim 10^{11}$  to  $10^{17}$  cm $^{-3}$ ) microscopic CSs (CSs) of small sizes ( $\sim 10$ – $10^4$  m) could explain not only the high CS temperatures but also the much larger observed thickness of macroscopic CSs, thanks to turbulent broadening.

## **A Comprehensive Study of the Initiation and Early Evolution of a Coronal Mass Ejection from Ultraviolet and White-Light Data**

A. [Bemporad](#), J. Raymond, G. Poletto, and M. Romoli

*The Astrophysical Journal*, 655:576–590, 2007, [File](#)

2000 January 31. Based on vector magnetograph data and magnetic field models, we find that field disruption in an active region (AR) was driven by flux emergence and shearing motions, leading to the CME and to post-CME arcades seen in the EUV.

## **CURRENT SHEET EVOLUTION IN THE AFTERMATH OF A CME EVENT**

*ApJ* 957 74 2023

<https://arxiv.org/pdf/2310.02412.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/acfe6c/pdf>

The trajectories of coronal mass ejections (CMEs) are often seen to substantially deviate from a purely radial propagation direction. Such deviations occur predominantly in the corona and have been attributed to "channeling" or deflection of the eruptive flux by asymmetric ambient magnetic fields. Here, we investigate an additional mechanism that does not require any asymmetry of the pre-eruptive ambient field. Using magnetohydrodynamic numerical simulations, we show that the trajectory of CMEs through the solar corona can significantly deviate from a radial direction when propagation takes place in a unipolar radial field. We demonstrate that the deviation is most prominent below  $\sim 15$  solar radii and can be attributed to an "effective  $I \times B$  force" that arises from the intrusion of a magnetic flux rope with a net axial electric current into a unipolar background field. These results are important for predictions of CME trajectories in the context of space weather forecasts, as well as for reaching a deeper understanding of the fundamental physics underlying CME interactions with the ambient fields in the extended solar corona.

## **On Fields and Mass Constraints for the Uniform Propagation of Magnetic-Flux Ropes Undergoing Isotropic Expansion**

Daniel Benjamín [Berdichevsky](#)

[Solar Physics](#) May 2013, Volume 284, [Issue 1](#), pp 245–259

<https://link.springer.com/content/pdf/10.1007%2Fs11207-012-0176-5.pdf>

An analytical 3-D magnetohydrodynamic (MHD) solution of a magnetic-flux rope (FR) is presented. This FR solution may explain the uniform propagation, beyond  $\sim 0.05$  AU, of coronal mass ejections (CMEs) commonly observed by today's missions like The Solar Mass Ejection Imager (SMEI), Solar and Heliospheric Observatory (SOHO) and Solar Terrestrial Relations Observatory (STEREO), tracked to tens of times the radius of the Sun, and in some cases up to 1 AU, and/or beyond. Once a CME occurs, we present arguments regarding its evolution based on its mass and linear momentum conservation. Here, we require that the gravitational and magnetic forces balance each other in the framework of the MHD theory for a simple model of the evolution of a CME, assuming it interacts weakly with the steady solar wind. When satisfying these ansätze we identify a relation between the transported mechanical mass of the interplanetary CME with its geometrical parameters and the intensity of the magnetic field carried by the structure. In this way we are able to estimate the mass of the interplanetary CME (ICME) for a list of cases, from the Wind mission records of ICME encountered near Earth, at 1 AU. We obtain a range for masses of  $\sim 109$  to 1013 kg, or assuming a uniform distribution, of  $\sim 0.5$  to 500  $\text{cm}^{-3}$  for the hadron density of these structures, a result that appears to be consistent with observations.

Correction: [Solar Physics](#) November 2019, 294:167 <https://link.springer.com/content/pdf/10.1007%2Fs11207-019-1557-9.pdf>

## **Solar Filament Eruptions in $H\alpha$ Doppler Velocity**

I. A. [Berezin](#)<sup>1</sup>, A. G. Tlatov<sup>1</sup>, and A. A. Pevtsov<sup>2</sup>

2023 ApJ 950 100

<https://iopscience.iop.org/article/10.3847/1538-4357/acd113/pdf>

We use observations taken with a novel solar telescope spectroheliograph to investigate the association between the early filament rise and coronal mass ejections (CMEs). The instrument allows the  $H\alpha$  full line profile to be registered in each pixel of the solar disk with a time cadence of about 1 minute. We analyze observations of three eruptive filaments in 2021 and show that patrol telescope measurements of the  $H\alpha$  line profile with a spectral resolution  $R = 40,000$  can be used to detect precursors of filament eruptions with an advance of several hours and to estimate the initial acceleration of CMEs. Our limited case study also suggests that while detecting an early filament rise may serve as an indicator of a possible eruption, the filament ascent alone is not a definite sign of a CME. **2021 February 20, 2021 August 28 and 2021 November 6**

## **RELATION BETWEEN THE CORONAL MASS EJECTION ACCELERATION AND THE NON-THERMAL FLARE CHARACTERISTICS**

S. [Berkebile-Stoiser](#), A. M. Veronig, B. M. Bein, and M. Temmer

2012 ApJ 753 88, [File](#)

We investigate the relationship between the main acceleration phase of coronal mass ejections (CMEs) and the particle acceleration in the associated flares as evidenced in Reuven Ramaty High Energy Solar Spectroscopic Imager non-thermal X-rays for a set of 37 impulsive flare-CME events. Both the CME peak velocity and peak acceleration yield distinct correlations with various parameters characterizing the flare-accelerated electron spectra. The highest correlation coefficient is obtained for the relation of the CME peak velocity and the total energy in accelerated electrons ( $c = 0.85$ ), supporting the idea that the acceleration of the CME and the particle acceleration in the associated flare draw their energy from a common source, probably magnetic reconnection in the current sheet behind the erupting structure. In general, the CME peak velocity shows somewhat higher correlations with the non-thermal flare parameters than the CME peak acceleration, except for the spectral index of the accelerated electron spectrum, which yields a higher correlation with the CME peak acceleration ( $c = -0.6$ ), indicating that the hardness of the flare-accelerated electron spectrum is tightly coupled to the impulsive acceleration process of the rising CME structure. We also obtained high correlations between the CME initiation height  $h_0$  and the non-thermal flare parameters, with the highest correlation of  $h_0$  to the spectral index  $\delta$  of flare-accelerated electrons ( $c = 0.8$ ). This means that CMEs erupting at low coronal heights, i.e., in regions of stronger magnetic fields, are accompanied by flares that are more efficient at accelerating electrons to high energies. In the majority of events ( $\sim 80\%$ ), the non-thermal flare emission starts after the CME acceleration, on

average delayed by 6 minutes, in line with the standard flare model where the rising flux rope stretches the field lines underneath until magnetic reconnection sets in. We find that the current sheet length at the onset of magnetic reconnection is  $21 \pm 7$  Mm. The flare hard X-ray peaks are well synchronized with the peak of the CME acceleration profile, and in 75% of the cases they occur within  $\pm 5$  minutes. Our findings provide strong evidence for the tight coupling between the CME dynamics and the particle acceleration in the associated flare in impulsive events, with the total energy in accelerated electrons being closely correlated with the peak velocity (and thus the kinetic energy) of the CME, whereas the number of electrons accelerated to high energies is decisively related to the CME peak acceleration and the height of the pre-eruptive structure.

### **Geoeffectiveness Prediction of CMEs**

[Diana Besliu-Ionescu](#) and [Marilena Mierla](#)

Front. Astron. Space Sci., 8:672203 2021 |

<https://www.frontiersin.org/articles/10.3389/fspas.2021.672203/full>

<https://doi.org/10.3389/fspas.2021.672203>

Coronal mass ejections (CMEs), the most important pieces of the puzzle that drive space weather, are continuously studied for their geomagnetic impact. We present here an update of a logistic regression method model, that attempts to forecast if a CME will arrive at the Earth and it will be associated with a geomagnetic storm defined by a minimum Dst value smaller than  $-30$  nT. The model is run for a selection of CMEs listed in the LASCO catalogue during the solar cycle 24. It is trained on three fourths of these events and validated for the remaining one fourth. Based on five CME properties (the speed at 20 solar radii, the angular width, the acceleration, the measured position angle and the source position – binary variable) the model successfully predicted 98% of the events from the training set, and 98% of the events from the validation one.

### **Small-Scale Activity Above the Penumbra of a Fast-Rotating Sunspot**

L. [Bharti](#), C. Quintero Noda, S. Rakesh, B. Sobha, A. Pandya, C. Joshi

[Solar Physics](#) March 2018, 293:46

High-resolution observations of small-scale activity above the filamentary structure of a fast-rotating sunspot of NOAA Active Region 10930 are presented. The penumbral filament that intrudes into the umbra shows a central dark core and substructures. It almost approached another end of the umbra, like a light bridge. The chromospheric Ca II H images show many jet-like structures with a bright leading edge above it. These bright jets move across the filament tips and show coordinated up and down motions. Transition region images also show brightening at the same location above the intrusion. Coronal 195 Å images suggest that one end of the bright coronal loop footpoints resides in this structure. The intrusion has opposite polarity with respect to the umbra. Strong downflows are observed at the edges along the length of the intrusion where the opposite-polarity field is enhanced. We also observe a counter-Evershed flow in the filamentary structure that also displays brightening and energy dissipation in the upper atmosphere. This scenario suggests that the jets and brightenings are caused by low-altitude reconnection driven by opposite-polarity fields and convective downflows above such structures.

### **Lambda-shaped jets from a penumbral intrusion into a sunspot umbra: a possibility for magnetic reconnection\***

L. [Bharti](#)<sup>1,2</sup>, S. K. Solanki<sup>1,3</sup> and J. Hirzberger

A&A 597, A127 (2017)

[http://www.aanda.org/articles/aa/full\\_html/2017/01/aa29656-16/aa29656-16.html](http://www.aanda.org/articles/aa/full_html/2017/01/aa29656-16/aa29656-16.html)

We present the results of high resolution co-temporal and co-spatial photospheric and chromospheric observations of sunspot penumbral intrusions. The data were taken with the Swedish Solar Telescope (SST) on the Canary Islands. Time series of Ca II H images show a series of transient jets extending roughly 3000 km above a penumbral intrusion into the umbra. For most of the time series, jets were seen along the whole length of the intruding bright filament. Some of these jets develop a clear  $\lambda$ -shaped structure, with a small loop appearing at their footpoint and lasting for around a minute. In the framework of earlier studies, the observed transient  $\lambda$  shape of these jets suggests that they could be caused by magnetic reconnection between a curved arcade-like or flux rope-like field in the lower part of the penumbral intrusion and the more vertical umbral magnetic field forming a cusp-shaped structure above the penumbral intrusion.

### **Fine structure above a light bridge in the transition region and corona**

Lokesh [Bharti](#)

MNRAS Letters 2015

<http://arxiv.org/pdf/1505.02412v1.pdf>

We present the results of multi wavelength, co-spatial and near co-temporal observations of jets above a sunspot light bridge. The data were obtained with the Solar Optical Telescope (SOT) on board Hinode, the Interface Region Spectrograph (IRIS) and the Atmospheric Imaging Assembly (AIA) on board the Solar Dynamic Observatory (SDO). Most of the jets in the Ca II H images show decreasing brightness with height while in the IRIS slit jaw images at 1330 Å jets show a bright leading edge. These jets show rising and falling motion as evident from the parabolic profile obtained from the time-distance diagram. The rising and falling speeds of the jets are similar. These jets show a coordinated behaviour between neighbouring jets moving jointly up and down. Some of the jets show a plasma ejection

from the leading edge which is also hotter at the transition region (TR) and coronal temperatures. A similar behaviour is seen in the AIA wave bands that suggests that jets above the LB reach up to the lower corona and the leading edges are heated up to coronal temperatures. Such jets are important means of transfer mass and energy to the transition region and corona above sunspots. **October 25, 2014.**

### **Solar flares associated coronal mass ejections in case of type II radio bursts**

Beena [Bhatt](#), Lalan Prasad, Harish Chandra, Suman Garia

Astrophysics and Space Science August 2016, 361:265

We have statistically studied 220 events from 1996 to 2008 (i.e. solar cycle 23). Two sets of flare-CME are examined: one with Deca-hectometric (DH) type II and other without DH type II radio burst. Out of 220 events 135 (flare-halo CME) are accompanied with DH type II radio burst and 85 are without DH type II radio burst. Statistical analysis is performed to examine the distribution of solar flare-halo CME around the solar disk and to investigate the relationship between solar flare and halo CME parameters in case of with and without DH type II radio burst. In our analysis we have observed that: (i) 10–20° latitudinal belt is more effective than the other belts for DH type II and without DH type II radio burst. In this belt, the southern region is more effective in case of DH type II radio burst, whereas in case of without DH type II radio burst dominance exists in the northern region. (ii) 0–10° longitudinal belt is more effective than the other belts for DH type II radio burst and without DH type II radio burst. In this belt, the western region is more effective in case of DH type II radio burst, while in case of without DH type II radio burst dominance exists in the eastern region. (iii) Mean speed of halo CMEs (1382 km/s) with DH type II radio burst is more than the mean speed of halo CMEs (775 km/s) without DH type II radio burst. (iv) Maximum number of M-class flares is found in both the cases. (v) Average speed of halo CMEs in each class accompanied with DH type II radio burst is higher than the average speed of halo CMEs in each class without DH type II radio burst. (vi) Average speed of halo CMEs, associated with X-class flares, is greater than the other class of solar flares in both the cases.

### **The energetic relationship among geoeffective solar flares, associated CMEs and SEPs**

Nipa J [Bhatt](#)<sup>1</sup>, Rajmal Jain<sup>2</sup> and Arun Kumar Awasthi<sup>2</sup>

Res. Astron. Astrophys. 13 978, 2013

<https://iopscience.iop.org/article/10.1088/1674-4527/13/8/009/pdf>

Major solar eruptions (flares, coronal mass ejections (CMEs) and solar energetic particles (SEPs)) strongly influence geospace and space weather. Currently, the mechanism of their influence on space weather is not well understood and requires a detailed study of the energetic relationship among these eruptive phenomena. From this perspective, we investigate 30 flares (observed by RHESSI), followed by weak to strong geomagnetic storms. Spectral analysis of these flares suggests a new power-law relationship ( $r \sim 0.79$ ) between the hard X-ray (HXR) spectral index (before flare-peak) and linear speed of the associated CME observed by LASCO/SOHO. For 12 flares which were followed by SEP enhancement near Earth, HXR and SEP spectral analysis reveals a new scaling law ( $r \sim 0.9$ ) **between the hardest X-ray flare spectrum and the hardest SEP spectrum. Furthermore, a strong correlation is obtained between the linear speed of the CME and the hardest spectrum of the corresponding SEP event ( $r \sim 0.96$ ). We propose that the potentially geoeffective flare and associated CME and SEP are well-connected** through a possible feedback mechanism, and should be regarded within the framework of a solar eruption. Owing to their space weather effects, these new results will help improve our current understanding of the Sun-Earth relationship, which is a major goal of research programs in heliophysics. **28-29 Oct 2003**

### **Exploring the Origin of Stealth Coronal Mass Ejections with Magnetofrictional Simulations**

[P. Bhowmik](#), [A. R. Yeates](#) & [O. E. K. Rice](#)

[Solar Physics](#) volume 297, Article number: 41 (2022)

<https://link.springer.com/content/pdf/10.1007/s11207-022-01974-x.pdf>

Coronal mass ejections (CMEs) – among the most energetic events originating from the Sun – can cause significant and sudden disruption to the magnetic and particulate environment of the heliosphere. Thus, in the current era of space-based technologies, early warning that a CME has left the Sun is crucial. Some CMEs exhibit signatures at the solar surface and in the lower corona as the eruption occurs, thus enabling their prediction before arriving at near-Earth satellites. However, a significant fraction of CMEs exhibit no such detectable signatures and are known as “stealth CMEs”. Theoretical and observational studies aiming to understand the physical mechanism behind stealth CMEs have identified coronal streamers as potential sources. In this paper, we show that such streamer-blowout eruptions – which do not involve the lift-off of a low-coronal magnetic flux rope – are naturally produced even in the quasi-static magnetofrictional model for the coronal magnetic field. Firstly, we show that magnetofriction can reproduce in this way a particular stealth CME event observed during **1 – 2 June 2008**. Secondly, we show that the magnetofrictional model predicts the occurrence of repeated eruptions without clear low-coronal signatures from such arcades, provided that the high, overlying magnetic field lines are sufficiently sheared by differential rotation. A two-dimensional parameter study shows that such eruptions are robust under variation of the parameters, and that the eruption frequency is primarily determined by the footpoint shearing. This suggests that magnetofrictional models could, in principle, provide early indication – even pre-onset – of stealth eruptions, whether or not they originate from the eruption of a low-coronal flux rope.

### **Two Classes of Eruptive Events During Solar Minimum**

[P. Bhowmik](#) & [A. R. Yeates](#)

*Solar Physics* volume 296, Article number: 109 (2021)

<https://arxiv.org/pdf/2107.01941>

<https://link.springer.com/content/pdf/10.1007/s11207-021-01845-x.pdf>

<https://doi.org/10.1007/s11207-021-01845-x>

During solar minimum, the Sun is relatively inactive with few sunspots observed on the solar surface. Consequently, we observe a smaller number of highly energetic events such as solar flares or coronal mass ejections (CMEs), which are often associated with active regions on the photosphere. Nonetheless, our magnetofrictional simulations during the minimum period suggest that the solar corona is still dynamically evolving in response to the large-scale shearing velocities on the solar surface. The non-potential evolution of the corona leads to the accumulation of magnetic free energy and helicity, which is periodically shed in eruptive events. We find that these events fall into two distinct classes: One set of events are caused by eruption and ejection of low-lying coronal flux ropes, and they could explain the origin of occasional CMEs during solar minimum. The other set of events are not driven by destabilisation of low-lying structures but rather by eruption of overlying sheared arcades. These could be associated with streamer blowouts or stealth CMEs. The two classes differ significantly in the amount of magnetic flux and helicity shed through the outer coronal boundary. We additionally explore how other measurables such as current, open magnetic flux, free energy, coronal holes, and the horizontal component of the magnetic field on the outer model boundary vary during the two classes of event. This study emphasises the importance and necessity of understanding the dynamics of the coronal magnetic field during solar minimum. **2018 11 08-13, 2019 01 24**

### **Partial eruption of a filament with twisting nonuniform fields**

Yi Bi, [Yunchun Jiang](#), [Jiayan Yang](#), [Yongyuan Xiang](#), [Yunfang Cai](#), [Weiwei Liu](#)

ApJ **805** 48 **2015**

<http://arxiv.org/pdf/1504.03090v1.pdf>

The eruption of the filament with the kink fashion is often regarded as a signature of the kink instability. However, the kink instability threshold for the filament magnetic structure has been not widely understood. Using the H-alpha observation from the New Vacuum Solar Telescope (NVST), we present a partial eruptive filament. In the eruption, a filament thread appeared to split from the middle portion of the filament and to break out in a kinklike fashion. During this period, the left filament material remained below, which erupted without the kinking motion later on. The coronal magnetic field lines associated with the filament are obtained from the nonlinear force-free field (NLFFF) extrapolations using the 12 minutes cadence vector magnetograms of the Helioseismic and Magnetic Imager (HMI) on board the Solar Dynamic Observatory (SDO). We studied the extrapolated field lines passing through the magnetic dips that are in good agreement with the observed filament. The field lines are non-uniformly twisted and appear to be made up by two twisted flux ropes winding about each other. One of them has higher twist than the other, and the highly twisted one has its dips aligned with the kinking eruptive thread at the beginning of its eruption. Before the eruption, moreover, the highly twisted flux rope was found to expand with the approximately constant field twist. In addition, the helicity flux maps deduced from the HMI magnetograms show that some helicity is injected into the overlying magnetic arcade, but no significant helicity is injected into the flux ropes. Accordingly, we suggest that the highly twisted flux rope became kink unstable when the instability threshold declined with the expansion of the flux rope. **2014 Nov 4**

### **Solar Filament Material Oscillations and Drainage before Eruption**

Yi Bi<sup>1,3</sup>, [Yunchun Jiang](#)<sup>1</sup>, [Jiayan Yang](#)<sup>1</sup>, [Junchao Hong](#)<sup>1,2</sup>, [Haidong Li](#)<sup>1</sup>, [Dan Yang](#)<sup>1,2</sup>, and [Bo Yang](#)  
**2014 ApJ 790 100**

Both large-amplitude longitudinal (LAL) oscillations and material drainage in a solar filament are associated with the flow of material along the filament axis, often followed by an eruption. However, the relationship between these two motions and a subsequent eruption event is poorly understood. We analyze a filament eruption using EUV imaging data captured by the Atmospheric Imaging Array on board the Solar Dynamics Observatory and the H $\alpha$  images from the Global Oscillation Network Group. Hours before the eruption, the filament was activated, with one of its legs undergoing a slow rising motion. The asymmetric activation inclined the filament relative to the solar surface. After the active phase, LAL oscillations were observed in the inclined filament. The oscillation period increased slightly over time, which may suggest that the magnetic fields supporting the filament evolve to be flatter during the slow rising phase. After the oscillations, a significant amount of filament material was drained toward one filament endpoint, followed immediately by the violent eruption of the filament. The material drainage may further support the change in magnetic topology prior to the eruption. Moreover, we suggest that the filament material drainage could play a role in the transition from a slow to a fast rise of the erupting filament.

### **ERUPTION OF A SOLAR FILAMENT CONSISTING OF TWO THREADS**

Yi Bi (毕以), [Yunchun Jiang](#) (姜云春), [Haidong Li](#) (李海东), [Junchao Hong](#) (洪俊超), and [Ruisheng Zheng](#)  
**2012 ApJ 758 42**

The trigger and driving mechanism for the eruption of a filament consisting of two dark threads was studied with unprecedented high cadence and resolution of He II 304 Å observations made by the Atmospheric Imaging Assembly (AIA) on board the Solar Dynamics Observatory (SDO) and the observations made by the Solar Magnetic Activity Research Telescope and the Extreme Ultraviolet Imager (EUVI) telescope on board the Solar Terrestrial Relations

Observatory Ahead (STEREO-A). The filament was located at the periphery of the active region NOAA 11228 and erupted on **2011 June 6**. At the onset of the eruption, a turbulent filament thread was found to be heated and to elongate in stride over a second one. After it rose slowly, most interestingly, the elongating thread was driven to contact and interact with the second one, and it then erupted with its southern leg being wrapped by a newly formed thread produced by the magnetic reconnection between fields carried by the two threads. Combining the observations from STEREO-A/EUVI and SDO/AIA 304 Å images, the three-dimensional shape of the axis of the filament was obtained and it was found that only the southern leg of the eruptive filament underwent rotation. We suggest that the eruption was triggered by the reconnection of the turbulent filament thread and the surrounding magnetic field, and that it was mainly driven by the kink instability of the southern leg of the eruptive filament that possessed a more twisted field introduced by the reconnection-produced thread.

## **A fundamental mechanism of solar eruption initiation in multipolar magnetic field**

[Xinkai Bian](#), [Chaowei Jiang](#), [Xueshang Feng](#), [Pingbing Zuo](#), [Yi Wang](#)

ApJ **956** 73 **2023**

<https://arxiv.org/pdf/2308.04924.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/acf5dc/pdf>

Recently we established a fundamental mechanism of solar eruption initiation, in which an eruption can be initiated from a bipolar field through magnetic reconnection in the current sheet (CS) that is formed slowly in the core field as driven by photospheric shearing motion. Here using a series of fully 3D MHD simulations with a range of different photospheric magnetic flux distributions, we extended this fundamental mechanism to the quadrupolar magnetic field containing a null point above the core field, which is the basic configuration of the classical breakout model. As is commonly believed, in such multipolar configuration, the reconnection triggered in the CS originated at the null point (namely, the breakout reconnection) plays the key role in eruption initiation by establishing a positive feedback-loop between the breakout reconnection and the expansion of the core field. However, our simulation showed that the key of eruption initiation in such multipolar configuration remains to be the slow formation of the CS in the sheared core rather than the onset of fast breakout reconnection. The breakout reconnection only helps the formation of the core CS by letting the core field expand faster, but the eruption cannot occur when the bottom surface driving is stopped well before the core CS is formed, even though the fast reconnection has already been triggered in the breakout CS. This study clarified the role of breakout reconnection and confirmed formation of the core CS as the key to the eruption initiation in a multipolar magnetic field.

## **MHD simulation of rapid change of photospheric magnetic field during solar eruption caused by magnetic reconnection**

[Xinkai Bian](#)<sup>1</sup> and [Chaowei Jiang](#)<sup>1</sup>

Front. Astron. Space Sci. **10**: 1097672. **2023**

doi: 10.3389/fspas.2023.1097672

<https://www.frontiersin.org/articles/10.3389/fspas.2023.1097672/pdf>

It has been well observed that the horizontal component of the magnetic field at photosphere changes rapidly and irreversibly after solar eruptions. Specifically, the horizontal magnetic field near the polarity inversion line increases substantially, while that near the center of the magnetic polarity decreases. Such a phenomenon is considered as the dynamic feedback from the corona to the photosphere, but the underlying mechanism remains in debate. Here based on a recent magnetohydrodynamics (MHD) simulation of homologous eruptions initiated by magnetic reconnection, we analyzed the rapid changes of the horizontal magnetic field, the magnetic inclination angle, the Lorentz force and as well as the derivative variation of the horizontal magnetic field. The simulation reproduces a pattern of rapid evolution of the horizontal field during the eruptions in agreement with typical observations. Our analysis suggests the physical reasons for this phenomenon: 1) The magnetic field near the polarity inversion line becomes more horizontal after flares due to the compression of the downward outflow of flare reconnection, and accordingly the magnetic inclination angle decreases and the downward Lorentz force increases; 2) The magnetic field near the center of the magnetic polarities become more vertical mainly due to the expansion effect of the velocity divergence term, and as a result the magnetic inclination angle and the upward Lorentz force increase.

## **The role of photospheric converging motion in initiation of solar eruptions**

[Xinkai Bian](#), [Chaowei Jiang](#), [Xueshang Feng](#)

Front. Astron. Space Sci. **9**: 982108 **2022**

<https://arxiv.org/pdf/2209.06561.pdf>

<https://doi.org/10.3389/fspas.2022.982108>

<https://www.frontiersin.org/articles/10.3389/fspas.2022.982108/pdf>

It is well known that major solar eruptions are often produced by active regions with continual photospheric shearing and converging motions. Here, through high accuracy magnetohydrodynamics simulation, we show how solar eruption is initiated in a single bipolar configuration as driven by first shearing and then converging motions at the bottom surface. Different from many previous simulations, we applied the converging motion without magnetic diffusion, thus it only increases the magnetic gradient across the polarity inversion line but without magnetic flux cancellation. The converging motion at the footpoints of the sheared arcade creates a current sheet in a quasi-static way, and the eruption is triggered by magnetic reconnection of the current sheet, which supports the same scenario as shown in our previous

simulation with only shearing motion. With the converging motion, the current sheet is formed at a lower height and has a higher current density than with shearing motion alone, which makes reconnection more effective and eruption stronger. Moreover, the converging motion renders a fast decay rate of the overlying field with height and thus favorable for an eruption. This demonstrates that the converging flow is more efficient to create the current sheet and more favorable for eruption than by solely the shearing flow.

## **Homologous Coronal Mass Ejections Caused by Recurring Formation and Disruption of Current Sheet within a Sheared Magnetic Arcade**

[Xinkai Bian](#), [Chaowei Jiang](#), [Xueshang Feng](#), [Pingbing Zuo](#), [Yi Wang](#)

ApJ 2022

<https://arxiv.org/pdf/2201.02909.pdf>

The Sun often produces coronal mass ejections with similar structure repeatedly from the same source region, and how these homologous eruptions are initiated remains an open question. Here, by using a new magnetohydrodynamic simulation, we show that homologous solar eruptions can be efficiently produced by recurring formation and disruption of coronal current sheet as driven by continuously shearing of the same polarity inversion line within a single bipolar configuration. These eruptions are initiated by the same mechanism, in which an internal current sheet forms slowly in a gradually sheared bipolar field and reconnection of the current sheet triggers and drives the eruption. Each of the eruptions does not release all the free energy but with a large amount left in the post-flare arcade below the erupting flux rope. Thus, a new current sheet can be more easily formed by further shearing of the post-flare arcade than by shearing a potential field arcade, and this is favorable for producing the next eruption. Furthermore, it is found that the new eruption is stronger since the newly formed current sheet has a larger current density and a lower height. In addition, our results also indicate the existence of a magnetic energy threshold for a given flux distribution, and eruption occurs once this threshold is approached.

## **Numerical Simulation of a Fundamental Mechanism of Solar Eruption with Different Magnetic Flux Distributions**

[Xinkai Bian](#), [Chaowei Jiang](#), [Xueshang Feng](#), [Pingbing Zuo](#), [Yi Wang](#), [Xinyi Wang](#)

A&A 658, A174 2022

<https://arxiv.org/pdf/2111.04984.pdf>

<https://doi.org/10.1051/0004-6361/202141996>

<https://www.aanda.org/articles/aa/pdf/2022/02/aa41996-21.pdf>

Solar eruptions are explosive release of coronal magnetic field energy as manifested in solar flares and coronal mass ejection. Observations have shown that the core of eruption-productive regions are often a sheared magnetic arcade, i.e., a single bipolar configuration, and, particularly, the corresponding magnetic polarities at the photosphere are elongated along a strong-gradient polarity inversion line (PIL). It remains unclear what mechanism triggers the eruption in a single bipolar field and why the one with a strong PIL is eruption-productive. Recently, using high accuracy simulations, we have established a fundamental mechanism of solar eruption initiation that a bipolar field as driven by quasi-static shearing motion at the photosphere can form an internal current sheet, and then fast magnetic reconnection triggers and drives the eruption. Here we investigate the behavior of the fundamental mechanism with different photospheric magnetic flux distributions, i.e., magnetograms, by combining theoretical analysis and numerical simulation. Our study shows that the bipolar fields of different magnetograms, as sheared continually, all exhibit similar evolutions from the slow storage to fast release of magnetic energy in accordance with the fundamental mechanism, which demonstrates the robustness of the mechanism. We further found that the magnetograms with stronger PIL produce larger eruptions, and the key reason is that the sheared bipolar fields with stronger PIL can achieve more non-potentiality, and their internal current sheet can form at a lower height and with a larger current density, by which the reconnection can be more efficient. This also provides a viable trigger mechanism for the observed eruptions in active region with strong PIL.

## **Relations between Coronal Mass Ejections and the Photospheric Magnetic Field in Cycles 23 and 24**

Irina A. [Bilenko](#)

2020 ApJ 889 1

<https://orcid.org/0000-0002-9543-0542>

The number of coronal mass ejections (CMEs) and their parameters and cycle variations were investigated and compared to the photospheric magnetic field evolution in cycles 23 and 24. The Coordinated Data Analysis Workshops (CDAW) catalog of white-light CMEs detected by the Solar and Heliospheric Observatory/Large Angle and Spectrometric Coronagraph coronagraphs and the data on the photospheric magnetic fields from the Kitt Peak Vacuum Telescope Spectromagnetograph (KPVT/Spectromagnetograph) and the Synoptic Optical Long-term Investigations of the Sun Vector-Spectromagnetograph (SOLIS/VSM) were used. The results suggest that not only did the number of CMEs increase in cycle 24, but that their parameters, cycle variations, distributions, and dependencies on the photospheric magnetic fields were also different. Various CME categories behave in different ways during solar cycles. The differences in the number and parameters of CMEs and their cycle variations may be related to the differences in the photospheric magnetic fields during the cycles. The strong photospheric magnetic fields maintained approximately the same strength from cycle 23 to cycle 24, whereas the weak fields became weaker and the area they occupied

increased. Taking into account that the global magnetic field diminished from cycle 23 to cycle 24, the increase in the number of CMEs in cycle 24 can be understood. A detailed analysis of the similarities and differences in CME parameters and their cycle evolution indicates that, along with the influence of changes in the CME detection mode in 2004 and 2010, the changes in CME rate and parameters were also associated with real differences in the behavior of strong and weak photospheric magnetic fields in cycles 23 and 24.

## **Influence of the Solar Global Magnetic-Field Structure Evolution on CMEs**

Irina A. **Bilenko**

Solar Physics, Volume 289, Issue 11, pp 4209-4237 **2014**

<https://arxiv.org/pdf/1804.08354.pdf>

We consider the influence of the solar global magnetic-field structure (GMFS) cycle evolution on the occurrence rate and parameters of coronal mass ejections (CMEs) in Solar Cycles 23–24. It has been shown that, over solar cycles, CMEs are not distributed randomly, but they are regulated by evolutionary changes in the GMFS. It is proposed that the generation of magnetic Rossby waves in the solar tachocline results in the GMFS cycle changes. Each Rossby wave period favors a particular GMFS. It is proposed that the changes in wave periods result in GMFS reorganization and consequently in CME location, occurrence rate, and parameter changes. The CME rate and parameters depend on the sharpness of the GMFS changes, the strength of the global magnetic field, and the phase of a cycle

## **From the Sun to the Earth: The 13 May 2005 Coronal Mass Ejection**

Solar Phys (**2010**) 265: 49–127

We report the results of a multi-instrument, multi-technique, coordinated study of the solar eruptive event of 13 May 2005. We discuss the resultant Earth-directed (halo) coronal mass ejection (CME), and the effects on the terrestrial space environment and upper Earth atmosphere. The interplanetary CME (ICME) impacted the Earth's magnetosphere and caused the most-intense geomagnetic storm of 2005 with a Disturbed Storm Time (*Dst*) index reaching  $-263$  nT at its peak. The terrestrial environment responded to the storm on a global scale. We have combined observations and measurements from coronal and interplanetary remote-sensing instruments, interplanetary and near-Earth *in-situ* measurements, remote-sensing observations and *in-situ* measurements of the terrestrial magnetosphere and ionosphere, along with coronal and heliospheric modelling. These analyses are used to trace the origin, development, propagation, terrestrial impact, and subsequent consequences of this event to obtain the most comprehensive view of a geo-effective solar eruption to date. This particular event is also part of a NASA-sponsored Living With a Star (LWS) study and an on-going US NSF-sponsored Solar, Heliospheric, and Interplanetary Environment (SHINE) community investigation.

## **Predicting Coronal Mass Ejections Using Machine Learning Methods**

Monica G. **Bobra**, Stathis Itonidis

ApJ 821 127 **2016**

<http://arxiv.org/pdf/1603.03775v1.pdf> **File**

Of all the activity observed on the Sun, two of the most energetic events are flares and Coronal Mass Ejections (CMEs). Usually, solar active regions that produce large flares will also produce a CME, but this is not always true (Yashiro et al., 2005). Despite advances in numerical modeling, it is still unclear which circumstances will produce a CME (Webb & Howard, 2012). Therefore, it is worthwhile to empirically determine which features distinguish flares associated with CMEs from flares that are not. At this time, no extensive study has used physically meaningful features of active regions to distinguish between these two populations. As such, we attempt to do so by using features derived from [1] photospheric vector magnetic field data taken by the Solar Dynamics Observatory's Helioseismic and Magnetic Imager instrument and [2] X-ray flux data from the Geostationary Operational Environmental Satellite's X-ray Flux instrument. We build a catalog of active regions that either produced both a flare and a CME (the positive class) or simply a flare (the negative class). We then use machine-learning algorithms to [1] determine which features distinguish these two

populations, and [2] forecast whether an active region that produces an M- or X-class flare will also produce a CME. We compute the True Skill Statistic, a forecast verification metric, and find that it is a relatively high value of approximately 0.8 plus or minus 0.2. We conclude that a combination of six parameters, which are all intensive in nature, will capture most of the relevant information contained in the photospheric magnetic field.

## **The Double-Bubble CME of the 2020 December 14 Total Solar Eclipse**

[Benjamin Boe](#), [Bryan Yamashiro](#), [Miloslav Druckmuller](#), [Shadia Habbal](#)

ApJL **914** L39 **2021**

<https://arxiv.org/pdf/2106.04027.pdf>

<https://doi.org/10.3847/2041-8213/ac05ca>

Total solar eclipses (TSEs) continue to provide an invaluable platform for exploring the magnetic topology of the solar corona and for studying dynamic events such as Coronal Mass Ejections (CMEs) -- with a higher spatial resolution over a larger spatially continuous extent than is possible to achieve with any other method at present. In this Letter, we present observations of the full extent of a 'double-bubble' CME structure from the solar surface out to over 5 solar radii, as captured during the **2020 December 14** TSE. Its evolution through the corona was recorded from two observing sites separated by 13 minutes in their times of totality. The eclipse observations are complemented by a plethora of space-based observations including: Extreme Ultraviolet observations of the solar disk and low corona from SDO/AIA and STEREO-A/EUVI, white-light coronagraph observations from SOHO/LASCO-C2, radio from STEREO-A/WAVES and WIND/WAVES, and X-ray from GOES-16. We also characterize the magnetic field with a potential field source surface model. This CME event itself is of particular interest, as it demonstrates interactions between a prominence channel and an active region that led to the double-bubble structure. Despite the plethora of space-based observations, only the eclipse data are able to provide the proper context to connect these observations and yield a detailed study of this unique CME.

## **CME Induced Thermodynamic Changes in the Corona as Inferred from Fe XI and Fe XIV Emission Observations during the 2017 August 21 Total Solar Eclipse**

[Benjamin Boe](#), [Shadia Habbal](#), [Miloslav Druckmuller](#), [Adalbert Ding](#), [Jana Hoderova](#), [Pavel Starha](#)

**2020 ApJ 888** 100

<https://arxiv.org/pdf/1911.11222.pdf>

<https://doi.org/10.3847/1538-4357/ab5e34>

We present the first remote sensing observations of the impact from a Coronal Mass Ejection (CME) on the thermodynamic properties of the solar corona between 1 and 3 Rs. Measurements of the Fe XI (789.2 nm) and Fe XIV (530.3 nm) emission were acquired with identical narrow-bandpass imagers at three observing sites during the 2017 August 21 Total Solar Eclipse. Additional continuum imagers were used to observe K+F corona scattering, which is critical for the diagnostics presented here. The total distance between sites along the path of totality was 1400 km, corresponding to a difference of 28 minutes between the times of totality at the first and last site. These observations were used to measure the Fe XI and Fe XIV emission relative to continuum scattering, as well as the relative abundance of Fe 10+ and Fe 13+ from the line ratio. The electron temperature ( $T_e$ ) was then computed via theoretical ionization abundance values. We find that the range of  $T_e$  is  $1.1\text{--}1.2 \times 10^6$  K in coronal holes and  $1.2\text{--}1.4 \times 10^6$  K in streamers. Statistically significant changes of  $T_e$  occurred throughout much of the corona between the sites as a result of serendipitous CME activity prior to the eclipse. These results underscore the unique advantage of multi-site and multi-wavelength total solar eclipse observations for probing the dynamic and thermodynamic properties of the corona over an uninterrupted distance range from 1 to 3 Rs.

## **Solar Jet on 2014 April 16 Modeled by Kelvin--Helmholtz Instability**

[M. Bogdanova](#), [I. Zhelyazkov](#), [R. Joshi](#), [R. Chandra](#)

**2017**

<https://arxiv.org/pdf/1711.10734.pdf>

We study here the arising of Kelvin--Helmholtz Instability (KHI) in one fast jet of **2014 April 16** observed by the Atmospheric Imaging Assembly (AIA) on board Solar Dynamics Observatory (SDO) in different UV and EUV wavelengths. The evolution of jet indicates the blob like structure at its boundary which could be the observational evidence of the KHI. We model the jet as a moving cylindrical magnetic flux tube of radius  $a$  embedded in a magnetic field  $B_i$  and surrounded by rest magnetized plasma with magnetic field  $B_e$ . We explore the propagation of the kink MHD mode along the jet that can become unstable against the KHI if its speed exceeds a critical value. Concerning magnetic fields topology we consider three different configurations, notably of (i) spatially homogeneous magnetic fields (untwisted magnetic flux tube), (ii) internal (label 'i') twisted magnetic field and external homogeneous one (label 'e') (single-twisted flux tube), and (iii) both internal and external twisted magnetic fields (double-twisted magnetic flux tube). Plasma densities in the two media  $\rho_i$  and  $\rho_e$  are assumed to be homogeneous. The density contrast is defined in two ways: first as  $\rho_e/\rho_i$  and second as  $\rho_e/(\rho_i + \rho_e)$ . Computations show that the KHI can occur at accessible flow velocities in all the cases of untwisted and single-twisted flux tubes. It turns out, however, that in the case of a double-twisted flux tube the KHI can merge at an accessible jet speed only when the density contrast is calculated from the ratio  $\rho_e/(\rho_i + \rho_e)$ . Evaluated KHI developing times and kink mode wave phase velocities at wavelength of 4 Mm lie in the ranges of 1--6.2 min and 202--271 km/s, respectively---all being reasonable for the modeled jet.

## **Validation of CME Detection Software (CACTus) by Means of Simulated Data, and Analysis of Projection Effects on CME Velocity Measurements**

K. **Bonte**, C. Jacobs, E. Robbrecht, A. De Groof, D. Berghmans and S. Poedts

Solar Physics, Volume 270, Number 1, 253-272, **2011**, **File**

In the context of space weather forecasting, an automated detection of coronal mass ejections (CMEs) becomes more and more important for efficiently handling a large data flow which is expected from recently-launched and future solar missions. In this paper we validate the detection software package “CACTus” by applying the program to synthetic data from our 3D time-dependent CME simulations instead of observational data. The main strength of this study is that we know in advance what should be detected. We describe the sensitivities and strengths of automated detection, more specific for the CACTus program, resulting in a better understanding of CME detection on one hand and the calibration of the CACTus software on the other hand, suggesting possible improvements of the package. In addition, the simulation is an ideal tool to investigate projection effects on CME velocity measurements

## **Eruptive Event Generator Based on the Gibson-Low Magnetic Configuration†**

D. **Borovikov**, I. V. Sokolov, W. B. Manchester, M. Jin, T. I. Gombosi

JGR Volume 122, Issue 8 Pages 7979–7984 **2017**

<http://onlinelibrary.wiley.com/doi/10.1002/2017JA024304/pdf>

Coronal Mass Ejections (CMEs), a kind of energetic solar eruptions, are an integral subject of space weather research. Numerical magnetohydrodynamic (MHD) modeling, which requires powerful computational resources, is one of the primary means of studying the phenomenon. With increasing accessibility of such resources, grows the demand for user-friendly tools that would facilitate the process of simulating CMEs for scientific and operational purposes. The Eruptive Event Generator based on Gibson-Low flux rope (EEGGL), a new publicly available computational model presented in this paper, is an effort to meet this demand. EEGGL allows one to compute the parameters of a model flux rope driving a CME via an intuitive graphical user interface (GUI). We provide a brief overview of the physical principles behind EEGGL and its functionality. Ways towards future improvements of the tool are outlined.

## **Three-Dimensional Properties of Coronal Mass Ejections from STEREO/SECCHI Observations**

E. **Bosman**, V. Bothmer, G. Nisticò, A. Vourlidas, R. A. Howard, J. A. Davies

Solar Physics, November **2012**, Volume 281, Issue 1, pp 167-185, **File**

We identify 565 coronal mass ejections (CMEs) between **January 2007 and December 2010** in observations from the twin STEREO/SECCHI/COR2 coronagraphs aboard the STEREO mission. Our list is in full agreement with the corresponding SOHO/LASCO CME Catalog ( [http://cdaw.gsfc.nasa.gov/CME\\_list/](http://cdaw.gsfc.nasa.gov/CME_list/) ) for events with angular widths of 45° and up. The monthly event rates behave similarly to sunspot rates showing a three- to fourfold rise between September 2009 and March 2010. We select 51 events with well-defined white-light structure and model them as three-dimensional (3D) flux ropes using a forward-modeling technique developed by Thernisien, Howard and Vourlidas (Astrophys. J. 652, 763–773, 2006). We derive their 3D properties and identify their source regions. We find that the majority of the CME flux ropes (82 %) lie within 30° of the solar equator. Also, 82 % of the events are displaced from their source region, to a lower latitude, by 25° or less. These findings provide strong support for the deflection of CMEs towards the solar equator reported in earlier observations, e.g. by Cremades and Bothmer (Astron. Astrophys. 422, 307–322, 2004). **Tables.**

## **Comparison of CME and ICME Structures Derived from Remote-Sensing and In Situ Observations**

V. **Bothmer**, N. Mrotzek

*Solar Physics* November **2017**, 292:157

<https://link.springer.com/article/10.1007/s11207-017-1171-7>

We present results from the comparison of the near-Sun and in situ analysis of two Earth-directed coronal mass ejections (CMEs) with different 3D orientations and solar source region characteristics. The CME on **14 July 2000**, the so-called Bastille Day storm, a well-studied event, was observed from a single-point perspective by the Large Angle and Spectrometric Coronagraph (LASCO) onboard the Solar and Heliospheric Observatory (SOHO). It caused a major geomagnetic storm with a peak Kp of 9. The CME originated from a magnetic bipolar photospheric source region with the polarity inversion line being oriented rather parallel to the heliographic equator. In contrast, the CME on **29 September 2013**, which caused a geomagnetic storm with a peak Kp intensity of 8-, originated from a magnetic quadrupolar photospheric source region with the polarity inversion line between the two bipoles almost vertically oriented with respect to the heliographic equator. The results of a graduated cylindrical shell (GCS) analysis of the CMEs near the Sun are compared with the minimum variance analysis (MVA) of the magnetic field structure of the interplanetary CME (ICME) measured in situ near Earth’s orbit. The results are in good agreement for the September 2013 CME and ICME, whereas the July 2000 ICME appears substantially inclined near Earth’s orbit. The discrepancy can likely be explained taking into account kinks in the CME’s near-Sun structure of the CME that expands into the interplanetary medium.

## **Photospheric Field Evolution in the Source Regions of Coronal Mass Ejections**

**Bothmer**, V.; Tripathi, D.

SOHO-17. 10 Years of SOHO and Beyond, Proceedings of the conference held 7-12 May, **2006** at Giardini Naxos, Sicily, Italy. Edited by H. Lacoste and L. Ouwehand. ESA SP-617. European Space Agency, 2006. Published on CDROM, p.20.1

Six coronal mass ejections associated with erupting quiescent filaments on the visible solar disk were identified in data from SoHO (Solar and Heliospheric Observatory) LASCO (Large Angle and Spectrometric Coronagraph), EIT (Extreme ultraviolet Imaging Telescope) and MDI (Michelson Doppler Imager) data and ground-based H $\alpha$  observations from Big Bear and Meudon observatories. These events were analysed to investigate whether their initiations could be related to changes of the underlying photospheric field. The results show that in five out of the six events, substantial changes in the photospheric magnetic field occurred in the source regions prior and around the CME's lift-off times as identified from emerging/diminishing flux detected by MDI. In one event large magnetic flux changes could be identified not in the source region itself, but in a neighbouring active region. The results demonstrate that new missions, such as STEREO and Hinode (Solar-B) in conjunction with SoHO and ground-based measurements, will provide joint data sets that have the potential to provide new insight into the physical causes of CMEs.

## **The ARTEMIS Catalog of LASCO Coronal Mass Ejections**

### **Automatic Recognition of Transient Events and Marseille Inventory from Synoptic maps**

Y. **Boursier** · P. Lamy · A. Llebaria · F. Goudail · S. Robelus

Solar Phys., **2009**, 257(1), Page: 125 – 147, DOI: 10.1007/s11207-009-9370-5, **File**

The LASCO-C2 coronagraph aboard the SOHO solar observatory has been providing a continuous flow of coronal images since 1996. Synoptic maps for each Carrington rotation have been built from these images, and offer a global view of the temporal evolution of the solar corona, particularly the occurrence of transient events. Coronal Mass Ejections (CMEs) present distinct signatures thus offering a novel approach to the problem of their identification and characterization. We present in this article an automated method of detection based on their morphological appearance on synoptic maps. It is based on adaptive filtering and segmentation, followed by merging with high-level knowledge. The program builds a catalog which lists the CMEs detected for each Carrington Rotation, together with their main estimated parameters: time of appearance, position angle, angular extent, average velocity and intensity. Our final catalog LASCO-ARTEMIS (Automatic Recognition of Transient Events and Marseille Inventory from Synoptic maps) is compared with existing catalogs, CDAW, CACTUS and SEEDS. We find that, likewise the automated CACTUS and SEEDS catalogs, we detect many more events than the CDAW catalog which is based on visual detection. The total number of detected CMEs strongly depends upon the sensitivity to small, faint and numerous events.

## **Three-Dimensional Kinematics of Coronal Mass Ejections from STEREO/SECCHI-COR2 Observations in 2007 – 2008**

Y. **Boursier** · P. Lamy · A. Llebaria

### **STEREO SCIENCE RESULTS AT SOLAR MINIMUM**

We present a new method to perform the three dimensional characterization of coronal mass ejections (CMEs) using stereoscopic images obtained with the STEREO/SECCHI-COR2 coronagraphs. Two approaches are proposed, and each associated algorithm gives the trajectory of the CME and its kinematical properties (velocity and acceleration profiles) intended for space weather forecast. The first approach is based on forward modeling appropriate to the reconstruction of surfaces in an optically thin medium, and performs a local approximation of the observed CME by a hemispherical shell, thus tracking the leading edge of the event. The second approach is based on tracking the center of gravity of the radiance of the CME in the images. More than 16 000 blind tests have been performed to assess the performance of each algorithm. For that purpose, we used three distinct libraries of simulated images of CMEs that correspond to three CME models: hemispherical shell, flux rope, and cloud-like. The two methods are applied to a set of CMEs observed in 2007 and 2008 by the SECCHI-COR2 coronagraphs, and when possible, our results are compared to those already published. The determinations of the direction of propagation and of the velocity are generally found in good agreement.

## **A Coronal Mass Ejection Impacting Parker Solar Probe at 14 Solar Radii**

Carlos R. **Braga**<sup>1</sup>, Vamsee Krishna Jagarlamudi<sup>1</sup>, Angelos Vourlidas<sup>1</sup>, Guillermo Stenborg<sup>1</sup>, and Teresa Nieves-Chinchilla<sup>2</sup>

**2024** ApJ 965 185

<https://iopscience.iop.org/article/10.3847/1538-4357/ad2b4e/pdf>

The relationship between CME properties in the corona and their interplanetary counterparts is not well understood. Until recently, a wide spatial gap existed between the two regions, which prevented us from disentangling the spatial and temporal evolution of CMEs. NASA's Parker Solar Probe (PSP) has imaged multiple CMEs since its launch in 2018, but these events either intercepted the spacecraft far from the corona or completely missed it. Here we describe one of the first CMEs observed simultaneously by remote sensing and in situ instruments, and compare the corresponding measured properties, such as orientation, cross section diameter, density, and speed. The CME encounter occurred on **2022 June 2**, while PSP was around 14 solar radii from the Sun center. We reconstruct the CME with forward modeling and determine its morphology and kinematics. The reconstruction suggests that PSP misses the CME apex but encounters its flank. The encounter time matches the period when the PSP in situ measurements indicate the passage of a CME. We also reconstruct the flux rope diameter and orientation using the in situ magnetic field measurements. The results are consistent with the CME reconstruction from imaging data. The close agreement between remote sensing and in situ analyses suggests that discrepancies found in past studies are more likely associated with the CME temporal evolution. We also find that the magnetic field of the CME flank extrapolated to 1 au is well below the average solar wind background and likely indistinguishable from it. This point could explain past events where the CMEs' interplanetary counterparts were not identified.

## **Coronal mass ejections observed by heliospheric imagers at 0.2 and 1 au The events on April 1 and 2, 2019**

Carlos R. **Braga**<sup>1,2</sup> and Angelos Vourlidas

A&A 650, A31 (2021)

<https://arxiv.org/pdf/2011.05229.pdf>

<https://www.aanda.org/articles/aa/pdf/2021/06/aa39490-20.pdf>

<https://doi.org/10.1051/0004-6361/202039490>

**Context.** We study two coronal mass ejections (CMEs) observed between **April 1 to 2, 2019** by both the inner Wide-Field Imager for Parker Solar Probe (WISPR-I) onboard the Parker Solar Probe (PSP) spacecraft (located between about 46 and 38 solar radii during this period) and the inner heliospheric imager (HI-1) onboard the Solar Terrestrial Relations Observatory Ahead (STEREO-A) spacecraft, orbiting the Sun at about 0.96 au. This is the first study of CME observations from two viewpoints in similar directions but at considerably different solar distances.

**Aims.** Our objective is to derive CME kinematics from WISPR-I observations and to compare them with results from HI-1. This allows us to understand how the PSP observations affect the CME kinematics, especially due to its proximity to the Sun.

**Methods.** We estimated the CME positions, speeds, accelerations, propagation directions, and longitudinal deflections using imaging observations from two spacecrafts and a set of analytical expressions that consider the CME as a point structure and take the rapid change in spacecraft position into account. We derived the kinematics using each viewpoint independently and both viewpoints as a constraint.

**Results.** We found that both CMEs are slow ( $<400 \text{ km s}^{-1}$ ), propagating eastward of the Sun-Earth line (westward of PSP and STEREO-A). The second CME seems to accelerate between  $\sim 0.1$  and  $\sim 0.2$  au and deflect westward with an angular speed consistent with the solar rotation speed. We found some discrepancies in the CME solar distance (up to 0.05 au, particularly for CME #1), latitude (up to  $\sim 10^\circ$ ), and longitude (up to  $24^\circ$ ) when comparing results from different fit cases (different observations or set of free parameters).

**Conclusions.** Discrepancies in longitude are likely due to the feature that is tracked visually, rather than instrumental biases or fit assumptions. For similar reasons, the CME #1 solar distance, as derived from WISPR-I observations, is larger than the HI-1 result, regardless of the fit parameters considered. Error estimates for CME kinematics do not show any clear trend associated with the observing instrument. The source region location and the lack of any clear in situ counterparts (both at near-Earth and at PSP) support our estimate of the propagation direction for both events.

## **Very narrow coronal mass ejections producing solar energetic particles**

K. **Bronarska**<sup>1</sup>, M. S. Wheatland<sup>2</sup>, N. Gopalswamy<sup>3</sup> and G. Michalek<sup>1</sup>

A&A 619, A34 (2018)

<https://sci-hub.ru/10.1051/0004-6361/201833237>

**Aims.** Our main aim is to study the relationship between low-energy solar particles (energies below 1 MeV) and very narrow coronal mass ejections (“jets” with angular width  $\leq 20^\circ$ ).

**Methods.** For this purpose, we considered 125 very narrow coronal mass ejections (CMEs) from 1999 to 2003 that are potentially associated with low-energy solar particles (LESPs). These events were chosen on the basis of their source location. We studied only very narrow CMEs at the western limb, which are expected to have good magnetic connectivity with Earth.

**Results.** We found 24 very narrow CMEs associated with energetic particles such as ions (protons and  $3\text{He}$ ), electrons, or both. We show that arrival times at Earth of energetic particles are consistent with onset times of the respective CMEs, and that in the same time intervals, there are no other potential sources of energetic particles. We also demonstrate statistical differences for the angular width distributions using the Kolmogorov–Smirnov test for angular widths for these 24 events. We consider a coherent sample of jets (mostly originating from boundaries of coronal holes) to identify properties of events that produce solar energetic particles (velocities, widths, and position angles). Our study presents a new approach and result: very narrow CMEs can generate low-energy particles in the vicinity of Earth without other activity on the Sun. The results could be very useful for space weather forecasting. **2000/07/10, 14 December 2001**

**Table 2.** Properties of 24 very narrow CMEs generating low-energy SEPs

## **Determination of projection effects of CMEs using quadrature observations with the two STEREO spacecraft**

**K.Bronarska, G.Michalek**

[Advances in Space Research](#) Volume 62, Issue 2, 15 July 2018, Pages 408-416

<https://sci-hub.ru/10.1016/j.asr.2018.04.031>

<https://doi.org/10.1016/j.asr.2018.04.031>

Since 1995 [coronal mass ejections](#) (CMEs) have been routinely observed thanks to the sensitive Large Angle and Spectrometric Coronagraphs (LASCO) on board the Solar and Heliospheric Observatory (SOHO) mission. Their observed characteristics are stored, among other, in the SOHO/LASCO catalog. These parameters are commonly used in scientific studies. Unfortunately, coronagraphic observations of CMEs are subject to projection effects. This makes it practically impossible to determine the true properties of CMEs and therefore makes it more difficult to forecast their geoeffectiveness. In this study, using [quadrature](#) observations with the two Solar Terrestrial Relations Observatory (STEREO) spacecrafts, we estimate the projection effect affecting velocity of CMEs included in the SOHO/LASCO catalog. It was demonstrated that this effect depends significantly on width and source location of CMEs. It can be very significant for narrow events and originating from the disk center. The effect diminishes with increasing width and absolute longitude of source location of CMEs. For very wide (width  $\geq 250^\circ$ ) or limb events (longitude  $\geq 70^\circ$ ) projection effects completely disappears.

## **Visibility of coronal mass ejections in SOHO/LASCO coronagraphs**★

**K.Bronarska, G.Michalek, S.Yashiro, S.Akiyama**

[Advances in Space Research](#) Volume 60, Issue 9, 1 November 2017, Pages 2108-2115

<http://sci-hub.ru/10.1016/j.asr.2017.07.033>

We studied the detection efficiency of coronal mass ejections (CMEs) of the Large Angle Spectrometric Coronagraph (LASCO) on board the Solar and Heliospheric Observatory (SOHO). For this purpose LASCO/SOHO observations are compared with these obtained by the two Solar Terrestrial Relations Observatory (STEREO) satellites in quadrature in the period of time **June-November 2011**. These unprecedented observations enable us to the direct detection of CMEs that are not visible in LASCO coronagraphs (invisible events). Determination of these events allowed us to evaluate the detection efficiency of LASCO coronagraphs. We found that the total visibility function is  $\approx 0.80$ . Having source location, from associated flares or other signatures observed in the corona, longitudinal variation of the visibility function was also found. It was demonstrated that invisible-to-LASCO CMEs are narrow (average width is only  $20^\circ$ ), slow (average velocity is  $328 \text{ km s}^{-1}$ ) and originate from the disk center. We have shown that the detection efficiency of the LASCO coronagraphs with typical data availability is sufficient to detect all potentially geoeffective CMEs.

## **Helicity-conserving relaxation in unstable and merging magnetic flux ropes**

**Philippa Browning, Mykola Gordovskyy, Alan Hood**

**2023**

<https://arxiv.org/pdf/2308.08277.pdf>

Twisted magnetic flux ropes are reservoirs of free magnetic energy. In a highly-conducting plasma such as the solar corona, energy release through multiple magnetic reconnections can be modelled as a helicity-conserving relaxation to a minimum energy state. One possible trigger for this relaxation is the ideal kink instability in a twisted flux rope. We show that this provides a good description for confined solar flares, and develop from idealised cylindrical models to realistic models of coronal loops. Using 3D magnetohydrodynamic simulations combined with test-particle simulations of non-thermal electrons and ions, we predict multiple observational signatures of such flares. We then show how interactions and mergers of flux ropes can release free magnetic energy, using relaxation theory to complement simulations of merging-compression formation in spherical tokamaks and heating avalanches in the solar corona.

## **Empirical Model of 10-130 MeV Solar Energetic Particle Spectra at 1 AU Based on Coronal Mass Ejection Speed and Direction**

Alessandro **Bruno**, **Ian G. Richardson**

Solar Phys. **2021**

<https://arxiv.org/pdf/2101.04234.pdf> **File**

We present a new empirical model to predict solar energetic particle (SEP) event-integrated and peak intensity spectra between 10 and 130 MeV at 1 AU, based on multi-point spacecraft measurements from the Solar Terrestrial Relations Observatory (STEREO), the Geostationary Operational Environmental Satellites (GOES) and the Payload for Antimatter Matter Exploration and Light-nuclei Astrophysics (PAMELA) satellite experiment. The analyzed data sample includes 32 SEP events occurring between 2010 and 2014, with a statistically significant proton signal at energies in excess of a few tens of MeV, unambiguously recorded at three spacecraft locations. The spatial distributions of SEP intensities are reconstructed by assuming an energy-dependent 2D Gaussian functional form, and accounting for the correlation between the intensity and the speed of the parent coronal mass ejection (CME), and the magnetic field line connection angle. The CME measurements used are from the SpaceWeather Database Of Notifications, Knowledge, Information (DONKI). The model performance, including its extrapolations to lower/higher energies, is

tested by comparing with the spectra of 20 SEP events not used to derive the model parameters. Despite the simplicity of the model, the observed and predicted event-integrated and peak intensities at Earth and at the STEREO spacecraft for these events show remarkable agreement, both in the spectral shapes and their absolute values.

**Table 1.** List of CMEs associated with the SEP events analyzed in this work. (2010-2014)

**Table 4.** List of CMEs associated with the SEP events used for testing the empirical model (2011-2017)

### **Recurrent 3He-rich solar energetic particle injections observed by Solar Orbiter at ~0.5 au\***

Rodríguez-Pacheco<sup>8</sup>, R. Gómez-Herrero<sup>8</sup> and R. F. Wimmer-Schweingruber<sup>9</sup>  
A&A 673, L5 (2023)

<https://www.aanda.org/articles/aa/pdf/2023/05/aa45875-23.pdf>

We report Solar Orbiter observations of six recurrent solar energetic particle injections in **2022 March 3–6** at ~0.5 au. All but one were associated with jets emanating from a plage near a large sunspot in active region 12 957. We saw large jets in injections with high 3He and Fe enrichments and minor jets in injections with no or lower enrichments.

Furthermore, the event with the highest enrichment showed a more compact configuration of the underlying photospheric magnetic field. The higher fluences as well as harder spectra were seen in the event with a simultaneous jet and wider eruption. However, in this case, the energy buildup time in the source might be required to produce such spectra. Extreme-ultraviolet images from Solar Orbiter revealed a number of intersecting loops at the base of jets not seen from 1 au that might be a precondition for the recurrent events.

### **Impulsive Solar Energetic Particle Events: EUV Waves and Jets** MINI **REVIEW**

R. Bucik

Front. Astron. Space Sci. 8 807961 2022 File

<https://www.frontiersin.org/articles/10.3389/fspas.2021.807961/full>

<https://doi.org/10.3389/fspas.2021.807961>

<https://arxiv.org/abs/2112.14282>

Impulsive solar energetic particle (ISEP) events show peculiar elemental composition, with enhanced 3He and heavy-ion abundances, markedly different from our solar system composition. Furthermore, the events are characterized by a wide variety of energy spectral shapes from power laws to rounded spectra toward the low energies. Solar sources of the events have been firmly associated with coronal jets. Surprisingly, new observations have shown that events are often accompanied by so-called extreme-ultraviolet (EUV) coronal waves – a large-scale phenomenon compared to jets.

This paper outlines the current understanding of the linkage of EUV waves with jets and energetic ions in ISEP events.

**2007 May 23, 2008 Nov 4, 2009 Dec 22, 2010 January 26, 2010 Feb 2, 2010 Jun 12, 2011 Jan 27, 2011 Feb 18, 2014 May 16**

2018 ApJL 869 L21

[sci-hub.ru/10.3847/2041-8213/aaf37f](https://sci-hub.ru/10.3847/2041-8213/aaf37f)

<https://arxiv.org/pdf/1812.07735.pdf>

Solar sources of suprathermal (<1 MeV nucleon<sup>-1</sup>) 3He-rich solar energetic particles (SEPs) have been commonly associated with jets originating in small, compact active regions at the periphery of near-equatorial coronal holes. Sources of relatively rare, high-energy (>10 MeV nucleon<sup>-1</sup>) 3He-rich SEPs remain unexplored. Here we present two of the most intense 3He-rich (3He/4He > 1) SEP events of the current solar cycle 24 measured on the Advanced Composition Explorer at energy >10 MeV nucleon<sup>-1</sup>. Although 3He shows high intensities, Z > 2 ions are below the detection threshold. The events are accompanied by type-III radio bursts, but no type-II emission as typically seen for suprathermal 3He-rich SEPs. The corresponding solar sources were analyzed using high-resolution, extreme-ultraviolet imaging and photospheric magnetic field observations on the Solar Dynamics Observatory. We find the sources of these events associated with jets originating at the boundary of large sunspots with complex βγδ magnetic configuration. Thus, details of the underlying photospheric field apparently are important to produce 3He to high energies in the examined events. **2011 February 18, 2015 August 24**

### **3He-Rich Solar Energetic Particles in Helical Jets on the Sun**

Radoslav Bucik, Davina E. Innes, Glenn M. Mason, Mark E. Wiedenbeck, Raul Gomez-Herrero, Nariaki V. Nitta

2018 ApJ 852 76

<https://arxiv.org/pdf/1711.09394.pdf>

Particle acceleration in stellar flares is ubiquitous in the Universe, however, our Sun is the only astrophysical object where energetic particles and their source flares can both be observed. The acceleration mechanism in solar flares,

tremendously enhancing (up to a factor of ten thousand) rare elements like  $^3\text{He}$  and ultra-heavy nuclei, has been puzzling for almost 50 years. Here we present some of the most intense  $^3\text{He}$ - and Fe-rich solar energetic particle events ever reported. The events were accompanied by non-relativistic electron events and type III radio bursts. The corresponding high-resolution, extreme-ultraviolet imaging observations have revealed for the first time a helical structure in the source flare with a jet-like shape. The helical jets originated in relatively small, compact active regions, located at the coronal hole boundary. A mini-filament at the base of the jet appears to trigger these events. The events were observed with the two Solar Terrestrial Relations Observatories STEREO on the backside of the Sun, during the period of increased solar activity in 2014. The helical jets may be a distinct feature of these intense events that is related to the production of high  $^3\text{He}$  and Fe enrichments. **2014 Apr 30, 17 July 2014, 2014 Jul 19, 2014 Jul 20**

## **Magnetohydrodynamic Modeling Investigations of Kelvin–Helmholtz Instability and Associated Magnetosonic Wave Emission along Coronal Mass Ejections**

Sara **Butler**<sup>1,2,3</sup>, Weiru Chen<sup>1,4</sup>, and Hava Turkakin<sup>1,5</sup>

**2022** ApJ 935 164

<https://iopscience.iop.org/article/10.3847/1538-4357/ac7b92/pdf>

Previous studies have suggested that the Kelvin–Helmholtz instability (KHI) and magnetohydrodynamic (MHD) wave emissions via the KHI along various shear flow boundaries in a solar–terrestrial environment may be possible. We expand upon these previous studies to investigate the linear and nonlinear evolution of the KHI and emission of MHD waves along the boundaries of coronal mass ejections (CMEs). Our results demonstrate that the KHI and MHD wave emission due to the KHI are possible along the CME boundaries during the KHI development. We found that magnetic field orientation in the region outside of the CME has strong effects on the strength of MHD wave emission. While a smaller parallel component of the magnetic field resulted in larger growth rates in the KHI development, a larger parallel component of the magnetic field resulted in stronger MHD wave emissions. For all cases we investigated, we identified emitted waves to be fast MHD waves. We suggest that these emitted MHD waves may be able to carry available kinetic energy from the CME flow to the outside of the CME, thereby contributing to solar coronal heating via energy dissipation.

## **Investigating the Kinematics of Coronal Mass Ejections with the Automated CORIMP Catalog**

Jason P. **Byrne**

J. Space Weather Space Clim., 5, A19 **2015**

<http://arxiv.org/pdf/1506.04046v1.pdf>

Studying coronal mass ejections (CMEs) in coronagraph data can be challenging due to their diffuse structure and transient nature, compounded by the variations in their dynamics, morphology, and frequency of occurrence. The large amounts of data available from missions like the Solar and Heliospheric Observatory (SOHO) make manual cataloging of CMEs tedious and prone to human error, and so a robust method of detection and analysis is required and often preferred. A new coronal image processing catalog called CORIMP has been developed in an effort to achieve this, through the implementation of a dynamic background separation technique and multiscale edge detection. These algorithms together isolate and characterise CME structure in the field-of-view of the Large Angle Spectrometric Coronagraph (LASCO) onboard SOHO. CORIMP also applies a Savitzky-Golay filter, along with quadratic and linear fits, to the height-time measurements for better revealing the true CME speed and acceleration profiles across the plane-of-sky. Here we present a sample of new results from the CORIMP CME catalog, and directly compare them with the other automated catalogs of Computer Aided CME Tracking (CACTus) and Solar Eruptive Events Detection System (SEEDS), as well as the manual CME catalog at the Coordinated Data Analysis Workshop (CDAW) Data Center and a previously published study of the sample events. We further investigate a form of unsupervised machine learning by using a k-means clustering algorithm to distinguish detections of multiple CMEs that occur close together in space and time. While challenges still exist, this investigation and comparison of results demonstrates the reliability and robustness of the **CORIMP catalog** (<http://alshamess.ifa.hawaii.edu/CORIMP/>), proving its effectiveness at detecting and tracking CMEs throughout the LASCO dataset. **2000 Jan. 02, 2000 Apr. 18, 2000 Apr. 23, 2001 Apr. 23, 2002 Apr. 21, 2004 Apr. 1**

## **Bridging EUV and white-light observations to inspect the initiation phase of a "two-stage" solar eruptive event**

**Byrne**, J. P., Morgan, H., Seaton, D. B., Bain, H. M., Habbal, S. R.

E-print, June **2014**; Solar Phys.

<http://arxiv.org/pdf/1406.4919v1.pdf>

The initiation phase of CMEs is a very important aspect of solar physics, as these phenomena ultimately drive space weather in the heliosphere. This phase is known to occur between the photosphere and low corona, where many models introduce an instability and/or magnetic reconnection that triggers a CME, often with associated flaring activity. To this end, it is important to obtain a variety of observations of the low corona in order to build as clear a picture as possible of the dynamics that occur therein. Here, we combine the EUV imagery of the SWAP instrument on board PROBA2 with the white-light imagery of the ground-based Mk4 coronameter at MLSO in order to bridge the observational gap that exists between the disk imagery of AIA on board SDO and the coronal imagery of LASCO on board SOHO. Methods of multiscale image analysis were applied to the observations to better reveal the coronal signal while suppressing noise

and other features. This allowed an investigation into the initiation phase of a CME that was driven by a rising flux rope structure from a "two-stage" flaring active region underlying an extended helmet streamer. It was found that the initial outward motion of the erupting loop system in the EUV observations coincided with the first X-ray flare peak, and led to a plasma pile-up of the white-light CME core material. The characterized CME core then underwent a strong jerk in its motion, as the early acceleration increased abruptly, simultaneous with the second X-ray flare peak. The overall system expanded into the helmet streamer to become the larger CME structure observed in the LASCO coronagraph images, which later became concave-outward in shape. Theoretical models for the event are discussed in light of these unique observations, and it is concluded that the formation of either a kink-unstable or torus-unstable flux rope may be the likeliest scenario. **8 March 2011**

## **Improved methods for determining the kinematics of coronal mass ejections and coronal waves**

J. P. **Byrne**, D. M. Long, P. T. Gallagher, D. S. Bloomfield, S. A. Maloney, R. T. J. McAteer, H. Morgan, S. R. Habbal

E-print, July **2013**; A&A 557, A102 (2013)

<http://arxiv.org/pdf/1307.8155v1.pdf>

**Context:** The study of solar eruptive events and associated phenomena is of great importance in the context of solar and heliophysics. Coronal mass ejections (CMEs) and coronal waves are energetic manifestations of the restructuring of the solar magnetic field and mass motion of the plasma. Characterising this motion is vital for deriving the dynamics of these events and thus understanding the physics driving their initiation and propagation. The development and use of appropriate methods for measuring event kinematics is therefore imperative.

**Aims:** Traditional approaches to the study of CME and coronal wave kinematics do not return wholly accurate nor robust estimates of the true event kinematics and associated uncertainties. We highlight the drawbacks of these approaches, and demonstrate improved methods for accurate and reliable determination of the kinematics.

**Methods:** The Savitzky-Golay filter is demonstrated as a more appropriate fitting technique for CME and coronal wave studies, and a residual resampling bootstrap technique is demonstrated as a statistically rigorous method for the determination of kinematic error estimates and goodness-of-fit tests.

**Results:** It is shown that the scatter on distance-time measurements of small sample size can significantly limit the ability to derive accurate and reliable kinematics. This may be overcome by (i) increasing measurement precision and sampling cadence, and (ii) applying robust methods for deriving the kinematics and reliably determining their associated uncertainties. If a priori knowledge exists and a pre-determined model form for the kinematics is available (or indeed any justified fitting-form to be tested against the data), then its precision can be examined using a bootstrapping technique to determine the confidence interval associated with the model/fitting parameters.

**Conclusions:** Improved methods for determining the kinematics of CMEs and coronal waves are demonstrated to great effect, overcoming many issues highlighted in traditional numerical differencing and error propagation techniques.

## **AUTOMATIC DETECTION AND TRACKING OF CORONAL MASS EJECTIONS. II. MULTISCALE FILTERING OF CORONAGRAPH IMAGES**

Jason P. **Byrne**<sup>1</sup>, Huw Morgan<sup>1,2</sup>, Shadia R. Habbal<sup>1</sup>, and Peter T. Gallagher

**2012 ApJ 752 145, File**

Studying coronal mass ejections (CMEs) in coronagraph data can be challenging due to their diffuse structure and transient nature, and user-specific biases may be introduced through visual inspection of the images. The large amount of data available from the Solar and Heliospheric Observatory (SOHO), Solar TERrestrial RELations Observatory (STEREO), and future coronagraph missions also makes manual cataloging of CMEs tedious, and so a robust method of detection and analysis is required. This has led to the development of automated CME detection and cataloging packages such as CACTus, SEEDS, and ARTEMIS. Here, we present the development of a new CORIMP (coronal image processing) CME detection and tracking technique that overcomes many of the drawbacks of current catalogs. It works by first employing the dynamic CME separation technique outlined in a companion paper, and then characterizing CME structure via a multiscale edge-detection algorithm. The detections are chained through time to determine the CME kinematics and morphological changes as it propagates across the plane of sky. The effectiveness of the method is demonstrated by its application to a selection of SOHO/LASCO and STEREO/SECCHI images, as well as to synthetic coronagraph images created from a model corona with a variety of CMEs. The algorithms described in this article are being applied to the whole LASCO and SECCHI data sets, and a catalog of results will soon be available to the public.

## **The Kinematics and Morphology of Solar Coronal Mass Ejections**

**Review**

J. P. **Byrne**

A thesis, **2012, File**

In this thesis the implementation of multiscale image processing techniques to identify and track the CME front through coronagraph images is detailed. An ellipse characterisation of the CME front is used to determine the CME kinematics and morphology with increased precision as compared to techniques used in current CME catalogues, and e\_orts are underway to automate this procedure for applying to a large number of CME observations for future analysis. It was found that CMEs do not simply undergo constant acceleration, but rather tend to show a higher acceleration early in

their propagation. The angular width of CMEs was also found to change as they propagate, normally increasing with height from the Sun. However these results were derived from plane-of-sky measurements with no correction for how the true CME geometry and direction affect the kinematics and morphology observed. With the advent of the unique dual perspectives of the STEREO spacecraft, the multiscale methods were extended to an elliptical tiepointing technique in order to reconstruct the front of a CME in three dimensions. Applying this technique to the Earth-directed CME of 12 December 2008 allowed an accurate determination of its true kinematics and morphology, and the CME was found to undergo early acceleration, non-radial motion, angular width expansion, and aerodynamic drag in the solar wind as it propagated towards Earth. This study and its conclusions are of vital importance to the fields of space weather monitoring and forecasting.

## The kinematics of coronal mass ejections using multiscale methods

J. P. **Byrne**, P. T. Gallagher<sup>1</sup>, R. T. J. McAteer<sup>1</sup>, and C. A. Young<sup>2</sup>

A&A 495, 325–334 (2009), DOI: [10.1051/0004-6361:200809811](https://doi.org/10.1051/0004-6361:200809811); **File**

<https://sci-hub.ru/10.1051/0004-6361:200809811>

**Aims.** The diffuse morphology and transient nature of coronal mass ejections (CMEs) make them difficult to identify and track using traditional image processing techniques. We apply multiscale methods to enhance the visibility of the faint CME front. This enables an ellipse characterisation to objectively study the changing morphology and kinematics of a sample of events imaged by the Large Angle Spectrometric Coronagraph (LASCO) onboard the Solar and Heliospheric Observatory (SOHO) and the Sun Earth Connection Coronal and Heliospheric Investigation (SECCHI) onboard the Solar Terrestrial Relations Observatory (STEREO). The accuracy of these methods allows us to test the CMEs for non-constant acceleration and expansion.

**Methods.** We exploit the multiscale nature of CMEs to extract structure with a multiscale decomposition, akin to a Canny edge detector. Spatio-temporal filtering highlights the CME front as it propagates in time. We apply an ellipse parameterisation of the front to extract the kinematics (height, velocity, acceleration) and changing morphology (width, orientation).

**Results.** The kinematic evolution of the CMEs discussed in this paper have been shown to differ from existing catalogues. These catalogues are based upon running-difference techniques that can lead to over-estimating CME heights. Our resulting kinematic curves are not well-fitted with the constant acceleration model. It is shown that some events have high acceleration below  $\sim 5 R_{\odot}$ . Furthermore, we find that the CME angular widths measured by these catalogues are over-estimated, and indeed for some events our analysis shows non-constant CME expansion across the plane-of-sky.

## First Simultaneous Views of the Axial and Lateral Perspectives of a Coronal Mass Ejection

I. **Cabello**, H. Cremades, L. Balmaceda, I. Dohmen

Solar Phys. Volume 291, [Issue 6](#), pp 1799-1817 **2016**

**File**

<http://arxiv.org/pdf/1607.07001v1.pdf>

The different appearances exhibited by coronal mass ejections (CMEs) are believed to be in part the result of different orientations of their main axis of symmetry, consistent with a flux-rope configuration. There are observational reports of CMEs seen along their main axis (axial perspective) and perpendicular to it (lateral perspective), but no simultaneous observations of both perspectives from the same CME have been reported to date. The stereoscopic views of the telescopes onboard the Solar-Terrestrial Relations Observatory (STEREO) twin spacecraft, in combination with the views from the Solar and Heliospheric Observatory (SOHO) and the Solar Dynamics Observatory (SDO), allow us to study the axial and lateral perspectives of a CME simultaneously for the first time. In addition, this study shows that the lateral angular extent ( $L$ ) increases linearly with time, while the angular extent of the axial perspective ( $D$ ) presents this behavior only from the low corona to  $\approx 5 R_{\odot}$ , where it slows down. The ratio  $L/D \approx 1.6$  obtained here as the average over several points in time is consistent with measurements of  $L$  and  $D$  previously performed on events exhibiting only one of the perspectives from the single vantage point provided by SOHO. **15 February 2011, 8 March 2011, 5 March 2013, 28 March 2013**

## A fast-filament eruption observed in the $H\alpha$ spectral line. I. Imaging spectroscopy diagnostic

**Denis P. Cabezas**, [Kiyoshi Ichimoto](#), [Ayumi Asai](#), [Satoru UeNo](#), [Satoshi Morita](#), [Ken-ichi Otsuji](#), [Kazunari Shibata](#)

A&A 690, A172 **2024**

<https://arxiv.org/pdf/2406.20020>

**Context.** Solar filament eruptions usually appear to occur in association with the sudden explosive release of magnetic energy accumulated in long-lived arched magnetic structures. It is the released energy that occasionally drives fast-filament eruptions that can be source regions of coronal mass ejections. **Aim.** The goal of this paper is to investigate the dynamic processes of a fast-filament eruption by using unprecedented high-resolution full-disk  $H\alpha$  imaging spectroscopy observations. **Methods.** The whole process of the eruption was captured in a wide spectral window of the  $H\alpha$  line ( $\pm 9.0 \text{ \AA}$ ). Applying the "cloud model" and obtaining two dimensional optical thickness spectra we derive the Doppler velocity, the true eruption profiles (height, velocity, and acceleration), and the trajectory of the filament eruption in 3D space. **Results.** The Doppler velocity maps show that the filament was predominantly blue-shifted. During the main and final process of the eruption, strongly blue-shifted materials are manifested traveling with velocities exceeding 250 km/s. The spectral analysis further revealed that the erupting filament is made of multiple components, some of which were Doppler-shifted approximately to  $-300 \text{ km/s}$ . It is found that the filament eruption attains a maximum true velocity and acceleration of about 600 km/s and  $2.5 \text{ km/s}^2$ , respectively, and its propagation direction deviates from the radial direction. On the other hand, downflows manifested as red-shifted plasma close to the

footpoints of the erupting filament move with velocities 45–125 km/s. We interpret these red-shifted signatures as draining material, and therefore mass loss of the filament that has implications for the dynamic and the acceleration process of the eruption. Furthermore, we have estimated the total mass of the H $\alpha$  filament resulting in  $\sim 5.4 \times 10^{15}$ g.

ApJ **2017**

<https://arxiv.org/pdf/1701.00308v1.pdf>

Coronal disturbances associated with solar flares, such as H $\alpha$  Moreton waves, X-ray waves, and extreme ultraviolet (EUV) coronal waves are discussed herein in relation to magnetohydrodynamics fast-mode waves or shocks in the corona. To understand the mechanism of coronal disturbances, full-disk solar observations with high spatial and temporal resolution over multiple wavelengths are of crucial importance. We observed a filament eruption, whose shape is like a "dandelion", associated with the M1.6 flare that occurred on **2011 February 16** in the H $\alpha$  images taken by the Flare Monitoring Telescope at Ica University, Peru. We derive the three-dimensional velocity field of the erupting filament. We also identify winking filaments that are located far from the flare site in the H $\alpha$  images, whereas no Moreton wave is observed. By comparing the temporal evolution of the winking filaments with those of the coronal wave seen in the extreme ultraviolet images data taken by the Atmospheric Imaging Assembly on board the *Solar Dynamics Observatory* and by the Extreme Ultraviolet Imager on board the *Solar Terrestrial Relations Observatory-Ahead*, we confirm that the winking filaments were activated by the EUV coronal wave.

### **Observational study of intermittent solar jets: p-mode modulation**

[Qiuzhuo Cai](#), [Guiping Ruan](#), [Chenxi Zheng](#), [Brigitte Schmieder](#), [Jinhan Guo](#), [Yao Chen](#), [Jiangtao Su](#), [Yang Liu](#), [Jihong Liu](#), [Wenda Cao](#)

A&A 682, A183 (2024)

<https://arxiv.org/pdf/2312.03571.pdf>

<https://www.aanda.org/articles/aa/pdf/2024/02/aa48053-23.pdf>

Aims. Recurring jets are observed in the solar atmosphere, which can erupt intermittently. By the observation of intermittent jets, we want to understand the causes of periodic eruption characteristics. Methods. We report intermittent jets observed by the GST. The analysis was aided by 1400 Å and 2796 Å data from IRIS. These observational instruments allowed us to analyze the temporal characteristics of jet events. Results. The jet continued for up to 4 hours. The time distance diagram shows that the peak of the jet has obviously periodic eruption characteristics (5 minutes) during 18:00 UT–18:50 UT. We also found periodic brightening phenomenon (5 minutes) during jets bursts in the observed bands in the Transition Region (1400 Å and 2796 Å), which may be a response to intermittent jets in the upper solar atmosphere. The time lag is 3 minutes. Evolutionary images in the TiO band revealed the horizontal movement of granulation at the location of jet. Compared to the quiet region of the Sun, we found that the footpoint of the jet is enhanced at the center of the H  $\alpha$  spectral line profile, with no significant changes in the line wings. This suggests the presence of prolonged heating at the footpoint of the jet. In the mixed-polarity magnetic field region of the jet, we observed magnetic flux emergence, cancellation, and shear indicating possible intermittent magnetic reconnection. That is confirmed by the NLFFF model reconstructed using the magneto-friction method. Conclusions. The multi-wavelength analysis indicates that the events we studied were triggered by magnetic reconnection caused by mixed-polarity magnetic fields. We suggest that the horizontal motion of the granulation in the photosphere drives the magnetic reconnection, which is modulated by p-mode oscillations. **August 6, 2016,**

### **Multiband Study of a Bidirectional Jet Occurred in the Upper Chromosphere**

Qiangwei Cai, [Chengcai Shen](#), [Lei Ni](#), [Katharine K. Reeves](#), [Kaifeng Kang](#), [Jun Lin](#)

JGR Volume 124, Issue 12 December 2019 Pages 9824–9846

<https://agupubs.onlinelibrary.wiley.com/doi/pdf/10.1029/2019JA027017>

<https://sci-hub.ru/10.1029/2019JA027017>

We present a study of a jet observed by the Solar Dynamics Observatory (SDO) and the Interface Region Imaging Spectrograph (IRIS), which provide high spatial-temporal resolution observational data of (extreme) ultraviolet images, spectra, and magnetograms. The jet was observed in multiple bands of AIA and manifested clear bidirectional flows in IRIS observations. The emission profiles of the Si IV 1402 Å line of the jet exhibited non-Gaussian features and double-peaked spectra, with the Doppler velocity and the nonthermal velocity up to 100 and 160 km s<sup>-1</sup>, respectively. The plasma flows of the jet projected on the sky plane and in the line of sight (LOS) are the typical observational evidence of magnetic reconnection. The EM loci curves indicated that the plasma contains multi-temperature components. The result deduced from the DEM method and changes in intensity of several spectral lines imply that the temperature of the plasma in the jet is heated to at least 10<sup>5.6</sup> K. The electron density is about 10<sup>11</sup> cm<sup>-3</sup> according to the intensity ratios of the O IV 1399.77/1401.16 Å doublet and Si IV 1402.77/O IV 1401.16 Å lines. Via different approaches, we reached the conclusion that the jet occurred in the upper chromosphere. Investigating the magnetograms

in the period when the jet appeared, we suggest that the jet results from the magnetic reconnection between the moving magnetic structure and the magnetic field nearby. **12 August 2014**

<https://link.springer.com/content/pdf/10.1007/s11207-020-1591-7.pdf>

Solar energetic particles (SEPs) are an important product of solar activity. They are connected to solar active regions and flares, coronal mass ejections (CMEs), EUV waves, shocks, Type II and III radio emissions, and X-ray bursts. These phenomena are major probes of the partition of energy in solar eruptions, as well as for the organization, dynamics, and relaxation of coronal and interplanetary magnetic fields. Many of these phenomena cause terrestrial space weather, posing multiple hazards for humans and their technology from space to the ground. Since particular flares, shocks, CMEs, and EUV waves produce SEP events but others do not, since propagation effects from the low corona to 1 AU appear important for some events but not others, and since Type II and III radio emissions and X-ray bursts are sometimes produced by energetic particles leaving these acceleration sites, it is necessary to study the whole system with a multi-frequency and multi-instrument perspective that combines both in-situ and remote observations with detailed modelling of phenomena. This article demonstrates this comprehensive approach, and shows its necessity, by analysing a trio of unusual and striking solar eruptions, radio and X-ray bursts, and SEP events that occurred on **4 November 2015**. These events show both strong similarities and differences from standard events and each other, despite having very similar interplanetary conditions and only two are sites and CME genesis regions. They are therefore major targets for further in-depth observational studies, and for testing both existing and new theories and models. Based on the very limited modelling available we identify the aspects that are and are not understood, and we discuss ideas that may lead to improved understanding of the SEP, radio, and space-weather events.

### **YOHKOH SXT FULL-RESOLUTION OBSERVATIONS OF SIGMOIDS: STRUCTURE, FORMATION, AND ERUPTION**

Richard C. [Canfield](#),<sup>1</sup> Maria D. Kazachenko,<sup>1</sup> Loren W. Acton,<sup>1</sup> D. H. Mackay,<sup>2</sup> Ji Son,<sup>3</sup> and Tanya L. Freeman<sup>4</sup>

The Astrophysical Journal, 671: L81–L84, 2007

<http://www.journals.uchicago.edu/doi/pdf/10.1086/524729>

We study the structure of 107 bright sigmoids using full-resolution (2.5\_ pixels) images from the *Yohkoh* Soft X-Ray Telescope (SXT) obtained between 1991 December and 2001 December. We find that none of these sigmoids are made of single loops of S or inverse-S shape; all comprise a pattern of multiple loops. We also find that all S-shaped sigmoids are made of right-bearing loops and all inverse-S-shaped sigmoids of left-bearing loops, without exception. We co-align the SXT images with Kitt Peak magnetograms to determine the magnetic field directions in each sigmoid. We use a potential-field source surface model to determine the direction of the overlying magnetic field. We find that sigmoids for which the relative orientation of these two fields has a parallel component outnumber antiparallel ones by more than an order of magnitude. We find that the number of sigmoids per active region varies with the solar cycle in a manner that is consistent with this finding. Finally, those few sigmoids that are antiparallel erupt roughly twice as often as those that are parallel. We briefly discuss the implications of these results in terms of formation and eruption mechanisms of flux tubes and sigmoids.

### **EVIDENCE FOR A PRE-ERUPTIVE TWISTED FLUX ROPE USING THE THEMIS VECTOR MAGNETOGRAPH**

A. [Canou](#), T. Amari, V. Bommier, B. Schmieder, G. Aulanier, and H. Li

ApJ 693 L27-L30, **2009**

<http://www.iop.org/EJ/abstract/1538-4357/693/1/L27>

Although there is evidence that twisted structures form during large-scale eruptive events, it is not yet clear whether these exist in the pre-eruptive phase as twisted flux ropes (TFRs) in equilibrium. This question has become a major issue since several theoretical mechanisms can lead to the formation of TFRs. These models consider either the evolution of a coronal configuration driven by photospheric changes or the emergence of TFR from the convection zone. We consider as a target for addressing this issue the active region NOAA AR 10808 known at the origin of several large-scale eruptive phenomena, and associated with the emergence of a  $\delta$ -spot. Using the THEMIS vector magnetogram as photospheric boundary conditions for our nonlinear force-free reconstruction model of the low corona and without any other assumption, we show that the resulting pre-eruptive configuration exhibits a TFR above the neutral line of the emerging  $\delta$ -spot. In addition, the free magnetic energy of this configuration could even be large enough to explain such resulting large-scale eruptive events. **2005 September 13**

## The Deflection of the Cartwheel CME: ForeCAT Results

Luisa [Capannolo](#)<sup>1</sup>, Merav Opher<sup>1</sup>, Christina Kay<sup>2</sup>, and Enrico Landi<sup>3</sup>

2017 ApJ 839 37 DOI 10.3847/1538-4357/aa6a16

<http://iopscience.iop.org/sci-hub.cc/0004-637X/839/1/37/>

[sci-hub.ru/10.3847/1538-4357/aa6a16](http://sci-hub.ru/10.3847/1538-4357/aa6a16)

We analyze the Cartwheel coronal mass ejection's (CME; **2008 April 9**) trajectory in the low corona with the ForeCAT model. This complex event presented a significant rotation in the low corona and a reversal in its original latitude direction. We successfully reproduce the observed CME's trajectory (latitude and longitude deflection) and speed. Through a test, we are able to constrain the CME's mass to  $(2.3-3.0) \times 10^{14}$  g and the CME's initial shape. We are able to constrain the expansion of the CME as well: the angular width linearly increases until  $2.1^\circ$ , and is constant afterward. In order to match the observed latitude, we include a non-radial initial speed of  $-42 \text{ km s}^{-1}$ . Despite allowing the CME to rotate in the model, the magnetic forces of the solar background are not able to reproduce the observed rotation. We suggest that the complex reversal in latitude and the significant rotation of the Cartwheel CME can be justified with an asymmetrical reconnection event that ejected the CME non-radially and also initiated its rotation.

## Internal magnetic field structures observed by PSP/WISPR in a filament related coronal mass ejection

[G.M. Cappello](#), [M. Temmer](#), [A. Vourlidis](#), [C. Braga](#), [P.C. Liewer](#), [J. Qiu](#), [G. Stenborg](#), [A. Kouloumvakos](#), [A.M. Veronig](#), [V. Bothmer](#)

A&A 688, A162 2024

<https://arxiv.org/pdf/2402.14682.pdf>

<https://www.aanda.org/articles/aa/pdf/2024/08/aa49613-24.pdf>

We track and investigate from white-light data taken with the Wide-field Instrument for Solar PRobe (WISPR) aboard Parker Solar Probe (PSP), localized density enhancements, reflecting small-scale magnetic structures belonging to a filament-related coronal mass ejection (CME). We aim to investigate the 3D location, morphology, and evolution of the internal magnetic fine structures of CMEs. Specifically, we ask: what is their relationship with the filament/source region and the flux rope? The fast tangential motion of the PSP spacecraft during its perihelion permits viewing the same event from multiple angles in short times relative to the event's evolution. Hence, we can derive the three-dimensional information of selected CME features from a single spacecraft using triangulation techniques. We group small-scale structures with roughly similar speeds, longitude and latitude, into three distinct morphological groups. We find twisted magnetic field patterns close to the eastern leg of the CME that may be related to 'horns' outlining the edges of the flux-rope cavity. Aligned thread-like bundles are identified close to the western leg. They may be related to confined density enhancements evolving during the filament eruption. High density blob-like features (magnetic islands) are widely spread in longitude ( $\sim 40^\circ$ ) close to the flanks and rear part of the CME. We demonstrate that CME flux ropes may comprise different morphological groups with a cluster behavior, apart from the blobs which instead span a wide range of longitudes. This may hint either to the three-dimensionality of the post-CME current sheet (CS) or to the influence of the ambient corona in the evolutionary behavior of the CS. Importantly, we show that the global appearance of the CME can be very different in WISPR (0.11--0.16 AU) and instruments near 1 AU because of shorter line-of-sight integration of WISPR. **8 Dec 2022**

## Unveiling the journey of a highly inclined CME

### Insights from the **March 13, 2012**, event with $110^\circ$ longitudinal separation

<https://doi.org/10.1051/0004-6361/202347083>

<https://arxiv.org/pdf/2401.17501.pdf>

<https://www.aanda.org/articles/aa/pdf/2024/04/aa47083-23.pdf>

Context. A fast ( $\sim 2000 \text{ km s}^{-1}$ ) and wide ( $> 110^\circ$ ) coronal mass ejection (CME) erupted from the Sun on **March 13, 2012**. Its interplanetary counterpart was detected in situ two days later by STEREO-A and near-Earth spacecraft, such as ACE, Wind, and Cluster. We suggest that at 1 au the CME extended at least  $110^\circ$  in longitude, with Earth crossing its east flank and STEREO-A crossing its west flank. Despite their separation, measurements from both positions showed very similar in situ CME signatures. The solar source region where the CME erupted was surrounded by three coronal holes (CHs). Their locations with respect to the CME launch site were east (negative polarity), southwest (positive polarity) and west (positive polarity). The solar magnetic field polarity of the area covered by each CH matches that observed at 1 au in situ. Suprathermal electrons at each location showed mixed signatures with only some intervals presenting clear counterstreaming flows as the CME transits both locations. The strahl population coming from the shortest magnetic connection of the structure to the Sun showed more intensity.

Aims. The aim of this work is to understand the propagation and evolution of the CME and its interaction with the surrounding CHs, to explain the similarities and differences between the observations at each spacecraft, and report what one of the most longitudinal expanded CME structures measured in situ would be.

Methods. Known properties of the large-scale structures from a variety of catalogues and previous studies were used to have a better overview of this particular event. In addition, multipoint observations were used to reconstruct the 3D geometry of the CME and determine the context of the solar and heliospheric conditions before the CME eruption and

during its propagation. The graduated cylindrical shell model (GCS) was used to reproduce the orientation, size and speed of the structure with a simple geometry. Also, the Drag-Based Model (DBM) was utilised to understand the conditions of the interplanetary medium better in terms of the drag undergone by the structure while propagating in different directions. Finally, a comparative analysis of the different regions of the structure through the different observatories was carried out in order to directly compare the in situ plasma and magnetic field properties at each location.

Results. The study presents important findings regarding the in situ measured CME on March 15, 2012, detected at a longitudinal separation of  $110^\circ$  in the ecliptic plane despite its initial inclination being around  $45^\circ$  when erupted (March 13). This suggests that the CME may have deformed and/or rotated, allowing it to be observed near its legs with spacecraft at a separation angle greater than  $100^\circ$ . The CME structure interacted with high-speed streams generated by the surrounding CHs. The piled-up plasma in the sheath region exhibited an unexpected correlation in magnetic field strength despite the large separation in longitude. In situ observations reveal that at both locations there was a flank encounter – where the spacecraft crossed the first part of the CME – then encountered ambient solar wind, and finally passed near the legs of the structure.

Conclusions. A scenario covering all evidence is proposed for both locations with a general view of the whole structure and solar wind conditions. Also, the study shows the necessity of having multipoint observations of large-scale structures in the heliosphere.

## Radio Observations of Coronal Mass Ejection Initiation and Development in the Low Solar Corona Review

[Eoin P. Carley](#), [Nicole Vilmer](#) and [Angelos Vourlidas](#)

Front. Astron. Space Sci. 7:551558. 2020 File

<https://www.frontiersin.org/articles/10.3389/fspas.2020.551558/full>

<https://sci-hub.ru/https://www.frontiersin.org/articles/10.3389/fspas.2020.551558/full>

Coronal mass ejections (CMEs) are large eruptions of plasma and magnetic field from the low solar corona into the heliosphere. These eruptions are often associated with energetic electrons that produce various kinds of radio emission. However, there is ongoing investigation into exactly where, when, and how the electron acceleration occurs during flaring and eruption, and how the associated radio emission can be exploited as a diagnostic of both particle acceleration and CME eruptive physics. Here, we review past and present developments in radio observations of flaring and eruption, from the destabilization of flux ropes to the development of a CME and the eventual driving of shocks in the corona. We concentrate primarily on the progress made in CME radio physics in the past two decades and show how radio imaging spectroscopy provides the ability to diagnose the locations and kinds of electron acceleration during eruption, which provides insight into CME eruptive models in the early stages of their evolution ( $\ll 10 R_\odot$ ). We finally discuss how new instrumentation in the radio domain will pave the way for a deeper understanding of CME physics in the near future. 20 Apr 1998, 2011-01-27, 2014-03-18, 2014-09-01, 2015 May 9, 2017 September 10

## Estimation of a Coronal Mass Ejection Magnetic Field Strength using Radio Observations of Gyrosynchrotron Radiation

[Eoin P. Carley](#), [Nicole Vilmer](#), [Paulo J. A. Simões](#), [Brían Ó Ferraigh](#)

A&A 608, A137 2017

<https://arxiv.org/pdf/1709.05184.pdf>

Coronal mass ejections (CMEs) are large eruptions of plasma and magnetic field from the low solar corona into interplanetary space. These eruptions are often associated with the acceleration of energetic electrons which produce various sources of high intensity plasma emission. In relatively rare cases, the energetic electrons may also produce gyrosynchrotron emission from within the CME itself, allowing for a diagnostic of the CME magnetic field strength. Such a magnetic field diagnostic is important for evaluating the total magnetic energy content of the CME, which is ultimately what drives the eruption. Here we report on an unusually large source of gyrosynchrotron radiation in the form of a type IV radio burst associated with a CME occurring on **2014-September-01**, observed using instrumentation from the Nan\c{c}ay Radio Astronomy Facility. A combination of spectral flux density measurements from the Nan\c{c}ay instruments and the Radio Solar Telescope Network (RSTN) from 300MHz to 5 GHz reveals a gyrosynchrotron spectrum with a peak flux density at  $>1$  GHz. Using this radio analysis, a model for gyrosynchrotron radiation, a non-thermal electron density diagnostic using the Fermi Gamma Ray Burst Monitor (GBM) and images of the eruption from the GOES Soft X-ray Imager (SXI), we are able to calculate both the magnetic field strength and the properties of the X-ray and radio emitting energetic electrons within the CME. We find the radio emission is produced by non-thermal electrons of energies  $>1$ MeV with a spectral index of  $\delta \sim 3$  in a CME magnetic field of 4.4 G at a height of  $1.3 R_\odot$ , while the X-ray emission is produced from a similar distribution of electrons but with much lower energies on the order of 10 keV. We conclude by comparing X-ray and radio-emitting electron distributions and how such an analysis can be used to define the plasma properties of a CME.

## Radio Diagnostics of electron acceleration sites during the eruption of a flux rope in the solar corona

[Eoin Carley](#)\*<sup>1,2</sup>, [Nicole Vilmer](#)<sup>3</sup>, and [Peter Gallagher](#)<sup>2</sup>

2016

<http://arxiv.org/pdf/1609.01463v1.pdf>

Electron acceleration in the solar corona is often associated with flares and the eruption of twisted magnetic structures known as flux ropes. However, the locations and mechanisms of such particle acceleration during the flare and eruption are still subject to much investigation. Observing the exact sites of particle acceleration can help confirm how the flare and eruption are initiated and how they evolve. Here we use the Atmospheric Imaging Assembly to analyse a flare and erupting flux rope on **2014-April-18**, while observations from the Nancay Radio Astronomy Facility allows us to diagnose the sites of electron acceleration during the eruption. Our analysis shows evidence for a pre-formed flux rope which slowly rises and becomes destabilised at the time of a C-class flare, plasma jet and the escape of  $>75$  keV electrons from rope center into the corona. As the eruption proceeds, continued acceleration of electrons with energies of  $\sim 5$  keV occurs above the flux rope for a period over 5 minutes. At flare peak, one site of electron acceleration is located close to the flare site while another is driven by the erupting flux rope into the corona at speeds of up to 400 km/s. Energetic electrons then fill the erupting volume, eventually allowing the flux rope legs to be clearly imaged from radio sources at 150-445MHz. Following the analysis of Joshi et al. (2015), we conclude that the sites of energetic electrons are consistent with flux rope eruption via a tether-cutting or flux cancellation scenario inside a magnetic fan-spine structure. In total, our radio observations allow us to better understand the evolution of a flux rope eruption and its associated electron acceleration sites, from eruption initiation to propagation into the corona.

### **Quasiperiodic acceleration of electrons by a plasmoid-driven shock in the solar atmosphere**

Eoin P. **Carley**, David M. Long, Jason P. Byrne, Pietro Zucca, D. Shaun Bloomfield, Joseph McCauley and Peter T. Gallagher

E-print, Oct **2013**; Nature Physics (**2013**) doi:10.1038/nphys2767

<https://sci-hub.ru/10.1038/nphys2767>

Cosmic rays and solar energetic particles may be accelerated to relativistic energies by shock waves in astrophysical plasmas. On the Sun, shocks and particle acceleration are often associated with the eruption of magnetized plasmoids, called coronal mass ejections (CMEs). However, the physical relationship between CMEs and shock particle acceleration is not well understood. Here, we use extreme ultraviolet, radio and white-light imaging of a solar eruptive event on **22 September 2011** to show that a CME-induced shock (Alfvén Mach number  $2.4^{+0.7}_{-0.8}$ ) was coincident with a coronal wave and an intense metric radio burst generated by intermittent acceleration of electrons to kinetic energies of  $2\text{--}46$  keV ( $0.1\text{--}0.4c$ ). Our observations show that plasmoid-driven quasiperpendicular shocks are capable of producing quasiperiodic acceleration of electrons, an effect consistent with a turbulent or rippled plasma shock surface.

### **Coronal Mass Ejection Mass, Energy, and Force Estimates Using STEREO**

Eoin P. **Carley**, R.T. James McAteer, Peter T. Gallagher

E-print, Apr **2012**, **2012 ApJ** 752 36, **File**

Understanding coronal mass ejection (CME) energetics and dynamics has been a long-standing problem, and although previous observational estimates have been made, such studies have been hindered by large uncertainties in CME mass. Here, the two vantage points of the Solar Terrestrial Relations Observatory (STEREO) COR1 and COR2 coronagraphs were used to accurately estimate the mass of the **2008 December 12** CME. Acceleration estimates derived from the position of the CME front in 3-D were combined with the mass estimates to calculate the magnitude of the kinetic energy and driving force at different stages of the CME evolution. The CME asymptotically approaches a mass of  $3.4^{+1.0}_{-1.0} \times 10^{15}$  g beyond  $\sim 10 R_{\text{sun}}$ . The kinetic energy shows an initial rise towards  $6.3^{+3.7}_{-3.7} \times 10^{29}$  erg at  $\sim 3 R_{\text{sun}}$ , beyond which it rises steadily to  $4.2^{+2.5}_{-2.5} \times 10^{30}$  erg at  $\sim 18 R_{\text{sun}}$ . The dynamics are described by an early phase of strong acceleration, dominated by a force of peak magnitude of  $3.4^{+2.2}_{-2.2} \times 10^{14}$  N at  $\sim 3 R_{\text{sun}}$ , after which a force of  $3.8^{+5.4}_{-5.4} \times 10^{13}$  N takes affect between  $\sim 7\text{--}18 R_{\text{sun}}$ . These results are consistent with magnetic (Lorentz) forces acting at heliocentric distances of  $<7 R_{\text{sun}}$ , while solar wind drag forces dominate at larger distances ( $>7 R_{\text{sun}}$ ).

### **Investigating the Dynamics and Density Evolution of Returning Plasma Blobs from the **2011 June 7** Eruption**

Jack **Carlyle**<sup>1,2</sup>, David R. Williams<sup>1</sup>, Lidia van Driel-Gesztelyi<sup>1,3,4</sup>, Davina Innes<sup>2</sup>, Andrew Hillier<sup>5</sup>, and Sarah Matthew

**2014 ApJ** 782 87

This work examines in-falling matter following an enormous coronal mass ejection on **2011 June 7**. The material formed discrete concentrations, or blobs, in the corona and fell back to the surface, appearing as dark clouds against the bright corona. In this work we examined the density and dynamic evolution of these blobs in order to formally assess the intriguing morphology displayed throughout their descent. The blobs were studied in five wavelengths (94, 131, 171, 193, and 211 Å) using the Solar Dynamics Observatory Atmospheric Imaging Assembly, comparing background emission to attenuated emission as a function of wavelength to calculate column densities across the descent of four separate blobs. We found the material to have a column density of hydrogen of approximately  $2 \times 10^{19} \text{ cm}^{-2}$ , which is comparable with typical pre-eruption filament column densities. Repeated splitting of the returning material is seen in a

manner consistent with the Rayleigh-Taylor instability. Furthermore, the observed distribution of density and its evolution is also a signature of this instability. By approximating the three-dimensional geometry (with data from STEREO-A), volumetric densities were found to be approximately  $2 \times 10^{-14}$  g cm<sup>-3</sup>, and this, along with observed dominant length scales of the instability, was used to infer a magnetic field of the order 1 G associated with the descending blobs.

### **Magnetic Energy Powers the Corona: How We Can Understand its 3D Storage & Release**

[Amir Caspi](#), [Daniel B. Seaton](#), [Roberto Casini](#), [Cooper Downs](#), [Sarah E. Gibson](#), [Holly Gilbert](#), [Lindsay Glesener](#), [Silvina E. Guidoni](#), [J. Marcus Hughes](#), [David McKenzie](#), [Joseph Plowman](#), [Katharine K. Reeves](#), [Pascal Saint-Hilaire](#), [Albert Y. Shih](#), [Matthew J. West](#)

White paper to the Decadal Survey for Solar and Space Physics (Heliophysics) 2024-2033 **2023**

<https://arxiv.org/pdf/2305.17146.pdf>

The coronal magnetic field is the prime driver behind many as-yet unsolved mysteries: solar eruptions, coronal heating, and the solar wind, to name a few. It is, however, still poorly observed and understood. We highlight key questions related to magnetic energy storage, release, and transport in the solar corona, and their relationship to these important problems. We advocate for new and multi-point co-optimized measurements, sensitive to magnetic field and other plasma parameters, spanning from optical to  $\gamma$ -ray wavelengths, to bring closure to these long-standing and fundamental questions. We discuss how our approach can fully describe the 3D magnetic field, embedded plasma, particle energization, and their joint evolution to achieve these objectives.

### **Radio emission observed in decimetric waves associated with the onset of CMEs**

J.R. [Cecatto](#), A.C. Soares, F.C.R. Fernandes, F.R.H. Madsen, M.C. Andrade, H.S. Sawant

Journal of Atmospheric and Solar-Terrestrial Physics, Volume 67, Issues 17-18, December **2005**, Pages 1674-1679

Since the first observations by Skylab and SMM satellites coronal mass ejections (CME) have been more and more investigated. However, until now their origin and trigger mechanism remain an open question no matter if they are associated to flares or not. Recent observations over a broad spectrum suggest that flare energy is released in regions from where the decimetric emission is coming. Then, investigations of decimetric radio emission observed in association with CME phenomena may give clues to solve the previously mentioned questions. Using the Brazilian solar spectroscope (BSS), observations of solar bursts dynamic spectra with high time (100, 50, 20 ms) and frequency (50–100 channels) resolutions have been carried out daily ( $\sim$ 11–19 UT) within the range of 1000–2500 MHz. A sample of 274 CMEs were recorded by the large angle spectroscopic coronagraph (LASCO) instrument, on board the solar and heliospheric observatory (SOHO) satellite, within 11–19 UT, during the period of 1999–2002. From those, 42 CMEs are associated to BSS data and selected for analysis. It is interesting to note that in about half of the cases only one type of burst radio emission was recorded while in the remaining cases either two or more types were observed. There is a dominance of either continuum and/or pulsations. Here, we describe the association of burst radio emission with the starting time of CME phenomena.

### **Recent insights on CME deflections at low heights**

**Review**

Mariana [Cécere](#), Andrea Costa, Hebe Cremades, and Guillermo Stenborg

Front. Astron. Space Sci. 10 :1260432. **2023**

<https://www.frontiersin.org/articles/10.3389/fspas.2023.1260432/pdf>

It has been shown that the magnetic structures surrounding coronal mass ejection (CME) events play a crucial role in their development and evolution along the first few solar radii. In particular, active regions, coronal holes, pseudostreamers, and helmet streamers are among the main coronal structures involved in the deviation of the trajectory of CMEs from their radial direction. Therefore, comprehensive observational studies along with their theoretical interpretation, aided by numerical simulations of the early evolution of CMEs, are the key ingredients to help determine their 3D trajectory in the interplanetary medium to narrow down the error in the estimation of the time of arrival of geoeffective events. In this mini-review, we compile the last decade of theoretical, numerical, and observational research that has shed light on the causes influencing the early deflection of CMEs away from their otherwise radial trajectory.

### **Evidence for a Magnetic Reconnection Origin of Plasma Outflows along Post-CME Rays**

Jongchul [Chae](#)<sup>1</sup>, Kyuhyoun Cho<sup>1</sup>, Ryun-Young Kwon<sup>2,3</sup>, and Eun-Kyung Lim

**2017** ApJ 841 49

<http://sci-hub.ru/10.3847/1538-4357/aa6d7a>

Bright rays are often observed after coronal mass ejections (CMEs) erupt. These rays are dynamical structures along which plasmas move outward. We investigated the outflows along the post-CME rays observed by the COR2 on board STEREO Behind on **2013 September 21 and 22**. We tracked two CMEs, two ray tips, and seven blobs using the NAVÉ optical flow technique. As a result, we found that the departure times of blobs and ray tips from the optimally chosen starting height coincided with the occurrence times of the corresponding recurrent small flares within 10 minutes. These small flares took place many hours after the major flares. This result supports a magnetic reconnection origin of the outward flows along the post-CME ray and the importance of magnetic islands for understanding the process of magnetic reconnection. The total energy of magnetic reconnection maintaining the outflows for 40 hr is

estimated at  $10^{22}$  erg. Further investigations of plasma outflows along post-CME rays will shed much light on the physical properties of magnetic reconnection occurring in the solar corona.

## **Measuring Solar Doppler Velocities in the He ii 30.38 nm Emission Using the EUV Variability Experiment (EVE)**

P. C. [Chamberlin](#)

Solar Phys. 2016

The EUV Variability Experiment (EVE) onboard the Solar Dynamics Observatory has provided unprecedented measurements of the solar EUV irradiance at high temporal cadence with good spectral resolution and range since May 2010. The main purpose of EVE was to connect the Sun to the Earth by providing measurements of the EUV irradiance as a driver for space weather and Living With a Star studies, but after launch the instrument has demonstrated the significance of its measurements in contributing to studies looking at the sources of solar variability for pure solar physics purposes. This paper expands upon previous findings that EVE can in fact measure wavelength shifts during solar eruptive events and therefore provide Doppler velocities for plasma at all temperatures throughout the solar atmosphere from the chromosphere to hot flaring temperatures. This process is not straightforward as EVE was not designed or optimized for these types of measurements. In this paper we describe the many detailed instrumental characterizations needed to eliminate the optical effects in order to provide an absolute baseline for the Doppler shift studies. An example is given of a solar eruption on **7 September 2011** (SOL2011-09-07), associated with an X1.2 flare, where EVE Doppler analysis shows plasma ejected from the Sun in the He ii 30.38 nm emission at a velocity of almost 120 kms<sup>-1</sup> along the line-of-sight.

## **Filament Eruption Driving EUV Loop Contraction then Expansion above a Stable Filament**

[Ramesh Chandra](#), [Pascal Demoulin](#), [Pooja Devi](#), [Reetika Joshi](#), [Brigitte Schmieder](#)

ApJ 922 227 2021

<https://arxiv.org/pdf/2109.07821.pdf>

<https://doi.org/10.3847/1538-4357/ac2837>

We analyze the observations of EUV loop evolution associated with the filament eruption located at the border of an active region. The event SOL**2013-03-16T14:00** was observed with a large difference of view point by the Solar Dynamics Observatory and Solar Terrestrial Relations Observatory --A spacecraft. The filament height is fitted with the sum of a linear and exponential function. These two phases point to different physical mechanisms such as: tether-cutting reconnection and a magnetic instability. While no X-ray emission is reported, this event presents the classical eruption features like: separation of double ribbons and the growth of flare loops. We report the migration of the southern foot of the erupting filament flux rope due to the interchange reconnection with encountered magnetic loops of a neighbouring AR. Parallel to the erupting filament, a stable filament remains in the core of active region. The specificity of this eruption is that coronal loops, located above the nearly joining ends of the two filaments, first contract in phase, then expand and reach a new stable configuration close to the one present at the eruption onset. Both contraction and expansion phases last around 20 min. The main difference with previous cases is that the PIL bent about 180 deg around the end of the erupting filament because the magnetic configuration is at least tri-polar. These observations are challenging for models which interpreted previous cases of loop contraction within a bipolar configuration. New simulations are required to broaden the complexity of the configurations studied.

## **Solar flares associated coronal mass ejection accompanied with DH type II radio burst in relation with interplanetary magnetic field, geomagnetic storms and cosmic ray intensity**

Harish [Chandra](#), [Beena Bhatt](#)

[New Astronomy Volume 60](#), April 2018, Pages 22-32

[sci-hub.ru/10.1016/j.newast.2017.10.001](http://sci-hub.ru/10.1016/j.newast.2017.10.001)

In this paper, we have selected 114 flare-CME events accompanied with Deca-hectometric (DH) type II radio burst chosen from 1996 to 2008 (i.e., solar cycle 23). Statistical analyses are performed to examine the relationship of flare-CME events accompanied with DH type II radio burst with Interplanetary Magnetic field (IMF), Geomagnetic storms (GSs) and Cosmic Ray Intensity (CRI). The collected sample events are divided into two groups. In the first group, we considered 43 events which lie under the CME span and the second group consists of 71 events which are outside the CME span. Our analysis indicates that flare-CME accompanied with DH type II radio burst is inconsistent with CSHKP flare-CME model. We apply the Chree analysis by the superposed epoch method to both set of data to find the geo-effectiveness. We observed different fluctuations in IMF for arising and decay phase of solar cycle in both the cases. Maximum decrease in Dst during arising and decay phase of solar cycle is different for both the cases. It is noted that when flare lie outside the CME span CRI shows comparatively more variation than the flare lie under the CME span. Furthermore, we found that flare lying under the CME span is more geo effective than the flare outside of CME span. We noticed that the time lag between IMF Peak value and GSs, IMF and CRI is on average one day for both the cases. Also, the time lag between CRI and GSs is on average 0 to 1 day for both the cases. In case flare lie under the CME span we observed high correlation (0.64) between CRI and Dst whereas when flare lie outside the CME span a weak correlation (0.47) exists. Thus, flare position with respect to CME span play a key role for geo-effectiveness of CME.

## **A Study of a long duration B9 flare-CME event and associated piston-driven shock**

R. **Chandra**, P. F. Chen, A. Fulara, A. K. Srivastava, W. Uddin

Adv. Space Research [Volume 61, Issue 2](#), 15 January 2018, Pages 705-714

<https://arxiv.org/pdf/1710.08734.pdf>

We present and discuss here the observations of a small long duration GOES B- class flare associated with a quiescent filament eruption, a global EUV wave and a CME on **2011 May 11**. The event was well observed by the Solar Dynamics Observatory (SDO), GONG H $\{\alpha\}$ , STEREO and HiRAS spectrograph. As the filament erupted, ahead of the filament we observed the propagation of EIT wave fronts, as well as two flare ribbons on both sides of the polarity inversion line (PIL) on the solar surface. The observations show the co-existence of two types of EUV waves, i.e., a fast and a slow one. A type II radio burst with up to the third harmonic component was also associated with this event. The evolution of photospheric magnetic field showed flux emergence and cancellation at the filament site before its eruption.

## **Investigation of recurrent EUV jets from highly dynamic magnetic field region**

Navin **Chandra**, Ramesh Chandra, Yang Guo, Tetsuya Magara, Ivan Zhelyazkov, Young-Jae Moon, Wahab Uddin

Astrophysics and Space Science January 2017, 362:10

<https://link.springer.com/content/pdf/10.1007/s10509-016-2983-x.pdf>

In this work, we present observations and interpretations of recurrent extreme ultraviolet (EUV) jets that occurred between **2012 July 1 21:00 UT and 2012 July 2 10:00 UT** from the western edge of the NOAA active region 11513. *Solar Dynamics Observatory/Atmospheric Imaging Assembly (SDO/AIA)*, *SDO/Helioseismic and Magnetic Imager (SDO/HMI)* and *Reuven Ramaty High Energy Solar Spectroscopic Imager (RHESSI)* observations have been used for the present study. Observations as well as potential-field source-surface (PFSS) extrapolation suggest an open field configuration in the vicinity of the jet activity area. 18 EUV jets were observed from the western edge of the active region along the open field channel. All the jet events appeared to be non-homologous and show different morphological properties and evolution. Some of the jets were small and narrow in size while the others were huge and wide. The average speed of these jets ranges from  $\sim 47$  to  $\sim 308$   $\text{kms}^{-1}$ . *SDO/AIA* 171 Å intensity profiles at the base of these jets show bumps corresponding to each jet, which is an evidence of recurrent magnetic reconnections. The magnetic field observation at the foot points of the jets revealed a very complex and dynamic magnetic activity which includes flux emergence, flux cancellation, dynamic motions, merging, separation, etc. We suggest that the recurrent jets are the result of recurrent magnetic reconnections among the various emerging bipolar fields themselves as well as with the open fields.

## **Two Step Filament Eruption During 14-15 March 2015**

R. **Chandra**, B. Filippov, R. Joshi, B. Schmieder

Solar Phys. 292:81 2017 DOI: 10.1007/s11207-017-1104-5

<https://arxiv.org/pdf/1704.08860.pdf>

<http://sci-hub.ru/10.1007/s11207-017-1104-5>

We present here an interesting two-step filament eruption during 14-15 March 2015. The filament was located in NOAA AR 12297 and associated with a halo Coronal Mass Ejection (CME). We use observations from the Atmospheric Imaging Assembly (AIA) and Heliospheric Magnetic Imager (HMI) instruments onboard the Solar Dynamics Observatory (SDO), and from the Solar and Heliospheric Observatory (SOHO) Large Angle and Spectrometric Coronagraph (LASCO). We also use H-alpha data from the Global Oscillation Network Group (GONG) telescope and the Kanzelhöhe Solar Observatory. The filament shows a first step eruption on **14 March 2015** and it stops its rise at a projected altitude  $\sim 125$  Mm on the solar disk. It remains at this height for  $\sim 12$  hrs. Finally it erupts on **15 March 2015** and produced a halo CME. We also find jet activity in the active region during both days, which could help the filament de-stabilization and eruption. The decay index is calculated to understand this two-step eruption. The eruption could be due to the presence of successive instability-stability-instability zones as the filament is rising.

## **Blowout Jets and Impulsive Eruptive Flare in a Bald-Patch Topology**

R. **Chandra**, C.H. Mandrini, B. Schmieder, B. Joshi, G.D. Cristiani, H. Cremades, E. Pariat, F.A. Nuevo, A.K. Srivastava, W. Uddin

A&A 598, A41 (2017)

<https://arxiv.org/pdf/1610.01918v1.pdf> File

Context: A subclass of broad EUV and X-ray jets, called blowout jets, have become a topic of research since they could be the link between standard collimated jets and CMEs. }

Aim: Our aim is to understand the origin of a series of broad jets, some accompanied by flares and associated with narrow and jet-like CMEs.

Methods: We analyze observations of a series of recurrent broad jets observed in AR 10484 on **21-24 October 2003**. In particular, one of them occurred simultaneously with an M2.4 flare on 23 October at 02:41 UT (SOLA2003-10-23). Both events were observed by ARIES H-alpha Solar Tower-Telescope, TRACE, SOHO, and RHESSI instruments. The flare was very impulsive and followed by a narrow CME. A local force-free model of AR 10484 is the basis to compute its topology. We find bald patches (BPs) at the flare site. This BP topology is present for at least two days before. Large-scale field lines, associated with the BPs, represent open loops. This is confirmed by a global PFSS model.

Following the brightest leading edge of the H-alpha and EUV jet emission, we can temporarily associate it with a narrow CME.

Results: Considering their characteristics, the observed broad jets appear to be of the blowout class. As the most plausible scenario, we propose that magnetic reconnection could occur at the BP separatrices forced by the destabilization of a continuously reformed flux rope underlying them. The reconnection process could bring the cool flux-rope material into the reconnected open field lines driving the series of recurrent blowout jets and accompanying CMEs.

Conclusions: Based on a model of the coronal field, we compute the AR 10484 topology at the location where flaring and blowout jets occurred from 21 to 24 October 2003. This topology can consistently explain the origin of these events.

**Хорошее Введение про CMEs and jets**

### **Peculiar Stationary EUV Wave Fronts in the eruption on 2011 May 11**

R. **Chandra**, P. F. Chen, A. Fulara, A. K. Srivastava, W. Uddin

ApJ **2016 File**

<http://arxiv.org/pdf/1602.08693v1.pdf>

<https://iopscience.iop.org/article/10.3847/0004-637X/822/2/106/pdf>

We present and interpret the observations of extreme ultraviolet (EUV) waves associated with a filament eruption on **2011 May 11**. The filament eruption also produces a small B-class two ribbon flare and a coronal mass ejection (CME). The event is observed by the Solar Dynamic Observatory (SDO) with high spatio-temporal resolution data recorded by Atmospheric Imaging Assembly (AIA). As the filament erupts, we observe two types of EUV waves (slow and fast) propagating outwards. The faster EUV wave has a propagation velocity of  $\sim 500$  km/s and the slower EUV wave has an initial velocity of  $\sim 120$  km/s. We report for the first time that not only the slower EUV wave stops at a magnetic separatrix to form bright stationary fronts, but also the faster EUV wave transits a magnetic separatrix, leaving another stationary EUV front behind.

### **Sunspot Waves and Triggering of Homologous Active Region Jets**

Ramesh **Chandra**, G.R. Gupta, Sargam Mulay, Durgesh Tripathi

MNRAS, Volume 446, Issue 4, p.3741-3748 **2015**

<http://arxiv.org/pdf/1410.8315v1.pdf>

<https://watermark.silverchair.com/stu2305.pdf>

We present and discuss multi-wavelength observations of five homologous recurrent solar jets that occurred in active region NOAA 11133 on **11 December, 2010**. These jets were well observed by the Solar Dynamic observatory (SDO) with high spatial and temporal resolution. The speed of the jets ranged between 86 and 267 km/s. A type III radio burst was observed in association with all the five jets. The investigation of the over all evolution of magnetic field in the source regions suggested that the flux was continuously emerging on longer term. However, all the jets but J5 were triggered during a local dip in the magnetic flux, suggesting the launch of the jets during localised submergence of magnetic flux. Additionally, using the PFSS modelling of the photospheric magnetic field, we found that all the jets were ejected in the direction of open field lines. We also traced sunspot oscillations from the sunspot interior to foot-point of jets and found presence of  $\sim 3$  minute oscillations in all the SDO/AIA passbands. The wavelet analysis revealed an increase in amplitude of the oscillations just before the trigger of the jets, that decreased after the jets were triggered. The observations of increased amplitude of the oscillation and its subsequent decrease provides evidence of wave-induced reconnection triggering the jets.

### **Solar Energetic Particle Events during the Rise Phases of Solar Cycles 23 and 24**

R. **Chandra**, N. Gopalswamy, P. Mäkelä, H. Xie, S. Yashiro, S. Akiyama, W. Uddin, A.K. Srivastava, N.C. Joshi, R. Jain, A.K. Awasthi, P.K. Manoharan, K. Mahalakshmi, V.C. Dwivedi, D.P. Choudhary, N.V. Nitta  
Advances in Space Research, **Volume 52, Issue 12**, Pages 2102-2111 **2013, File**

<https://sci-hub.ru/10.1016/j.asr.2013.09.006>

<https://doi.org/10.1016/j.asr.2013.09.006>

We present a comparative study of the properties of coronal mass ejections (CMEs) and flares associated with the solar energetic particle (SEP) events in the rising phases of solar cycles (SC) 23 (1996-1998) (22 events) and 24 (2009-2011) (20 events), which are associated with type II radio bursts. Based on the SEP intensity, we divided the events into three categories, i.e. weak (intensity  $< 1$  pfu), minor ( $1 \text{ pfu} < \text{intensity} < 10$  pfu) and major (intensity  $> 10$  pfu). We examine the correlation of SEP intensity with flare size and CME properties. We find that most of the major SEP events are associated with halo or partial halo CMEs originating close to the sun center and western-hemisphere. The fraction of halo CMEs in SC 24 is larger than the SC 23. For the minor SEP events one event in SC23 and one event in SC24 have widths  $< 120^\circ$  and all other events are associated with halo or partial halo CMEs as in the case of major SEP events. In case of weak SEP events, majority (more than 60%) of events are associated with CME width  $< 120^\circ$ . For both the SC the average CMEs speeds are similar. For major SEP events, average CME speeds are higher in comparison to minor and weak events. The SEP event intensity and GOES X-ray flare size are poorly correlated. During the rise phase of solar cycle 23 and 24, we find north-south asymmetry in the SEP event source locations: in cycle 23 most sources are

located in the south, whereas during cycle 24 most sources are located in the north. This result is consistent with the asymmetry found with sunspot area and intense flares. **Tables**

## **Simulation of Homologous and Cannibalistic Coronal Mass Ejections produced by the Emergence of a Twisted Flux Rope into the Solar Corona**

Piyali [Chatterjee](#) and Yuhong Fan

2013 ApJ 778 L8

We report the first results of a magnetohydrodynamic simulation of the development of a homologous sequence of three coronal mass ejections (CMEs) and demonstrate their so-called cannibalistic behavior. These CMEs originate from the repeated formations and partial eruptions of kink unstable flux ropes as a result of continued emergence of a twisted flux rope across the lower boundary into a pre-existing coronal potential arcade field. The simulation shows that a CME erupting into the open magnetic field created by a preceding CME has a higher speed. The second of the three successive CMEs is cannibalistic, catching up and merging with the first into a single fast CME before exiting the domain. All the CMEs including the leading merged CME, attained speeds of about  $1000 \text{ km s}^{-1}$  as they exit the domain. The reformation of a twisted flux rope after each CME eruption during the sustained flux emergence can naturally explain the X-ray observations of repeated reformations of sigmoids and "sigmoid-under-cusp" configurations at a low-coronal source of homologous CMEs.

**ERRATUM:** 2014 ApJ 792 L24

We have found that the magnetic and kinetic energies were erroneously over-estimated by a factor of  $4\pi$  in making the plot in Figure 2 of the published paper. A corrected version of Figure 2 is included below.

## **Stationarity and periodicities of linear speed of coronal mass ejection: a statistical signal processing approach**

Anirban [Chattopadhyay](#), Mofazzal Hossain Khondekar & Anup Kumar Bhattacharjee

[Astrophysics and Space Science](#) September 2017, 362:179

In this paper initiative has been taken to search the periodicities of linear speed of Coronal Mass Ejection in solar cycle 23. Double exponential smoothing and Discrete Wavelet Transform are being used for detrending and filtering of the CME linear speed time series. To choose the appropriate statistical methodology for the said purpose, Smoothed Pseudo Wigner-Ville distribution (SPWVD) has been used beforehand to confirm the non-stationarity of the time series. The Time-Frequency representation tool like Hilbert Huang Transform and Empirical Mode decomposition has been implemented to unearth the underneath periodicities in the non-stationary time series of the linear speed of CME. Of all the periodicities having more than 95% Confidence Level, the relevant periodicities have been segregated out using Integral peak detection algorithm. The periodicities observed are of low scale ranging from 2–159 days with some relevant periods like 4 days, 10 days, 11 days, 12 days, 13.7 days, 14.5 and 21.6 days. These short range periodicities indicate the probable origin of the CME is the active longitude and the magnetic flux network of the sun. The results also insinuate about the probable mutual influence and causality with other solar activities (like solar radio emission, ApAp index, solar wind speed, etc.) owing to the similitude between their periods and CME linear speed periods. The periodicities of 4 days and 10 days indicate the possible existence of the Rossby-type waves or planetary waves in Sun.

## **Simultaneous Eruption and Shrinkage of Preexisting Flare Loops during a Subsequent Solar Eruption**

[Huadong Chen](#), [Lyndsay Fletcher](#), [Guiping Zhou](#), [Xin Cheng](#), [Ya Wang](#), [Sargam Mulay](#), [Ruisheng Zheng](#), [Suli Ma](#), [Xiaofan Zhang](#)

2024 ApJ 976 207

<https://iopscience.iop.org/article/10.3847/1538-4357/ad8c25/pdf>

<https://arxiv.org/pdf/2410.12202>

We investigated two consecutive solar eruption events in the solar active region 12994 at the solar eastern limb on **2022 April 15**. We found that the flare loops formed by the first eruption were involved in the second eruption. During the initial stage of the second flare, the middle part of these flare loops (E-loops) erupted outward along with the flux ropes below, while the parts of the flare loops (I-loops1 and I-loops2) on either side of the E-loops first rose and then contracted. Approximately 1 hr after the eruption, the heights of I-loops1 and I-loops2 decreased by 9 Mm and 45 Mm, respectively, compared to before the eruption. Their maximum descent velocities were  $30 \text{ km s}^{-1}$  and  $130 \text{ km s}^{-1}$ , respectively. The differential emission measure results indicate that the plasma above I-loops1 and I-loops2 began to be heated about 23 minutes and 44 minutes after the start of the second flare, respectively. Within  $\sim 20$  minutes, the plasma temperature in these regions increased from  $\sim 3 \text{ MK}$  to  $\sim 6 \text{ MK}$ . We proposed an adiabatic heating mechanism where magnetic energy would be converted into thermal and kinetic energy when the prestretched loops contract. Our calculations show that the magnetic energy required to heat the two high-temperature regions are 1029–1030 erg, which correspond to a loss of field strength of 2–3 G.

## **Theoretical Studies on the Evolution of Solar Filaments in Response to New Emerging Flux**

[Yuhao Chen](#), [Jialiang Hu](#), [Guanchong Cheng](#), [Jing Ye](#), [Zhixing Mei](#), [Chengcai Shen](#), [Jun Lin](#)

ApJL 977 L26 2024

<https://arxiv.org/pdf/2411.13839>

<https://iopscience.iop.org/article/10.3847/2041-8213/ad94ea/pdf>

New emerging flux (NEF) has long been considered a mechanism for solar eruptions, but detailed process remains an open question. In this work, we explore how NEF drives a coronal magnetic configuration to erupt. This configuration is created by two magnetic sources of strengths  $M$  and  $S$  embedded in the photosphere, one electric-current-carrying flux rope (FR) floating in the corona, and an electric current induced on the photospheric surface by the FR. The source  $M$  is fixed accounting for the initial background field, and  $S$  changes playing the role of NEF. We introduce the channel function  $C$  to forecast the overall evolutionary behavior of the configuration. Location, polarity, and strength of NEF governs the evolutionary behavior of FR before eruption. In the case of  $|S/M| < 1$  with reconnection occur between new and old fields, the configuration in equilibrium evolves to the critical state, invoking the catastrophe. In this case, if polarities of the new and old fields are opposite, reconnection occurs as NEF is close to FR; and if polarities are the same, reconnection happens as NEF appears far from FR. With different combinations of the relative polarity and the location, the evolutionary behavior of the system gets complex, and the catastrophe may not occur. If  $|S/M| > 1$  and the two fields have opposite polarity, the catastrophe always takes place; but if the polarities are the same, catastrophe occurs only as NEF is located far from FR; otherwise, the evolution ends up either with failed eruption or without catastrophe at all.

## **An Introduction on Solar Imaging Data Analytic Challenges and Opportunities for Statisticians**

**Review**

[Yang Chen](#), [Ward Manchester](#), [Meng Jin](#), [Alexei Pevtsov](#)

2024

<https://arxiv.org/pdf/2405.12331>

We give a gentle introduction to solar imaging data, focusing on challenges and opportunities of data-driven approaches for solar eruptions. The various solar phenomena prediction problems that might benefit from statistical methods are presented. Available data and software will be described. State-of-art solar eruption forecasting with data driven approaches are summarized and discussed. Based on the characteristics of the datasets and state-of-art approaches, we point out several promising directions to explore from statistical modeling and computational perspectives.

## **Observations of a Failed Solar Filament Eruption Involving External Reconnection**

[Yuehong Chen](#), [Xin Cheng](#), [Jun Chen](#), [Yu Dai](#), [Mingde Ding](#)

ApJ 959 67 2023

<https://arxiv.org/pdf/2311.17637.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ad09d8/pdf>

We report a failed solar filament eruption that involves external magnetic reconnection in a quadrupolar magnetic configuration. The evolution exhibits three kinematic evolution phases: a slow-rise phase, an acceleration phase, and a deceleration phase. In the early slow rise, extreme-ultraviolet (EUV) brightenings appear at the expected null point above the filament and are connected to the outer polarities by the hot loops, indicating the occurrence of a breakout reconnection. Subsequently, the filament is accelerated outward, accompanied by the formation of low-lying high-temperature post-flare loops ( $> 15$  MK), complying with the standard flare model. However, after 2--3 minutes, the erupting filament starts to decelerate and is finally confined in the corona. The important finding is that the confinement is closely related to an external reconnection as evidenced by the formation of high-lying large-scale hot loops ( $> 10$  MK) with their brightened footpoints at the outer polarities, the filament fragmentation and subsequent falling along the newly formed large-scale loops, as well as a hard X-ray source close to one of the outer footpoint brightenings. We propose that, even though the initial breakout reconnection and subsequent flare reconnection commence and accelerate the filament eruption, the following external reconnection between the erupting flux rope and overlying field, as driven by the upward filament eruption, makes the eruption finally failed, as validated by the numerical simulation of a failed flux rope eruption. 2022 May 3

## **Can the Parker Solar Probe Detect a CME-flare Current Sheet?**

[Yuhao Chen](#), [Zhong Liu](#), [Pengfei Chen](#), [David F. Webb](#), [Qi Hao](#), [Jialiang Hu](#), [Guanchong Cheng](#), [Zhixing Mei](#), [Jing Ye](#), [Qian Wang](#), [Jun Lin](#)

ApJS 269 22 2023

<https://arxiv.org/pdf/2309.06432.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4365/acf8c7/pdf>

A current sheet (CS) is the central structure in the disrupting magnetic configuration during solar eruptions. More than 90% of the free magnetic energy (the difference between the energy in the non-potential magnetic field and that in the potential one) stored in the coronal magnetic field beforehand is converted into heating and kinetic energy of the plasma, as well as accelerating charged particles, by magnetic reconnection occurring in the CS. However, the detailed physical properties and fine structures of the CS are still unknown since there is no relevant information obtained via in situ detections. The Parker Solar Probe (PSP) may provide us such information should it traverse a CS in the eruption. The perihelion of PSP's final orbit is located at about 10 solar radii from the center of the Sun, so it can observe the CS at a very close distance, or even traverses the CS, which provides us a unique opportunity to look into fine properties and structures of the CS, helping reveal the detailed physics of large-scale reconnection that was impossible before. We evaluate the probability that PSP can traverse a CS, and examine the orbit of a PSP-like spacecraft that has the highest probability to traverse a CS.

### **1. INTRODUCTION**

## **An Atypical Plateau-like Extreme-ultraviolet Late-phase Solar Flare Driven by the Non-radial Eruption of a Magnetic Flux Rope**

[Yuehong Chen](#), [Yu Dai](#), [Mingde Ding](#)

A&A 675, A147 2023

<https://arxiv.org/pdf/2305.14980.pdf>

<https://www.aanda.org/articles/aa/pdf/2023/07/aa45914-23.pdf>

Recent observations in extreme-ultraviolet (EUV) wavelengths reveal an EUV late phase in some solar flares, which is characterized by a second peak in the warm coronal emissions (about 3 MK) occurring several tens of minutes to a few hours after the corresponding main flare peak. We aim to clarify the physical origin of an atypical plateau-like EUV late phase in an X1.8-class solar flare occurring on **2011 September 7** from active region (AR) 11283. We first characterize the plateau-like late phase using EUV Variability Experiment (EVE) full-disk integrated irradiance observations and Atmospheric Imaging Assembly (AIA) spatially-resolved imaging observations on board the Solar Dynamics Observatory (SDO). Then we perform a nonlinear force-free-field (NLFFF) extrapolation, from which a filament-hosting magnetic flux rope (MFR) is revealed. The eruption of the MFR is tracked both in the plane of the sky (POS) and along the line of sight (LOS) through visual inspection and spectral fitting, respectively. Finally, we carry out differential emission measure (DEM) analysis to explore the thermodynamics of the late-phase loops. The MFR shows a non-radial eruption from a fan-spine magnetic structure. The eruption of the MFR and its interaction with overlying arcades invoke multiple magnetic reconnections, which are responsible for the production of different groups of late-phase loops. Afterwards, the late-phase loops enter a long-lasting cooling stage, appearing sequentially in AIA passbands of decreasing response temperatures. Due to their different lengths, the different groups of late-phase loops cool down at different cooling rates, which makes their warm coronal emission peaks temporally separated from each other. Combining the emissions from all late-phase loops together, an elongated plateau-like late phase is formed.

## **A Model for Confined Solar Eruptions Including External Reconnection**

[Jun Chen](#), [Xin Cheng](#), [Bernhard Kliem](#), [Mingde Ding](#)

ApJL 951 L35 2023

<https://arxiv.org/pdf/2306.04993.pdf>

<https://iopscience.iop.org/article/10.3847/2041-8213/acdef5/pdf>

The violent disruption of the coronal magnetic field is often observed to be restricted to the low corona, appearing as a confined eruption. The possible causes of the confinement remain elusive. Here, we model the eruption of a magnetic flux rope in a quadrupolar active region, with the parameters set such that magnetic X-lines exist both below and above the rope. This facilitates the onset of magnetic reconnection in either place but with partly opposing effects on the eruption. The lower reconnection initially adds poloidal flux to the rope, increasing the upward hoop force and supporting the rise of the rope. However, when the flux of the magnetic side lobes enters the lower reconnection, the flux rope is found to separate from the reconnection site and the flux accumulation ceases. At the same time, the upper reconnection begins to reduce the poloidal flux of the rope, decreasing its hoop force; eventually this cuts the rope completely. The relative weight of the two reconnection processes is varied in the model, and it is found that their combined effect and the tension force of the overlying field confine the eruption if the flux ratio of the outer to the inner polarities exceeds a threshold, which is about 1.3 for our Cartesian box and chosen parameters. We hence propose that external reconnection between an erupting flux rope and overlying flux can play a vital role in confining eruptions.

## **Eruption of a Magnetic Flux Rope in a Comprehensive Radiative Magnetohydrodynamic Simulation of flare-productive active regions**

[Feng Chen](#), [Matthias Rempel](#), [Yuhong Fan](#)

ApJ 2023

<https://arxiv.org/pdf/2303.05405.pdf>

Radiative magnetohydrodynamic simulation includes sufficiently realistic physics to allow for the synthesis of remote sensing observables that can be quantitatively compared with observations. We analyze the largest flare in a simulation of the emergence of large flare-productive active regions described by Chen et al. The flare is accompanied by a spectacular coronal mass ejection and reaches M2 class, as measured from synthetic soft X-ray flux. The eruption reproduces many key features of observed solar eruptions. A pre-existing magnetic flux rope is formed along the highly sheared polarity inversion line between a sunspot pair and is covered by an overlying multi-pole magnetic field. During the eruption, the progenitor flux rope actively reconnects with the canopy field and evolves to the large-scale multi-thermal flux rope that is observed in the corona. Meanwhile, the magnetic energy released via reconnection is channeled down to the lower atmosphere and gives rise to bright soft X-ray post-flare loops and flare ribbons that reproduce the morphology and dynamic evolution of observed flares. The model helps to shed light on questions of where and when the a flux rope may form and how the magnetic structures in an eruption are related to observable emission properties.

## **Radio Imaging Spectropolarimetry of CMEs and CME Progenitors**

Science white paper submitted to the 2024 Solar and Space Physics Decadal Survey. **2023**

All submitted white papers (including this one) are available at [this https URL](https://arxiv.org/pdf/2301.12188.pdf)  
<https://arxiv.org/pdf/2301.12188.pdf>

Coronal mass ejections (CMEs) are the most important drivers of space weather. Central to most CMEs is thought to be the eruption of a bundle of highly twisted magnetic field lines known as magnetic flux ropes. A comprehensive understanding of CMEs and their impacts hence requires detailed observations of physical parameters that lead to the formation, destabilization, and eventual eruption of the magnetic flux ropes. Recent advances in remote-sensing observations of coronal cavities, filament channels, sigmoids, EUV "hot channels," white light CMEs, and in situ observations of magnetic clouds points to the possibility of significant progress in understanding CMEs. In this white paper, we provide a brief overview of the potential of radio diagnostics for CMEs and CME progenitors, with a particular focus on the unique means for constraining their magnetic field and energetic electron population. Using synthetic observations based on realistic 3D MHD models, we also demonstrate the transformative potential of advancing such diagnostics by using broadband radio imaging spectropolarimetry with a high image dynamic range and high image fidelity. To achieve this goal, a solar-dedicated radio facility with such capabilities is recommended for implementation in the coming decade.

### **Quantifying Energy Release in Solar Flares and Solar Eruptive Events: New Frontiers with a Next-Generation Solar Radio Facility**

Bin [Chen](#) (1), [Dale E. Gary](#) (1), [Sijie Yu](#) (1), [Surajit Mondal](#) (1), [Gregory D. Fleishman](#) (1), [Xiaocan Li](#) (2), [Chengcai Shen](#) (3), [Fan Guo](#) (4), [Stephen M. Science white paper to the 2024 Solar and Space Physics Decadal Survey **2023**

<https://arxiv.org/pdf/2301.12192.pdf>

Solar flares and the often associated solar eruptive events serve as an outstanding laboratory to study the magnetic reconnection and the associated energy release and conversion processes under plasma conditions difficult to reproduce in the laboratory, and with considerable spatiotemporal details not possible elsewhere in the universe. In the past decade, thanks to advances in multi-wavelength imaging spectroscopy, as well as developments in theories and numerical modeling, significant progress has been made in improving our understanding of solar flare/eruption energy release. In particular, broadband imaging spectroscopy at microwave wavelengths offered by the Expanded Owens Valley Solar Array (EOVSA) has enabled the revolutionary capability of measuring the time-evolving coronal magnetic fields at or near the flare reconnection region. However, owing to EOVSA's limited dynamic range, imaging fidelity, and angular resolution, such measurements can only be done in a region around the brightest source(s) where the signal-to-noise is sufficiently large. In this white paper, after a brief introduction to the outstanding questions and challenges pertinent to magnetic energy release in solar flares and eruptions, we will demonstrate how a next-generation radio facility with many (~100-200) antenna elements can bring the next revolution by enabling high dynamic range, high fidelity broadband imaging spectropolarimetry along with a sub-second time resolution and arcsecond-level angular resolution. We recommend to prioritize the implementation of such a ground-based instrument within this decade. We also call for facilitating multi-wavelength, multi-messenger observations and advanced numerical modeling in order to achieve a comprehensive understanding of the "system science" of solar flares and eruptions. **2017 Sept. 10**

### **Similarities and Differences of SARs in Solar Cycle 24**

Anqin [Chen](#), [Ting Li](#) & [Jingxiu Wang](#)

[Solar Physics](#) volume 297, Article number: 142 (2022)

<https://doi.org/10.1007/s11207-022-02076-4>

Solar Cycle 24 is a particularly weak cycle and there are only six super active regions (SARs). Except for NOAA active region (AR) 12192, all other SARs are coronal mass ejection rich (CME-rich) and produced CMEs faster than 1000 kms<sup>-1</sup>–11000 kms<sup>-1</sup>. By studying the similarities and differences between CME-poor SARs and CME-rich SARs in Solar Cycle 24, we aim to improve our understanding of the cause of major explosive solar activity events. Using the magnetograms of the Helioseismic and Magnetic Imager (HMI) and the images of the Atmospheric Imaging Assembly (AIA) on board the Solar Dynamics Observatory (SDO), the magnetic-field characteristics of the six SARs and their established overall or even global magnetic connectivity are studied. It is found that the area of strong magnetic shear ( $A\psi A\psi$ ) of all the six SARs is larger than 100 Mm<sup>2</sup>100 Mm<sup>2</sup>, and the composite magnetic-field index (IcomIcom: Chen and Wang in *Astron. Astrophys.* 543, A49, 2012) of them is higher than 1. However, the total free magnetic-energy density (EfreeEfree) and the IcomIcom for the majority of them are relatively low compared to the SARs in Solar Cycles 22 and 23. Compared with their very high total unsigned magnetic flux, the CME-poor AR 12192 has a lower EfreeEfree, a shorter magnetic-neutral line with steep horizontal gradient, a smaller  $A\psi A\psi$ , and a lower IcomIcom. It is also revealed that the current helicity proxy, in terms of either the twist parameter or the best force-free parameter, has a good correlation with the fastest CME velocities of the SARs and serves as a good criterion to distinguish the CME-poor SARs from the CME-rich SARs. Except for NOAA AR 12192, all other SARs are found to connect closely with other ARs, and the AR cluster is a common feature of CME-rich SARs.

### **Multispacecraft Remote Sensing and In Situ Observations of the 2020 November 29 Coronal Mass Ejection and Associated Shock: From Solar Source to Heliospheric Impacts**

[Chong Chen](#), [Ying D. Liu](#), [Bei Zhu](#)

ApJ 937 44 2022

<https://arxiv.org/pdf/2207.07534.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac7ff6/pdf>

We investigate the source eruption, propagation and expansion characteristics, and heliospheric impacts of the **2020 November 29** coronal mass ejection (CME) and associated shock, using remote sensing and in situ observations from multiple spacecraft. A potential--field source--surface model is employed to examine the coronal magnetic fields surrounding the source region. The CME and associated shock are tracked from the early stage to the outer corona using extreme ultraviolet and white light observations. Forward models are applied to determine the structures and kinematics of the CME and the shock near the Sun. The shock shows an ellipsoidal structure, expands in all directions, and encloses the whole Sun as viewed from both SOHO and STEREO A, which results from the large expansion of the CME flux rope and its fast acceleration. The structure and potential impacts of the shock are mainly determined by its radial and lateral expansions. The CME and shock arrive at Parker Solar Probe and STEREO A. Only based on the remote sensing observations, it is difficult to predict whether and when the CME/shock would arrive at the Earth. Combining Wind in situ measurements and WSA-ENLIL simulation results, we confirm that the far flank of the CME (or the CME leg) arrives at the Earth with no shock signature. These results highlight the importance of multipoint remote sensing and in situ observations for determining the heliospheric impacts of CMEs.

### **Numerical Investigations of Catastrophe in Coronal Magnetic Configuration Triggered by Newly Emerging Flux**

Yuhao [Chen](#)<sup>1,2</sup>, Jing Ye<sup>1,3</sup>, Zhixing Mei<sup>1,3</sup>, Chengcai Shen<sup>4</sup>, Ilia I. Roussev<sup>5</sup>, Terry G. Forbes<sup>6</sup>, Jun Lin<sup>1,2,3</sup>, and Udo Ziegler<sup>7</sup>

2022 ApJ 933 148

<https://iopscience.iop.org/article/10.3847/1538-4357/ac73ef/pdf>

We performed 2D magnetohydrodynamical numerical experiments to study the response of the coronal magnetic configuration to the newly emerging magnetic flux. The configuration includes an electric-current-carrying flux rope modeling the prominence floating in the corona and the background magnetic field produced by two separated magnetic dipoles embedded in the photosphere. Parameters for one dipole are fixed in space and time to model the quiet background, and those for another one are time dependent to model the new flux. These numerical experiments duplicate important results of the analytic solution but also reveal new results. Unlike previous works, the configuration here possesses no symmetry, and the flux rope could move in any direction. The non-force-free environment causes the deviation of the flux rope equilibrium in the experiments from that determined in the analytic solution. As the flux rope radius decreases, the equilibrium could be found, and it evolves quasi-statically until the flux rope reaches the critical location at which the catastrophe occurs. As the radius increases, no equilibrium exists at all. During the catastrophe, two current sheets form in different ways. One forms as the surrounding closed magnetic field is stretched by the catastrophe, and another one forms as the flux rope squeezes the magnetic field nearby. Although reconnection happens in both the current sheets, it erases the first one quickly and enhances the second simultaneously. These results indicate the occurrence of the catastrophe in asymmetric and non-force-free environment, and the non-radial motion of the flux rope following the catastrophe.

An Extreme Ultraviolet (EUV) jet that occurred around 22:30 on **July 2, 2012** was observed by the Atmospheric Imaging Assembly (AIA) on-board the Solar Dynamics Observatory (SDO). There were two phases of the jet. In Phase 1, two blobs were observed. In Phase 2, the intensity of the jet was almost coherent initially. One minute later, three blobs were formed at the same time in the jet, and the width of the jet changed after the formation of these blobs. The formation and evolution processes of the blobs in these two phases are analyzed in this paper. The physical parameters of the blobs are determined. The measured width of the blobs is 0.8 – 2.3 Mm, and the apparent velocities of the blobs are from 59 km s<sup>-1</sup> to 185 km s<sup>-1</sup>. The formation mechanism of the blobs is likely to be tear-mode instability. **2012 July 2**

### **Solar Prominence Bubble and Plumes Caused By an Eruptive Magnetic Flux Rope**

<https://doi.org/10.3847/2041-8213/ac3bd0>

Prominence bubbles and plumes often form near the lower prominence--corona boundary. They are believed to play an important role in mass supply and evolution of solar prominences. However, how they form is still an open question. In this Letter we present a unique high-resolution H $\alpha$  observation of a quiescent prominence by the New Vacuum Solar Telescope. Two noteworthy bubble--plume events are studied in detail. The two events are almost identical, except that

an erupting mini filament appeared below the prominence–bubble interface in the second event, unlike the first one or any of the reported bubble observations. Analysis of the H $\alpha$  and extreme-ultraviolet data indicates that the rising magnetic flux rope (MFR) in the mini filament is the cause of bubble expansion and that the interaction between the prominence and MFR results in plume formation. These observations provided clear evidence that emerging MFR may be a common trigger of bubbles and suggested a new mechanism of plumes in addition to Rayleigh–Taylor instability and reconnection. **14 April 2021**

### **Partial Eruption, Confinement, and Twist Buildup and Release of a Double-decker Filament**

ApJ **923** 142 **2021**

<https://arxiv.org/pdf/2111.13174.pdf>

<https://doi.org/10.3847/1538-4357/ac2ba1>

We investigate the failed partial eruption of a filament system in NOAA AR 12104 on **2014 July 5**, using multiwavelength EUV, magnetogram, and H $\alpha$  observations, as well as magnetic field modeling. The filament system consists of two almost co-spatial segments with different end points, both resembling a C shape. Following an ejection and a precursor flare related to flux cancellation, only the upper segment rises and then displays a prominent twisted structure, while rolling over toward its footpoints. The lower segment remains undisturbed, indicating that the system possesses a double-decker structure. The erupted segment ends up with a reverse-C shape, with material draining toward its footpoints, while losing its twist. Using the flux rope insertion method, we construct a model of the source region that qualitatively reproduces key elements of the observed evolution. At the eruption onset, the model consists of a flux rope atop a flux bundle with negligible twist, which is consistent with the observational interpretation that the filament possesses a double-decker structure. The flux rope reaches the critical height of the torus instability during its initial relaxation, while the lower flux bundle remains in stable equilibrium. The eruption terminates when the flux rope reaches a dome-shaped quasi-separatrix layer that is reminiscent of a magnetic fan surface, although no magnetic null is found. The flux rope is destroyed by reconnection with the confining overlying flux above the dome, transferring its twist in the process.

### **Direct Observation of A Large-scale CME Flux Rope Event Arising from an Unwinding Coronal Jet**

[Hechao Chen](#), [Jiayan Yang](#), [Junchao Hong](#), [Haidong Li](#), [Yadan Duan](#)

ApJ **911** 33 **2021**

<https://arxiv.org/pdf/2102.13336.pdf> [File](#)

<https://doi.org/10.3847/1538-4357/abe6a8>

Coronal mass ejections (CMEs) and coronal jets are two types of common solar eruptive phenomena, which often independently happen at different spatial scales. In this work, we present a stereoscopic observation of a large-scale CME flux rope arising from an unwinding blowout jet in a multipolar complex magnetic system. Based on a multi-band observational analysis, we find that this whole event starts with a small filament whose eruption occurs at a coronal geyser site after a series of homologous jets. Aided by magnetic field extrapolations, it reveals that the coronal geyser site forms above an elongate opposite-polarity interface, where the emergence-driven photospheric flux cancellation and repetitive reconnection are responsible for those preceding recurrent jets and also contribute to the ultimate filament destabilization. By interacting with overlying fields, the erupting filament breaks one of its legs and results in an unwinding blowout jet. Our estimation suggests that around 1.4–2.0 turns of twist release in its jet spire. This prominent twist transport in jet spire rapidly creates a newborn larger-scale flux rope from the jet base to a remote site. Soon after its formation, this large-scale flux rope erupts towards the outer corona causing an Earth-directed CME. In its source region, two sets of distinct post-flare loops form in succession, indicating this eruption involves two-stage of flare magnetic reconnection. This work not only reveals a real magnetic coupling process between different eruptive activities but provides a new hint for understanding the creation of large-scale CME flux ropes during the solar eruption. **2 Jul 2012**

### **High-resolution Chromospheric Observations of a Solar Minifilament: Formation and Destabilization**

Hechao [Chen](#)<sup>1,2,3</sup>, Junchao Hong<sup>1,3,4</sup>, Bo Yang<sup>1,3</sup>, Zhe Xu<sup>5,3</sup>, and Jiayan Yang

**2020** ApJ 902 8

<https://doi.org/10.3847/1538-4357/abb1c1>

Using H $\alpha$  line core and off-band imaging data from the New Vacuum Solar Telescope in China, we present a high-resolution observation on the entire life cycle of a solar minifilament from its birth to its final eruption. We find that the minifilament originates from a series of cascade-like reconfigurations of chromospheric fine structures. During which, owing to strong photospheric shearing and converging flows near its polarity inversion line, basic short chromospheric fibrils first slowly coalesce to elongated dark threads, and then further create a longer filament channel in a "head-to-tail" linkage scenario. In this course, obvious magnetic flux cancellation simultaneously proceeds below it, and further facilitates its destabilization. In its onset phase, clear clues indicate that the minifilament first starts to rise without brightening signals; instead, after a slow-to-fast acceleration, obvious runaway reconnection soon takes over its final jet-like eruption. Besides, off-band observations further reveal that the formed minifilament has a possible flux-rope configuration, and chromospheric upflows that detected in its early forming phase persistently supplies cool plasma into

its channel. This observation is consistent with earlier observations and supports the view that both miniature and large-scale filaments may share analogous formation and destabilization mechanisms.

### **Coronal Mini-jets in an Activated Solar Tornado-like Prominence**

[Huadong Chen](#), [Jun Zhang](#), [Bart De Pontieu](#), [Suli Ma](#), [Bernhard Kliem](#), [Eric Priest](#)

ApJ 899 19 2020

<https://arxiv.org/pdf/2006.08252.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ab9cad/pdf>

High-resolution observations from the Interface Region Imaging Spectrometer (IRIS) reveal the existence of a particular type of small solar jets, which arose singly or in clusters from a tornado-like prominence suspended in the corona. In this study, we perform a detailed statistical analysis of 43 selected mini-jets in the tornado event. Our results show that the mini-jets typically have: (1) a projected length of 1.0-6.0 Mm, (2) a width of 0.2-1.0 Mm, (3) a lifetime of 10-50 s, (4) a velocity of 100-350 km s<sup>-1</sup>, and (5) an acceleration of 3-20 km s<sup>-2</sup>. Based on spectral diagnostics and EM-Loci analysis, these jets seem to be multi-thermal small-scale plasma ejections with an estimated average electron density of  $\sim 2.4 \times 10^{10}$  cm<sup>-3</sup> and an approximate mean temperature of  $\sim 2.6 \times 10^5$  K. Their mean kinetic energy density, thermal energy density and dissipated magnetic field strength are roughly estimated to be  $\sim 9$  erg cm<sup>-3</sup>, 3 erg cm<sup>-3</sup>, and 16 G, respectively. The accelerations of the mini-jets, the UV and EUV brightenings at the footpoints of some mini-jets, and the activation of the host prominence suggest that the tornado mini-jets are probably created by fine-scale external or internal magnetic reconnections (a) between the prominence field and the enveloping or background field or (b) between twisted or braided flux tubes within the prominence. The observations provide insight into the geometry of such reconnection events in the corona and have implications for the structure of the prominence magnetic field and the instability that is responsible for the eruption of prominences and coronal mass ejections. **2015 March 19-20**

### **Observational Analysis on the Early Evolution of a CME Flux-rope: Pre-flare reconnection and Flux-rope's Footpoint Drift**

Hechao [Chen](#), [Jiayan Yang](#), [Kaifan Ji](#), [Yadan Duan](#)

ApJ 887 118 2019

<https://arxiv.org/pdf/1911.00257.pdf>

<https://doi.org/10.3847/1538-4357/ab527e>

We study the early evolution of a hot-channel-like magnetic flux rope (MFR) toward eruption. Combining with imaging observation and magnetic field extrapolation, we find that the hot channel possibly originated from a pre-existing seed MFR with a hyperbolic flux tube (HFT). In the precursor phase, three-dimensional tether-cutting reconnection at the HFT is most likely resulting in the heating and buildup of the hot channel. In this process, the forming hot channel was rapidly enlarged at its spatial size and slipped its feet to two remote positions. Afterward, it instantly erupted outwards with an exponential acceleration, leaving two core dimmings near its feet. We suggest that pre-flare reconnection at the HFT played a crucial role in enlarging the seed MFR and facilitating the onset of its final solar eruption. Moreover, a recently predicted drifting of MFR's footpoints was detected at both core dimmings. In particular, we find that MFR's west footpoint drift was induced by a new reconnection geometry among the erupting MFR's leg and thereby inclined arcades. As MFR's west footpoints gradually drifted to a new position, a set of newborn atypical flare loops connected into the west core dimming, causing a rapid decrease of dimmed area inside this core dimming and also generating a secondary flare ribbon at their remote feet. This reveals that core dimmings may suffer a pronounced diminishment due to the eruptive MFR's footpoint drift, implying that mapping the real footpoints of the erupting MFR down to the Sun's surface is more difficult than previously thought. **2014 March 20**

### **Characteristics of a Gradual Filament Eruption and Subsequent CME Propagation in Relation to a Strong Geomagnetic Storm**

Chong [Chen](#), [Ying D. Liu](#), [Rui Wang](#), [Xiaowei Zhao](#), [Huidong Hu](#), [Bei Zhu](#)

ApJ 884:90 2019

<https://arxiv.org/pdf/1908.11100.pdf>

<https://sci-hub.se/10.3847/1538-4357/ab3f36>

An unexpected strong geomagnetic storm occurred on **2018 August 26**, which was caused by a slow coronal mass ejection (CME) from a gradual eruption of a large quiet-region filament. We investigate the eruption and propagation characteristics of this CME in relation to the strong geomagnetic storm with remote sensing and in situ observations. Coronal magnetic fields around the filament are extrapolated and compared with EUV observations. We determine the propagation direction and tilt angle of the CME flux rope near the Sun using a graduated cylindrical shell (GCS) model and the Sun-to-Earth kinematics of the CME with wide-angle imaging observations from STEREO A. We reconstruct the flux-rope structure using a Grad-Shafranov technique based on the in situ measurements at the Earth and compare it with those from solar observations and the GCS results. Our conclusions are as follows: (1) the eruption of the filament was unusually slow and occurred in the regions with relatively low critical heights of the coronal field decay index; (2) the axis of the CME flux rope rotated in the corona as well as in interplanetary space, which tended to be aligned with the local heliospheric current sheet; (3) the CME was bracketed between slow and fast solar winds, which enhanced the magnetic field inside the CME at 1 AU; (4) the geomagnetic storm was caused by the enhanced magnetic field and a southward orientation of the flux rope at 1 AU from the rotation of the flux rope.

## Observing Current Sheet Formation Forced by Non-radial Rotating Motion of Mini-filaments

Hechao [Chen](#)<sup>1,2,3</sup>, Jiayan Yang<sup>1,3</sup>, Yadan Duan<sup>4</sup>, and Kaifan Ji<sup>1,3</sup>

2019 *ApJ* 879 74

[sci-hub.se/10.3847/1538-4357/ab24ce](https://doi.org/10.3847/1538-4357/ab24ce)

In this paper, we study two externally forced magnetic reconnection events near NOAA active region 12494 for their current sheet (CS) formation. In both events, small-scale reconnection happened between mini-filaments and other preexisting magnetic fields. Initially, mini-filaments underwent obvious non-radial rotating motion due to their loss of equilibrium. With their clockwise/anti-clockwise rotation, the axial fluxes of the mini-filaments slowly came to squeeze the anti-parallel ambient fields, leading to an X-shaped structure. As the squeezing effect strengthened, CS regions gradually formed and grew in length, with a temperature around 1.8 MK. Afterward, clear cusp regions, plasma heating (~5 MK), and newborn magnetic structures came to be in sequence. Finally, mini-filaments erupted in a complex fashion due to the involvement of external reconnection. Based on the multiwavelength imaging observations, the apparent thickness/length, temperature/emission of the CS regions and their related plasma flows are carefully analyzed. Their reconnection rates are roughly estimated as 0.01–0.06 and 0.01–0.02. In particular, a chain of high-speed plasmoid ejections was detected along with a set of the reconnected field lines in Event1, implying the onset of tearing-mode instability inside its CS region. These observations indicate that non-radial rotating motion of filaments can serve as external flows to drive reconnection, and also provide a basic scenario of CS formation within small-scale magnetic reconnection processes. **2016 February 6**

## Untwisting and Disintegration of a Solar Filament Associated with Photospheric Flux Cancellation

Huadong [Chen](#), [Ruisheng Zheng](#), [Leping Li](#), [Suli Ma](#), [Yi Bi](#), [Shuhong Yang](#)

*ApJ* 871 229 2019

<https://arxiv.org/pdf/1812.07139.pdf>

Using the high-resolution observations from New Vacuum Solar Telescope (NVST) jointly with the Solar Dynamics Observatory data, we investigate two successive confined eruptions (Erup1 and Erup2) of a small filament in a decaying active region on **2017 November 10**. During the process of Erup1, the overlying magnetic arcade is observed to inflate with the rising filament at beginning and then stop the ongoing of the explosion. In the hot EUV channel, a coronal sigmoidal structure appears during the first eruption and fade away after the second one. The untwisting rotation and disintegration of the filament in Erup2 are clearly revealed by the NVST H<sub>α</sub> intensity data, hinting at a pre-existing twisted configuration of the filament. By tracking two rotating features in the filament, the average rotational angular velocity of the unwinding filament is found to be ~10.5 degree/min. A total twist of ~1.3 pi is estimated to be stored in the filament before the eruption, which is far below the criteria for kink instability. In the course of several hours prior to the event, some photospheric flux activities, including the flux convergence and cancellation, are detected around the northern end of the filament, where some small-scale EUV brightenings are also captured. Moreover, strongly-sheared transverse fields are found in the cancelling magnetic features from the vector magnetograms. Our observational results support the flux cancellation model, in which the interaction between the converging and sheared opposite-polarity fluxes destabilizes the filament and triggers the ensuing ejection.

## Witnessing tether-cutting reconnection at the onset of a partial eruption

Hechao [Chen](#), [Yadan Duan](#), [Jiayan Yang](#), [Bo Yang](#), [Jun Dai](#)

2018 *ApJ* 869 78

<https://arxiv.org/pdf/1811.01606.pdf>

[sci-hub.tw/10.3847/1538-4357/aaead1](https://doi.org/10.3847/1538-4357/aaead1)

In this paper, we study the onset process of a solar eruption on **21 February 2015**, focusing on its unambiguous precursor phase. With multi-wavelength imaging observations from the Atmospheric Imaging Assembly (AIA), definitive tether-cutting (TC) reconnection signatures, i.e., flux convergence and cancellation, bidirectional jets, as well as topology change of hot loops, were clearly observed below the pre-eruption filament. As TC reconnection progressed between the sheared arcades that enveloped the filament, a channel-like magnetic flux rope (MFR) arose in multi-wavelength AIA passbands wrapping around the main axis of the filament. With the subsequent ascent of the newborn MFR, the filament surprisingly split into three branches. After a 7-hour slow rise phase, the high-lying branch containing by the MFR abruptly accelerated causing a two-ribbon flare; while the two low-lying branches remained stable forming a partial eruption. Complemented by kinematic analysis and decay index calculation, we conclude that TC reconnection played a key role in building up the eruptive MFR and triggering its slow rise. The onset of the torus instability may have led the high-lying branch into the standard eruption scenario in the fashion of a catastrophe.

## Magnetic Reconnection Null Points as the Origin of Semi-relativistic Electron Beams in a Solar Jet

Bin [Chen](#), [Sijie Yu](#), [Marina Battaglia](#), [Samaiyah Farid](#), [Antonia Savcheva](#), [Katharine K. Reeves](#), [Säm Krucker](#), [T. S. Bastian](#), [Fan Guo](#), [Svetlin Tassev](#)

*ApJ* 866(1), 62 2018

<https://arxiv.org/pdf/1808.05951.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/aadb89/pdf>

[https://web.njit.edu/~binchen/download/publications/Chen+2018\\_TP3/Chen\\_et\\_al\\_2018\\_type3\\_apj.pdf](https://web.njit.edu/~binchen/download/publications/Chen+2018_TP3/Chen_et_al_2018_type3_apj.pdf)

Magnetic reconnection, the central engine that powers explosive phenomena throughout the Universe, is also perceived as one of the principal mechanisms for accelerating particles to high energies. Although various signatures of magnetic reconnection have been frequently reported, observational evidence that links particle acceleration directly to the reconnection site has been rare, especially for space plasma environments currently inaccessible to in situ measurements. Here we utilize broadband radio dynamic imaging spectroscopy available from the Karl G. Jansky Very Large Array to observe decimetric type III radio bursts in a solar jet with high angular ( $\sim 20''$ ), spectral ( $\sim 1\%$ ), and temporal resolution (50 milliseconds). These observations allow us to derive detailed trajectories of semi-relativistic (tens of keV) electron beams in the low solar corona with unprecedentedly high angular precision ( $< 0''.65$ ). We found that each group of electron beams, which corresponds to a cluster of type III bursts with 1-2-second duration, diverges from an extremely compact region ( $\sim 600\text{ km}^2$ ) in the low solar corona. The beam-diverging sites are located behind the erupting jet spire and above the closed arcades, coinciding with the presumed location of magnetic reconnection in the jet eruption picture supported by extreme ultraviolet/X-ray data and magnetic modeling. We interpret each beam-diverging site as a reconnection null point where multitudes of magnetic flux tubes join and reconnect. Our data suggest that the null points likely consist of a high level of density inhomogeneities possibly down to 10-km scales. These results, at least in the present case, strongly favor a reconnection-driven electron acceleration scenario. **2014 November 1**

## Diagnosing the magnetic field structure of a coronal cavity observed during the 2017 total solar eclipse

Yajie [Chen](#), [Hui Tian](#), [Yingna Su](#), [Zhongquan Qu](#), [Linhua Deng](#), [Patricia R. Jibben](#), [Zihao Yang](#), [Jingwen Zhang](#), [Tanmoy Samanta](#), [Jiansen He](#), [Linghua Wang](#), [Yingjie Zhu](#), [Yue Zhong](#), [Yu Liang](#)

ApJ **856** 21 **2018**

<https://arxiv.org/pdf/1802.04432.pdf>

We present an investigation of a coronal cavity observed above the western limb in the coronal red line Fe X 6374  $\{\AA\}$  using a telescope of Peking University and in the green line Fe XIV 5303  $\{\AA\}$  using a telescope of Yunnan Observatories, Chinese Academy of Sciences during the total solar eclipse on **2017 August 21**. A series of magnetic field models are constructed based on the magnetograms taken by the Helioseismic and Magnetic Imager onboard the Solar Dynamics Observatory (SDO) one week before the eclipse. The model field lines are then compared with coronal structures seen in images taken by the Atmospheric Imaging Assembly on board SDO and in our coronal red line images. The best-fit model consists of a flux rope with a twist angle of  $3.1\pi$ , which is consistent with the most probable value of the total twist angle of interplanetary flux ropes observed at 1 AU. Linear polarization of the Fe XIII 10747  $\{\AA\}$  line calculated from this model shows a "lagomorphic" signature that is also observed by the Coronal Multichannel Polarimeter of the High Altitude Observatory. We also find a ring-shaped structure in the line-of-sight velocity of Fe XIII 10747  $\{\AA\}$ , which implies hot plasma flows along a helical magnetic field structure, in the cavity. These results suggest that the magnetic structure of the cavity is a highly twisted flux rope, which may erupt eventually. The temperature structure of the cavity has also been investigated using the intensity ratio of Fe XIII 10747  $\{\AA\}$  and Fe X 6374  $\{\AA\}$ .

## Solar Tornadoes Triggered by Interaction between Filaments and EUV Jets

Huadong [Chen](#)<sup>1</sup>, Jun Zhang<sup>1</sup>, Suli Ma<sup>1,2</sup>, Xiaoli Yan<sup>3</sup>, and Jianchao Xue

**2017** ApJL **841** L13

<http://sci-hub.cc/10.3847/2041-8213/aa71a2>

We investigate the formations and evolutions of two successive solar tornadoes in/near AR 12297 during **2015 March 19–20**. Recurrent EUV jets close to two filaments were detected along a large-scale coronal loop prior to the appearances of the tornadoes. Under the disturbances from the activities, the filaments continually ascended and finally interacted with the loops tracked by the jets. Subsequently, the structures of the filaments and the loop were merged together, probably via magnetic reconnections, and formed tornado-like structures with a long spiral arm. Our observations suggest that solar tornadoes can be triggered by the interaction between filaments and nearby coronal jets, which has rarely been reported before. At the earlier development phase of the first tornado, about 30 small-scale sub-jets appeared in the tornado's arm, accompanied by local EUV brightenings. They have an ejection direction approximately vertical to the axis of the arm and a typical maximum speed of  $\sim 280\text{ km s}^{-1}$ . During the ruinations of the two tornadoes, fast plasma outflows from the strong EUV brightenings inside tornadoes are observed, in company with the unangling or unwinding of the highly twisted tornado structures. These observational features indicate that self reconnections probably occurred between the tangled magnetic fields of the tornadoes and resulted in the rapid disintegrations and disappearances of the tornadoes. According to the reconnection theory, we also derive the field strength of the tornado core to be  $\sim 8\text{ G}$ .

## Double Coronal X-ray and Microwave Sources Associated With A Magnetic Breakout Solar Eruption

Yao [Chen](#), Zhao Wu, Wei Liu, Richard A. Schwartz, Di Zhao, Bing Wang, Guohui Du

**2017**

<https://arxiv.org/pdf/1705.06074.pdf>

Double coronal hard X-ray (HXR) sources are believed to be critical observational evidence of bi-directional energy release through magnetic reconnection in a large-scale current sheet in solar ares. Here we present a study on double coronal sources observed in both HXR and microwave regimes, revealing new characteristics distinct from earlier reports. This event is associated with a footpoint-occulted X1.3-class flare (**25 April 2014**, starting at 00:17 UT) and a coronal mass ejection that are likely triggered by the magnetic breakout process, with the lower source extending upward from the top of the partially-occulted flare loops and the upper source co-incident with rapidly squeezing-in side lobes (at a speed of  $\sim 250$  km/s on both sides). The upper source can be identified at energies as high as 70-100 keV. The X-ray upper source is characterized by flux curves different from the lower source, a weak energy dependence of projected centroid altitude above 20 keV, a shorter duration and a HXR photon spectrum slightly-harder than those of the lower source. In addition, the microwave emission at 34 GHz also exhibits a similar double source structure and the microwave spectra at both sources are in line with gyro-synchrotron emission given by non-thermal energetic electrons. These observations, especially the co-occurrence of the very-fast squeezing-in motion of side lobes and the upper source, indicate that the upper source is associated with (possibly caused by) this fast motion of arcades. This sheds new lights on the origin of the corona double-source structure observed in both HXRs and microwaves.

### **A Complex Solar Coronal Jet with Two Phases**

Jie **Chen**, Jiangtao Su, Yuanyong Deng, E. R. Priest

ApJ **840** 54 **2017**

<https://arxiv.org/pdf/1704.02072.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/aa6c59/pdf>

Jets often occur repeatedly from almost the same location. In this paper, a complex solar jet was observed with two phases to the west of NOAA AR 11513 on **July 2nd, 2012**. If it had been observed at only moderate resolution, the two phases and their points of origin would have been regarded as identical. However, at high resolution we find the two phases merge into one another and the accompanying footpoint brightenings occur at different locations. The phases originate from different magnetic patches rather than being one phase originating from the same patch. Photospheric line of sight (LOS) magnetograms show that the bases of the two phases lie in two different patches of magnetic flux which decrease in size during the occurrence of the two phases. Based on these observations, we suggest the driving mechanism of the two successive phases is magnetic cancellation of two separate magnetic fragments with an opposite polarity fragment between them.

### **Undercover EUV Solar Jets Observed by the Interface Region Imaging Spectrograph**

N.-H. **Chen**, D. E. Innes

ApJ **833** 22 **2016**

<https://arxiv.org/pdf/1610.08149v1.pdf>

It is well-known that extreme ultraviolet emission emitted at the solar surface is absorbed by overlying cool plasma. Especially in active regions dark lanes in EUV images suggest that much of the surface activity is obscured. Simultaneous observations from IRIS, consisting of UV spectra and slit-jaw images give vital information with sub-arcsecond spatial resolution on the dynamics of jets not seen in EUV images. We studied a series of small jets from recently formed bipole pairs beside the trailing spot of active region 11991, which occurred on **2014 March 5** from 15:02:21 UT to 17:04:07 UT. There were collimated outflows with bright roots in the SJI 1400  $\{\AA\}$  (transition region) and 2796  $\{\AA\}$  (upper chromosphere) that were mostly not seen in AIA 304  $\{\AA\}$  (transition region) and AIA 171  $\{\AA\}$  (lower corona) images. The Si IV spectra show strong blue-wing but no red-wing enhancements in the line profiles of the ejecta for all recurrent jets indicating outward flows without twists. We see two types of Mg II line profiles produced by the jets spires: reversed and non-reversed. Mg II lines remain optically thick but turn into optically thin in the highly Doppler shifted wings. The energy flux contained in each recurrent jet is estimated using a velocity differential emission measure technique which measures the emitting power of the plasma as a function of line-of-sight velocity. We found that all the recurrent jets release similar energy ( $108 \text{ erg cm}^{-2} \text{ s}^{-1}$ ) toward the corona and the downward component is less than 3%.

### **IMAGING A MAGNETIC-BREAKOUT SOLAR ERUPTION**

Yao **Chen**<sup>1</sup>, Guohui Du<sup>1</sup>, Di Zhao<sup>1</sup>, Zhao Wu<sup>1</sup>, Wei Liu<sup>2</sup>, Bing Wang<sup>1</sup>, Guiping Ruan<sup>1</sup>, Shiwei Feng<sup>1</sup>, and Hongqiang Song

**2016** ApJ **820** L37

The fundamental mechanism initiating coronal mass ejections (CMEs) remains controversial. One of the leading theories is magnetic breakout, in which magnetic reconnection occurring high in the corona removes the confinement on an energized low-corona structure from the overlying magnetic field, thus allowing it to erupt. Here, we report critical observational evidence of this elusive breakout reconnection in a multi-polar magnetic configuration that leads to a CME and an X-class, long-duration flare. Its occurrence is supported by the presence of pairs of heated cusp-shaped loops around an X-type null point and signatures of reconnection inflows. Other peculiar features new to the breakout picture include sequential loop brightening, coronal hard X-rays at energies up to  $\sim 100$  keV, and extended high-corona X-rays above the later restored multi-polar structure. These observations, from a novel perspective with clarity never achieved before, present crucial clues to understanding the initiation mechanism of solar eruptions.

## **Tether-cutting Reconnection between Two Solar Filaments Triggering Outflows and a Coronal Mass Ejection**

Huadong **Chen**, Jun Zhang, Leping Li, Suli Ma

ApJLetter **818** L27 **2016**

<http://arxiv.org/pdf/1602.00378v1.pdf>

Triggering mechanisms of solar eruptions have long been a challenge. A few previous case studies have indicated that preceding gentle filament merging via magnetic reconnection may launch following intense eruption, according with the tether-cutting (TC) model. However, detailed process of TC reconnection between filaments has not been exhibited yet. In this work, we report the high resolution observations from the Interface Region Imaging Spectrometer (IRIS) of TC reconnection between two sheared filaments in NOAA active region 12146. The TC reconnection commenced since 15:35 UT on **2014 August 29** and triggered an eruptive GOES C4.3-class flare 8 minutes later. An associated coronal mass ejection appeared in the field of view of SOHO/LASCO C2 about 40 minutes later. Thanks to the high spatial resolution of IRIS data, bright plasma outflows generated by the TC reconnection are clearly observed, which moved along the subarcsecond fine-scale flux tube structures in the erupting filament. Based on the imaging and spectral observations, the mean plane-of-sky and line-of-sight velocities of the TC reconnection outflows are separately measured to be 79 and 86 km/s, which derives an average real speed of 120 km/s. In addition, it is found that spectral features, such as peak intensities, Doppler shifts, and line widths in the TC reconnection region evidently enhanced compared with those in the nearby region just before the flare.

## **RECURRENT SOLAR JETS INDUCED BY A SATELLITE SPOT AND MOVING MAGNETIC FEATURES**

Jie **Chen**<sup>1</sup>, Jiangtao Su<sup>1</sup>, Zhiqiang Yin<sup>1</sup>, T. G. Priya<sup>1,2</sup>, Hongqi Zhang<sup>1</sup>, Jihong Liu<sup>3</sup>, Haiqing Xu<sup>1</sup>, and Sijie Yu<sup>1</sup>

**2015** ApJ 815 71

Recurrent and homologous jets were observed to the west edge of active region NOAA 11513 at the boundary of a coronal hole. We find two kinds of cancellations between opposite polarity magnetic fluxes, inducing the generation of recurrent jets. First, a satellite spot continuously collides with a pre-existing opposite polarity magnetic field and causes recurrent solar jets. Second, moving magnetic features, which emerge near the sunspot penumbra, pass through the ambient plasma and eventually collide with the opposite polarity magnetic field. Among these recurrent jets, a blowout jet that occurred around 21:10 UT is investigated. The rotation of the pre-existing magnetic field and the shear motion of the satellite spot accumulate magnetic energy, which creates the possibility for the jet to experience blowout right from the standard.

## **Confined Flares in Solar Active Region 12192 from 2014 October 18 to 29**

Huadong **Chen**, Jun Zhang, Suli Ma, Shuhong Yang, Leping Li, Xin Huang, Junmin Xiao

ApJL **2015**

<http://arxiv.org/pdf/1507.00651v1.pdf>

Using the observations from the Atmospheric Imaging Assembly (AIA) and Helioseismic and Magnetic Imager (HMI) aboard the Solar Dynamics Observatory (SDO), we investigate six X-class and twenty-nine M-class flares occurring in solar active region (AR) 12192 from October 18 to 29. Among them, thirty (including six X- and twenty-four M-class) flares originated from the AR core and the other five M-flares appeared at the AR periphery. Four of the X-flares exhibited similar flaring structures, indicating they were homologous flares with analogous triggering mechanism. The possible scenario is: photospheric motions of emerged magnetic fluxes lead to shearing of the associated coronal magnetic field, which then yields a tether-cutting favorable configuration. Among the five periphery M-flares, four were associated with jet activities. The HMI vertical magnetic field data show that the photospheric fluxes of opposite magnetic polarities emerged, converged and canceled with each other at the footpoints of the jets before the flares. Only one M-flare from the AR periphery was followed by a coronal mass ejection (CME). From October 20 to 26, the mean decay index of the horizontal background field within the height range of 40?105 Mm is below the typical threshold for torus instability onset. This suggests that a strong confinement from the overlying magnetic field might be responsible for the poor CME production of AR 12192.

**Table 1.** X- and M-class flares in Solar AR 12192

## **Direct Observations of Tether-cutting Reconnection During a Major Solar Event From 2014 February 24 to 25**

Huadong **Chen**, Jun Zhang, Xin Cheng, Suli Ma, Shuhong Yang, Ting Li

ApJL, **797** L15 **2014**

<http://arxiv.org/pdf/1411.4454v1.pdf>

Using the multi-wavelength data from Atmospheric Imaging Assembly on board the Solar Dynamic Observatory, we investigated two successive solar flares, a C5.1 confined flare and an X4.9 ejective flare with a halo coronal mass

ejection, in NOAA AR 11990 from **2014 Feb 24 to 25**. Before the confined are onset, EUV brightening beneath the filament was detected. As the are began, a twisted helical flux rope (FR) wrapping around the filament moved upward and then stopped, and in the meantime an obvious X-ray source below it was observed. Prior to the ejective X4.9 flare, some pre-existing loop structures in the active region interacted with each other, which produced a brightening region beneath the filament. Meanwhile, a small flaring loop appeared below the interaction region and some new helical lines connecting the far ends of the loop structures was gradually formed and continually added into the former twisted FR. Then, due to the resulting imbalance between the magnetic pressure and tension, the new FR together with the filament erupted outward. Our observations coincide well with tether-cutting model, suggesting that the two flares probably have the same triggering mechanism, i.e., tether-cutting reconnection. To our knowledge, this is the first direct observation of tether-cutting reconnection occurring between the pre-existing loops in active region. In the ejective flare case, the erupting filament exhibited an omega-like kinked structure and underwent an exponential rise after a slow-rise phase, indicating the kink instability might be also responsible for the eruption initiation.

## **Direct Evidence of an Eruptive, Filament-Hosting Magnetic Flux Rope Leading to a Fast Solar Coronal Mass Ejection**

Bin **Chen**, Timothy S. Bastian, Dale E. Gary

ApJ, 794, 149 **2014**

<http://arxiv.org/pdf/1408.6473v1.pdf>

<https://iopscience.iop.org/article/10.1088/0004-637X/794/2/149/pdf>

[https://web.njit.edu/~binchen/download/publications/Chen+2014\\_MFR/Chen+2014\\_MFR.pdf](https://web.njit.edu/~binchen/download/publications/Chen+2014_MFR/Chen+2014_MFR.pdf)

Magnetic flux ropes (MFRs) are believed to be at the heart of solar coronal mass ejections (CMEs). A well-known example is the prominence cavity in the low corona that sometimes makes up a three-part white-light CME upon its eruption. Such a system, which is usually observed in quiet-Sun regions, has long been suggested to be the manifestation of an MFR with relatively cool filament material collecting near its bottom. However, observational evidence of eruptive, filament-hosting MFR systems has been elusive for those originating in active regions. By utilizing multi-passband extreme-ultra-violet (EUV) observations from SDO/AIA, we present direct evidence of an eruptive MFR in the low corona that exhibits a hot envelope and a cooler core; the latter is likely the upper part of a filament that undergoes a partial eruption, which is later observed in the upper corona as the coiled kernel of a fast, white-light CME. This MFR-like structure exists more than one hour prior to its eruption, and displays successive stages of dynamical evolution, in which both ideal and non-ideal physical processes may be involved. The timing of the MFR kinematics is found to be well correlated with the energy release of the associated long-duration C1.9 flare. **We suggest that the long-duration flare is the result of prolonged energy release associated with the vertical current sheet induced by the erupting MFR.** **2012 March 3**

## **Overlying Extreme-ultraviolet Arcades Preventing Eruption of a Filament Observed by AIA/SDO**

Huadong **Chen**<sup>1,2</sup>, Suli Ma<sup>1</sup>, and Jun Zhang

**2013** ApJ 778 70

Using the multi-wavelength data from the Atmospheric Imaging Assembly/Solar Dynamic Observatory (AIA/SDO) and the Sun Earth Connection Coronal and Heliospheric Investigation/Solar Terrestrial Relations Observatory (SECCHI/STEREO), we report a failed filament eruption in NOAA AR 11339 on **2011 November 3**. The eruption was associated with an X1.9 flare, but without any coronal mass ejection (CME), coronal dimming, or extreme ultraviolet (EUV) waves. Some magnetic arcades above the filament were observed distinctly in EUV channels, especially in the AIA 94 Å and 131 Å wavebands, before and during the filament eruption process. Our results show that the overlying arcades expanded along with the ascent of the filament at first until they reached a projected height of about 49 Mm above the Sun's surface, where they stopped. The following filament material was observed to be confined by the stopped EUV arcades and not to escape from the Sun. After the flare, a new filament formed at the low corona where part of the former filament remained before its eruption. These results support that the overlying arcades play an important role in preventing the filament from successfully erupting outward. We also discuss in this paper the EUV emission of the overlying arcades during the flare. It is rare for a failed filament eruption to be associated with an X1.9 class flare, but not with a CME or EUV waves. Therefore, this study also provides valuable insight into the triggering mechanism of the initiation of CMEs and EUV waves.

## **Statistical study of coronal mass ejection source locations: 2. Role of active regions in CME production**

**Chen**, Caixia; Wang, Yuming; Shen, Chenglong; Ye, Pinzhong; Zhang, Jie; Wang, S.

J. Geophys. Res., Vol. 116, No. A12, A12108, **2011**

<http://dx.doi.org/10.1029/2011JA016844>

<http://onlinelibrary.wiley.com/doi/10.1029/2011JA016844/pdf>

This is the second paper of the statistical study of coronal mass ejection (CME) source locations, in which the relationship between CMEs and active regions (ARs) is statistically studied on the basis of the information of CME source locations and the ARs automatically extracted from magnetic synoptic charts of Michelson Doppler Imager (MDI) during 1997–1998. Totally, 224 CMEs with a known location and 108 MDI ARs are included in our sample. It is found that about 63% of the CMEs are related with ARs, at least about 53% of the ARs produced one or more CMEs, and particularly about 14% of ARs are CME-rich (3 or more CMEs were generated) during one transit across the visible disk. Several issues are then tried to clarify: whether or not the CMEs originating from ARs are distinct from others, whether or not the CME kinematics depend on AR properties, and whether or not the CME productivity depends on AR properties. The statistical results suggest that (1) there is no evident difference between AR-related and non-AR-related CMEs in terms of CME speed, acceleration and width, (2) the size, strength and complexity of ARs do little with the kinematic properties of CMEs, but have significant effects on the CME productivity, and (3) the sunspots in all the most productive ARs at least belong to  $\beta\gamma$  type, whereas 90% of those in CME-less ARs are  $\alpha$  or  $\beta$  type only. A detailed analysis on CME-rich ARs further reveals that (1) the distribution of the waiting time of same-AR CMEs, consists of two parts with a separation at about 15 hours, which implies that the CMEs with a waiting time shorter than 15 hours are probably truly physical related, and (2) an AR tends to produce such related same-AR CMEs at a pace of 8 hours, but cannot produce two or more fast CMEs ( $>800 \text{ km s}^{-1}$ ) within a time interval of 15 hours. This interesting phenomenon is particularly discussed.

**Table 4. Most Productive ARs and Corresponding CMEs**

## Coronal Mass Ejections: Models and Their Observational Basis

Peng-Fei **Chen**

Living Rev. Solar Phys., 8, (2011), 1, File

**Review**

<http://solarphysics.livingreviews.org/Articles/lrsp-2011-1/> - best files and two movies

Coronal mass ejections (CMEs) are the largest-scale eruptive phenomenon in the solar system, expanding from active region-sized nonpotential magnetic structure to a much larger size. The bulk of plasma with a mass of  $\sim 10^{11} - 10^{13} \text{ kg}$  is hauled up all the way out to the interplanetary space with a typical velocity of several hundred or even more than  $1000 \text{ km s}^{-1}$ , with a chance to impact our Earth, resulting in hazardous space weather conditions. They involve many other much smaller-sized solar eruptive phenomena, such as X-ray sigmoids, filament/prominence eruptions, solar flares, plasma heating and radiation, particle acceleration, EIT waves, EUV dimmings, Moreton waves, solar radio bursts, and so on. It is believed that, by shedding the accumulating magnetic energy and helicity, they complete the last link in the chain of the cycling of the solar magnetic field. In this review, I try to explicate our understanding on each stage of the fantastic phenomenon, including their pre-eruption structure, their triggering mechanisms and the precursors indicating the initiation process, their acceleration and propagation. Particular attention is paid to clarify some hot debates, e.g., whether magnetic reconnection is necessary for the eruption, whether there are two types of CMEs, how the CME frontal loop is formed, and whether halo CMEs are special.

## A CORONAL SEISMOLOGICAL STUDY WITH STREAMER WAVES

Y. **Chen**<sup>1</sup>, S. W. Feng<sup>1</sup>, B. Li<sup>1</sup>, H. Q. Song<sup>1</sup>, L. D. Xia<sup>1</sup>, X. L. Kong<sup>1</sup>, and Xing Li<sup>2</sup>

Astrophysical Journal, 728:147 (6pp), 2011, File

We present a novel method to evaluate the Alfvén speed and the magnetic field strength along the streamer plasma sheet in the outer corona. The method is based on recent observations of streamer waves, which are regarded as the fast kink body mode carried by the plasma sheet structure and generated upon the impact of a fast coronal mass ejection (CME) on a nearby streamer. The mode propagates outward with a phase speed consisting of two components. One is the phase speed of the mode in the plasma rest frame and the other is the speed of the solar wind streaming along the plasma sheet. The former can be well represented by the Alfvén speed outside the plasma sheet, according to a linear wave dispersion analysis with a simplified slab model of magnetized plasmas. The radial profiles of the Alfvén speed can be deduced with constraints put on the speed of the solar wind, which is done by making use of the measurements of streamer blobs flowing passively in the wind. The radial profiles of the strength of the coronal magnetic field can be depicted once the electron density distribution is specified, this is done by inverting the observed polarized brightness data. Comparing the diagnostic results corresponding to the first wave trough and the following crest, we find that both the Alfvén speed and magnetic field strength at a fixed distance decline with time. This is suggestive of the recovering process of the CME-disturbed corona.

## STREAMER WAVES DRIVEN BY CORONAL MASS EJECTIONS

Y. **Chen**, H. Q. Song, B. Li, L. D. Xia, Z. Wu, H. Fu, and Xing Li<sup>1</sup>

Astrophysical Journal, 714:644–651, 2010 May; File

Between **2004 July 5 and July 7**, two intriguing fast coronal mass ejection (CME)–streamer interaction events were recorded by the Large Angle and Spectrometric Coronagraph. At the beginning of the events, the streamer was pushed aside from its equilibrium position upon the impact of the rapidly outgoing and expanding ejecta; then, the

streamer structure, mainly the bright streamer belt, exhibited elegant large-scale sinusoidal wavelike motions. The motions were apparently driven by the restoring magnetic forces resulting from the CME impingement, suggestive of magnetohydrodynamic kink mode propagating outward along the plasma sheet of the streamer. The mode is supported collectively by the streamer-plasma sheet structure and is therefore named “streamer wave” in the present study. With the white light coronagraph data, we show that the streamer wave has a period of about 1 hr, a wavelength varying from 2 to 4 solar radii, an amplitude of about a few tens of solar radii, and a propagating phase speed in the range 300–500 km s<sup>-1</sup>. We also find that there is a tendency for the phase speed to decline with increasing heliocentric distance. These observations provide good examples of large-scale wave phenomena carried by coronal structures and have significance in developing seismological techniques for diagnosing plasma and magnetic parameters in the outer corona.

## **Initiation and propagation of coronal mass ejections**

P. F. **Chen**

E-print, Feb 2008, **File**; J. Astron. & Astrophys.,

This paper reviews recent progress in the research on the initiation and propagation of CMEs. In the initiation part, several trigger mechanisms are discussed; In the propagation part, the **observations and modelings of EIT waves/dimmings**, as the EUV counterparts of CMEs, are described.

## **SOHO/SUMER Observations of Prominence Oscillation Before Eruption**

P. F. **Chen**, D. E. Innes, & S. K. Solanki

E-print, Feb 2008; A&A

[http://lanl.arxiv.org/PS\\_cache/arxiv/pdf/0802/0802.1961v1.pdf](http://lanl.arxiv.org/PS_cache/arxiv/pdf/0802/0802.1961v1.pdf)

Coronal mass ejections (CMEs), as a large-scale eruptive phenomenon, often reveal some precursors in the initiation phase, e.g., X-ray brightening, filament darkening, etc, which are useful for CME modeling and space weather forecast. With the SOHO/SUMER spectroscopic observations of the **2000 September 26** event, we propose another precursor for CME eruptions, namely, long-time prominence oscillations. The prominence oscillation-and-eruption event was observed by ground-based H $\alpha$  telescopes and space-borne white-light, EUV imaging and spectroscopic instruments. In particular, the SUMER slit was observing the prominence in a sit-and-stare mode. The observations indicate that a siphon flow was moving from the proximity of the prominence to a site at a projected distance of 270", which was followed by repetitive H $\alpha$  surges and continual prominence oscillations. The oscillation lasted 4 hours before the prominence erupted as a blob-like CME. The analysis of the multiwavelength data indicates that the whole series of processes fits well into the **emerging flux trigger mechanism for CMEs**. In this mechanism, emerging magnetic flux drives a siphon flow due to increased gas pressure where the background polarity emerges. It also drives H $\alpha$  surges through magnetic reconnection where the opposite polarity emerges. The magnetic reconnection triggers the prominence oscillations, as well as its loss of equilibrium, which finally leads to the eruption of the prominence. It is also found that the reconnection between the emerging flux and the pre-existing magnetic loop proceeds in an intermittent, probably quasi-periodic, way.

## **Two energy release processes for CMEs: MHD catastrophe and magnetic reconnection**

Y. **Chen**, Y.Q. Hu and L.D. Xia

[Advances in Space Research](#)

[Volume 40, Issue 12, 2007](#), Pages 1780-1786

It remains an open question how magnetic energy is rapidly released in the solar corona so as to create solar explosions such as solar flares and coronal mass ejections (CMEs). Recent studies have confirmed that a system consisting of a flux rope embedded in a background field exhibits a catastrophic behavior, and the energy threshold at the catastrophic point may exceed the associated open field energy. The accumulated free energy in the corona is abruptly released when the catastrophe takes place, and it probably serves as the main means of energy release for CMEs at least in the initial phase. Such a release proceeds via an ideal MHD process in contrast with nonideal ones such as magnetic reconnection. The catastrophe results in a sudden formation of electric current sheets, which naturally provide proper sites for fast magnetic reconnection. The reconnection may be identified with a solar flare associated with the CME on one hand, and produces a further acceleration of the CME on the other. On this basis, several preliminary suggestions are made for future observational investigations, especially with the proposed Kuafu satellites, on the roles of the MHD catastrophe and magnetic reconnection in the magnetic energy release associated with CMEs and flares.

<https://iopscience.iop.org/article/10.3847/2041-8213/acf3e4/pdf>

Coronal mass ejections (CMEs) are explosive plasma phenomena prevalently occurring on the Sun and probably on other magnetically active stars. However, how their pre-eruptive configuration evolves toward the main explosion remains elusive. Here, based on comprehensive observations of a long-duration precursor in an event on **2012 March 13**, we determine that the heating and slow rise of the pre-eruptive hot magnetic flux rope (MFR) are achieved through a precursor reconnection located above cusp-shaped high-temperature precursor loops. It is observed that the hot MFR threads are built up continually with their middle initially showing an "M" shape and then being separated from the cusp of precursor loops, causing the slow rise of the entire MFR. The slow rise in combination with thermal-dominated hard X-ray source concentrated at the top of the precursor loops shows that the precursor reconnection is much weaker than the flare reconnection of the main eruption. We also perform a three-dimensional magnetohydrodynamics simulation that reproduces the early evolution of the MFR transiting from the slow to fast rise. It is also disclosed that it is the magnetic tension force pertinent to "M"-shaped threads that drives the slow rise, which, however, evolves into a magnetic pressure gradient dominated regime responsible for the rapid-acceleration eruption.

<https://arxiv.org/pdf/2304.08725.pdf>

<https://www.nature.com/articles/s41467-023-37888-w.pdf>

Magnetic reconnection is a key mechanism involved in solar eruptions and is also a prime possibility to heat the low corona to millions of degrees. Here, we present ultra-high-resolution extreme ultraviolet observations of persistent null-point reconnection in the corona at a scale of about 390 km over one hour observations of the Extreme-Ultraviolet Imager on board **Solar Orbiter** spacecraft. The observations show formation of a null-point configuration above a minor positive polarity embedded within a region of dominant negative polarity near a sunspot. The gentle phase of the persistent null-point reconnection is evidenced by sustained point-like high-temperature plasma (about 10 MK) near the null-point and constant outflow blobs not only along the outer spine but also along the fan surface. The blobs appear at a higher frequency than previously observed with an average velocity of about 80 km/s and life-times of about 40 s. The null-point reconnection also occurs explosively but only for 4 minutes, its coupling with a mini-filament eruption generates a spiral jet. These results suggest that magnetic reconnection, at previously unresolved scales, proceeds continually in a gentle and/or explosive way to persistently transfer mass and energy to the overlying corona. **2022 March 3**

### **Initiation and Early Kinematic Evolution of Solar Eruptions**

**X. Cheng**, **J. Zhang**, **B. Kliem**, **T. {Török}**, **C. Xing**, **Z. J. Zhou**, **B. Inhester**, **M. D. Ding**

*ApJ* 894:85 2020

<https://arxiv.org/pdf/2004.03790.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ab886a/pdf>

We investigate the initiation and early evolution of 12 solar eruptions, including six active region hot channel and six quiescent filament eruptions, which were well observed by the \textsl{Solar Dynamics Observatory}, as well as by the \textsl{Solar TERrestrial RELations Observatory} for the latter. The sample includes one failed eruption and 11 coronal mass ejections, with velocities ranging from 493 to 2140~km~s<sup>-1</sup>. A detailed analysis of the eruption kinematics yields the following main results. (1) The early evolution of all events consists of a slow-rise phase followed by a main-acceleration phase, the height-time profiles of which differ markedly and can be best fit, respectively, by a linear and an exponential function. This indicates that different physical processes dominate in these phases, which is at variance with models that involve a single process. (2) The kinematic evolution of the eruptions tends to be synchronized with the flare light curve in both phases. The synchronization is often but not always close. A delayed onset of the impulsive flare phase is found in the majority of the filament eruptions (5 out of 6). This delay, and its trend to be larger for slower eruptions, favor ideal MHD instability models. (3) The average decay index at the onset heights of the main acceleration is close to the threshold of the torus instability for both groups of events (although based on a tentative coronal field model for the hot channels), suggesting that this instability initiates and possibly drives the main acceleration. **2011-03-08, 2011-09-12, 2011-09-22, 2012-01-23, 2012-08-31, 2012-11-23, 2013-03-16, 2013-05-22, 2013-08-20, 2013-09-29, 2014-02-25, 2014-09-02**

**Table 1.** CME/flare properties of 12 eruption events

## Unambiguous Evidence of Filament Splitting-Induced Partial Eruptions

X. Cheng, B. Kliem, M. D. Ding

ApJ 856:48 2018

<https://arxiv.org/pdf/1802.04932.pdf>

<http://iopscience.iop.org/article/10.3847/1538-4357/aab08d/pdf>

Coronal mass ejections are often considered to result from the full eruption of a magnetic flux rope (MFR). However, it is recognized that, in some events, the MFR may release only part of its flux, with the details of the implied splitting not completely established due to limitations in observations. Here, we investigate two partial eruption events including a confined and a successful one. Both partial eruptions are a consequence of the vertical splitting of a filament-hosting MFR involving internal reconnection. A loss of equilibrium in the rising part of the magnetic flux is suggested by the impulsive onset of both events and by the delayed onset of reconnection in the confined event. The remaining part of the flux might be line-tied to the photosphere in a bald patch separatrix surface, and we confirm the existence of extended bald-patch sections for the successful eruption. The internal reconnection is signified by brightenings in the body of one filament and between the rising and remaining parts of both filaments. It evolves quickly into the standard current sheet reconnection in the wake of the eruption. As a result, regardless of being confined or successful, both eruptions produce hard X-ray sources and flare loops below the erupting but above the surviving flux, as well as a pair of flare ribbons enclosing the latter. **2014-12-24, 2015-11-04**

## Origin and Structures of Solar Eruptions I: Magnetic Flux Rope

(Invited **Review**)

Cheng, Xin; Guo, Yang; Ding, MingDe

Science China Earth Sciences, Volume 60, p. 1383-1407, 2017

<https://link.springer.com/content/pdf/10.1007%2Fs11430-017-9074-6.pdf>

<https://arxiv.org/pdf/1705.08198.pdf>

Coronal mass ejections (CMEs) and solar flares are the large-scale and most energetic eruptive phenomena in our solar system and able to release a large quantity of plasma and magnetic flux from the solar atmosphere into the solar wind. When these high-speed magnetized plasmas along with the energetic particles arrive at the Earth, they may interact with the magnetosphere and ionosphere, and seriously affect the safety of human high-tech activities in outer space. The travel time of a CME to 1 AU is about 1-3 days, while energetic particles from the eruptions arrive even earlier. An efficient forecast of these phenomena therefore requires a clear detection of CMEs/flares at the stage as early as possible. To estimate the possibility of an eruption leading to a CME/flare, we need to elucidate some fundamental but elusive processes including in particular the origin and structures of CMEs/flares. Understanding these processes can not only improve the prediction of the occurrence of CMEs/flares and their effects on geospace and the heliosphere but also help understand the mass ejections and flares on other solar-type stars. The main purpose of this review is to address the origin and early structures of CMEs/flares, from multi-wavelength observational perspective. First of all, we start with the ongoing debate of whether the pre-eruptive configuration, i.e., a helical magnetic flux rope (MFR), of CMEs/flares exists before the eruption and then emphatically introduce observational manifestations of the MFR. Secondly, we elaborate on the possible formation mechanisms of the MFR through distinct ways. Thirdly, we discuss the initiation of the MFR and associated dynamics during its evolution toward the CME/flare. Finally, we come to some conclusions and put forward some prospects in the future. **2011-07-03, 2012-07-07, 2012-07-14, 2013-05-22**

The multi-wavelength observations of the origin and structures of CMEs, ares, and magnetic flux ropes are presented.

## On the Characteristics of Footpoints of Solar Magnetic Flux Ropes during the Eruption

X. **Cheng**, M. D. Ding

ApJ Supplement Series **2016**

<http://arxiv.org/pdf/1605.04047v1.pdf>

We investigate the footpoints of four erupted magnetic flux ropes (MFRs) that appear as sigmoidal hot channels prior to the eruptions in the Atmospheric Imaging Assembly high temperature passbands. The simultaneous Helioseismic and Magnetic Imager observations disclose that one footpoint of the MFRs originates in the penumbra or penumbra edge with a stronger magnetic field, while the other in the moss region with a weaker magnetic field. The significant deviation of the axis of the MFRs from the main polarity inversion lines and associated filaments suggests that the MFRs have ascended to a high altitude, thus being distinguishable from the source sigmoidal ARs. The more interesting thing is that, with the eruption of the MFRs, the average inclination angle and direct current at the footpoints with stronger magnetic field tend to decrease, which is suggestive of a straightening and untwisting of the magnetic field in the MFR legs. Moreover, the associated flare ribbons also display an interesting evolution. They initially appear as sporadic brightenings at the two footpoints of and in the regions below the MFRs and then quickly extend to two slender sheared J-shaped ribbons with the two hooks corresponding to the two ends of the MFRs. Finally, the straight parts of the two ribbons separate from each other, evolving into two widened parallel ones. These features mostly conform to and support the recently proposed three-dimensional standard CME/flare model, i.e., the twisted MFR eruption stretches and leads to the reconnection of the overlying field that transits from a strong to weak shear with the increasing height. **2012-07-12, 2013-04-11, 2014-04-18, 2014-09-10**

### **Spectroscopic Diagnostics of Solar Magnetic Flux Ropes Using Iron Forbidden Line**

X. **Cheng**, M. D. Ding

ApJL 823 L4 **2016**

<http://arxiv.org/pdf/1605.00195v1.pdf>

In this Letter, we present Interface Region Imaging Spectrograph Fe XXI 1354.08 Å forbidden line emission of two magnetic flux ropes (MFRs) that caused two fast coronal mass ejections with velocities of  $\geq 1000$  km s<sup>-1</sup> and strong flares (X1.6 and M6.5) on 2014 September 10 and **2015 June 22**, respectively. The EUV images at the 131 Å and 94 Å passbands provided by the Atmospheric Imaging Assembly on board Solar Dynamics Observatory reveal that both MFRs initially appear as suspended hot channel-like structures. Interestingly, part of the MFRs is also visible in the Fe XXI 1354.08 forbidden line, even prior to the eruption, e.g., for the **SOL2014-09-10** event. However, the line emission is very weak and that only appears at a few locations but not the whole structure of the MFRs. This implies that the MFRs could be comprised of different threads with different temperatures and densities, based on the fact that the formation of the Fe XXI forbidden line requires a critical temperature ( $\sim 11.5$  MK) and density. Moreover, the line shows a non-thermal broadening and a blueshift in the early phase. It suggests that magnetic reconnection at that time has initiated; it not only heats the MFR and, at the same time, produces a non-thermal broadening of the Fe XXI line but also produces the poloidal flux, leading to the ascending of the MFRs.

### **A Two-ribbon White-light Flare Associated with a Failed Solar Eruption Observed by ONSET, SDO, and IRIS**

ApJ 809 46 **2015**

<http://arxiv.org/pdf/1507.02109v1.pdf>

Two-ribbon brightenings are one of the most remarkable characteristics of an eruptive solar flare and are often used for predicting the occurrence of coronal mass ejections (CMEs). Nevertheless, it was called in question recently whether all two-ribbon flares are eruptive. In this paper, we investigate a two ribbon-like white-light (WL) flare that is associated with a failed magnetic flux rope (MFR) eruption on **2015 January 13**, which has no accompanying CME in the WL coronagraph. Observations by *Optical and Near-infrared Solar Eruption Tracer* and *Solar Dynamics Observatory* reveal that, with the increase of the flare emission and the acceleration of the unsuccessfully erupting MFR, two isolated kernels appear at the WL 3600 Å passband and quickly develop into two elongated ribbon-like structures. The evolution of the WL continuum enhancement is completely coincident in time with the variation of *Fermi* hard X-ray 26–50 keV flux. Increase of continuum emission is also clearly visible at the whole FUV and NUV passbands observed by *Interface Region Imaging Spectrograph*. Moreover, in one WL kernel, the  $\text{Si IV}$ ,  $\text{C II}$ , and  $\text{Mg II}$  h/k lines display significant enhancement and non-thermal broadening. However, their Doppler velocity pattern is location-dependent. At the strongly bright pixels, these lines exhibit a blueshift; while at moderately bright ones, the lines are generally redshifted. These results show that the failed MFR eruption is also able to produce a two-ribbon flare and high-energy electrons that heat the lower atmosphere, causing the enhancement of the WL and FUV/NUV continuum emissions and chromospheric evaporation.

### **Imaging and Spectroscopic Diagnostics on the Formation of Two Magnetic Flux Ropes Revealed by SDO/AIA and IRIS**

X. Cheng, M. D. Ding, C. Fang

ApJ 804 82 2015

<http://arxiv.org/pdf/1502.07801v1.pdf>

Helical magnetic flux rope (MFR) is a fundamental structure of corona mass ejections (CMEs) and has been discovered recently to exist as a sigmoidal channel structure prior to its eruption in the extreme ultraviolet (EUV) high temperature passbands of the Atmospheric Imaging Assembly (AIA). However, when and where the MFR is built up are still elusive. In this paper, we investigate two MFRs (MFR1 and MFR2) in detail, whose eruptions produced two energetic solar flares and CMEs on **2014 April 18** and **2014 September 10**, respectively. The AIA EUV images reveal that for a long time prior to their eruption, both MFR1 and MFR2 are under formation, which is probably through magnetic reconnection between two groups of sheared arcades driven by the shearing and converging flows in the photosphere near the polarity inversion line. At the footpoints of the MFR1, the Interface Region Imaging Spectrograph Si IV, C II, and Mg II lines exhibit weak to moderate redshifts and a non-thermal broadening in the pre-flare phase. However, a relatively large blueshift and an extremely strong non-thermal broadening are found at the formation site of the MFR2. These spectral features consolidate the proposition that the reconnection plays an important role in the formation of MFRs. For the MFR1, the reconnection outflow may propagate along its legs, penetrating into the transition region and the chromosphere at the footpoints. For the MFR2, the reconnection probably takes place in the lower atmosphere and results in the strong blueshift and non-thermal broadening for the Mg II, C II, and Si IV lines.

### **On the Relationship Between a Hot-channel-like Solar Magnetic Flux Rope and its embedded Prominence**

X. Cheng, M. D. Ding, J. Zhang, A. K. Srivastava, Y. Guo, P. F. Chen, J. Q. Sun

2014, ApJ Letters, 789 L35

<http://arxiv.org/pdf/1406.4196v1.pdf>

Magnetic flux rope (MFR) is a coherent and helical magnetic field structure that is recently found probably to appear as an elongated hot-channel prior to a solar eruption. In this paper, we investigate the relationship between the hot-channel and associated prominence through analyzing a limb event on **2011 September 12**. In the early rise phase, the hot-channel was cospatial with the prominence initially. It then quickly expanded, resulting in a separation of the top of the hot-channel from that of the prominence. Meanwhile, both of them experienced an instantaneous morphology transformation from a  $\Lambda$  shape to a reversed-Y shape and the top of these two structures showed an exponential increase in height. These features are a good indication for the occurrence of the kink instability. Moreover, the onset of the kink instability is found to coincide in time with the impulsive enhancement of the flare emission underneath the hot-channel, suggesting that the ideal kink instability likely also plays an important role in triggering the fast flare reconnection besides initiating the impulsive acceleration of the hot-channel and distorting its morphology. We conclude that the hot-channel is most likely the MFR system and the prominence only corresponds to the cool materials that are collected in the bottom of the helical field lines of the MFR against the gravity.

### **Formation of a Double-decker Magnetic Flux Rope in the Sigmoidal Solar Active Region 11520**

X. Cheng, M. D. Ding, J. Zhang, X. D. Sun, Y. Guo, Y. M. Wang, B. Kliem, Y. Y. Deng

E-print, May 2014; ApJ 2014 789 93

<http://arxiv.org/pdf/1405.4923v1.pdf>

In this paper, we address the formation of a magnetic flux rope (MFR) that erupted on **2012 July 12** and caused a strong geomagnetic storm event on July 15. Through analyzing the long-term evolution of the associated active region observed by the Atmospheric Imaging Assembly and the Helioseismic and Magnetic Imager on board the Solar Dynamics Observatory, it is found that the twisted field of an MFR, indicated by a continuous S-shaped sigmoid, is built up from two groups of sheared arcades near the main polarity inversion line half day before the eruption. The temperature within the twisted field and sheared arcades is higher than that of the ambient volume, suggesting that magnetic reconnection most likely works there. The driver behind the reconnection is attributed to shearing and converging motions at magnetic footpoints with velocities in the range of 0.1--0.6 km s<sup>-1</sup>. The rotation of the preceding sunspot also contributes to the MFR buildup. Extrapolated three-dimensional non-linear force-free field structures further reveal the locations of the reconnection to be in a bald-patch region and in a hyperbolic flux tube. About two hours before the eruption, indications for a second MFR in the form of an S-shaped hot channel are seen. It lies above the original MFR that continuously exists and includes a filament. The whole structure thus makes up a stable double-decker MFR system for hours prior to the eruption. Eventually, after entering the domain of instability, the high-lying MFR impulsively erupts to generate a fast coronal mass ejection and X-class flare; while the low-lying MFR remains behind and continuously maintains the sigmoidicity of the active region.

### **Tracking the Evolution of A Coherent Magnetic Flux Rope Continuously from the Inner to the Outer Corona**

X. **Cheng**, M. D. Ding, Y. Guo, J. Zhang, A. Vourlidas, Y. D. Liu, O. Olmedo, J. Q. Sun, and C. Li  
E-print, Oct 2013, **File**; 2014 ApJ 780 28

[http://sprg.ssl.berkeley.edu/~liuxying/pubs/2014\\_apj\\_cheng.pdf](http://sprg.ssl.berkeley.edu/~liuxying/pubs/2014_apj_cheng.pdf)

The magnetic flux rope (MFR) is believed to be the underlying magnetic structure of coronal mass ejections (CMEs). However, it remains unclear how an MFR evolves into and forms the multi-component structure of a CME. In this paper, we perform a comprehensive study of an extreme-ultraviolet (EUV) MFR eruption on **2013 May 22** by tracking its morphological evolution, studying its kinematics, and quantifying its thermal property. As EUV brightenings begin, the MFR starts to rise slowly and shows helical threads winding around an axis. Meanwhile, cool filamentary materials descend spirally down to the chromosphere. These features provide direct observational evidence of intrinsically helical structure of the MFR. Through detailed kinematical analysis, we find that the MFR evolution experiences two distinct phases: a slow rise phase and an impulsive acceleration phase. We attribute the first phase to the magnetic reconnection within the quasi-separatrix-layers surrounding the MFR, and the much more energetic second phase to the fast magnetic reconnection underneath the MFR. We suggest that the transition between these two phases be caused by the torus instability. Moreover, we identify that the MFR evolves smoothly into the outer corona and appears as a coherent structure within the white light CME volume. The MFR in the outer corona was enveloped by bright fronts that originated from plasma pile-up in front of the expanding MFR. The fronts are also associated with the preceding sheath region followed the outmost MFR-driven shock.

### **Investigating Two Successive Flux Rope Eruptions In A Solar Active Region**

X. **Cheng**, J. Zhang, M. D. Ding, O. Olmedo, X. D. Sun, Y. Guo & Y. Liu

E-print, April 2013; ApJL 2013 ApJ 769 L25

[http://sprg.ssl.berkeley.edu/~liuxying/pubs/2013\\_apj\\_cheng2.pdf](http://sprg.ssl.berkeley.edu/~liuxying/pubs/2013_apj_cheng2.pdf)

We investigate two successive flux rope (FR1 and FR2) eruptions resulting in two coronal mass ejections (CMEs) on **2012 January 23**. Both FRs appeared as an EUV channel structure in the images of high temperature passbands of the Atmospheric Imaging Assembly prior to the CME eruption. Through fitting their height evolution with a function consisting of linear and exponential components, we determine the onset time of the FR impulsive acceleration with high temporal accuracy for the first time. Using this onset time, we divide the evolution of the FRs in the low corona into two phases: a slow rise phase and an impulsive acceleration phase. In the slow rise phase of the FR1, the appearance of sporadic EUV and UV brightening and the strong shearing along the polarity inverse line indicates that the quasi-separatrix-layer reconnection likely initiates the slow rise. On the other hand for the FR2, we mainly contribute its slow rise to the FR1 eruption, which partially opened the overlying field and thus decreased the magnetic restriction. At the onset of the impulsive acceleration phase, the FR1 (FR2) reaches the critical height of 84.4pm11.2 Mm (86.2pm13.0 Mm) where the decline of the overlying field with height is fast enough to trigger the torus instability. After a very short interval (~2 minutes), the flare emission began to enhance. These results reveal the compound activity involving multiple magnetic FRs and further suggest that the ideal torus instability probably plays the essential role of initiating the impulsive acceleration of CMEs.

### **THE DRIVER OF CORONAL MASS EJECTIONS IN THE LOW CORONA: A FLUX ROPE**

X. **Cheng**<sup>1,2,3</sup>, J. Zhang<sup>2</sup>, M. D. Ding<sup>1,3</sup>, Y. Liu<sup>4,5</sup>, and W. Poomvises

2013 ApJ 763 43, **File**

[http://sprg.ssl.berkeley.edu/~liuxying/pubs/2013\\_apj\\_cheng.pdf](http://sprg.ssl.berkeley.edu/~liuxying/pubs/2013_apj_cheng.pdf)

Recent Solar Dynamic Observatory observations reveal that coronal mass ejections (CMEs) consist of a multi-temperature structure: a hot flux rope and a cool leading front (LF). The flux rope first appears as a twisted hot channel in the Atmospheric Imaging Assembly (AIA) 94 Å and 131 Å passbands. The twisted hot channel initially lies along the polarity inversion line and then rises and develops into a semi-circular flux-rope-like structure during the impulsive acceleration phase of CMEs. In the meantime, the rising hot channel compresses the surrounding magnetic field and plasma, which successively stack into the CME LF. In this paper, we study in detail two well-observed CMEs that occurred on **2011 March 7 and 2011 March 8**, respectively. Each of them is associated with an M-class flare. Through a kinematic analysis we find that (1) the hot channel rises earlier than the first appearance of the CME LF and the onset of the associated flare and (2) the speed of the hot channel is always faster than that of the LF, at least in the field of view of AIA. Thus, the hot channel acts as a continuous driver of the CME formation and eruption in the early acceleration phase. Subsequently, the two CMEs in white-light images can be well reproduced by the graduated cylindrical shell flux rope model. These results suggest that the pre-existing flux rope plays a key role in CME initiation and formation.

### **DIFFERENTIAL EMISSION MEASURE ANALYSIS OF MULTIPLE STRUCTURAL COMPONENTS OF CORONAL MASS EJECTIONS IN THE INNER CORONA**

X. **Cheng**<sup>1,2,3</sup>, J. Zhang<sup>2</sup>, S. H. Saar<sup>4</sup>, and M. D. Ding

2012 ApJ 761 62

In this paper, we study the temperature and density properties of multiple structural components of coronal mass ejections (CMEs) using differential emission measure (DEM) analysis. The DEM analysis is based on the six-passband EUV observations of solar corona from the Atmospheric Imaging Assembly on board the Solar Dynamic Observatory. The structural components studied include the hot channel in the core region (presumably the magnetic flux rope of the CME), the bright loop-like leading front (LF), and coronal dimming in the wake of the CME. We find that the presumed flux rope has the highest average temperature (>8 MK) and density ( $\sim 1.0 \times 10^9 \text{ cm}^{-3}$ ), resulting in an enhanced

emission measure over a broad temperature range ( $3 \leq T(\text{MK}) \leq 20$ ). On the other hand, the CME LF has a relatively cool temperature ( $\sim 2$  MK) and a narrow temperature distribution similar to the pre-eruption coronal temperature ( $1 \leq T(\text{MK}) \leq 3$ ). The density in the LF, however, is increased by 2%-32% compared with that of the pre-eruption corona, depending on the event and location. In coronal dimmings, the temperature is more broadly distributed ( $1 \leq T(\text{MK}) \leq 4$ ), but the density decreases by  $\sim 35\% \sim 40\%$ . These observational results show that: (1) CME core regions are significantly heated, presumably through magnetic reconnection; (2) CME LFs are a consequence of compression of ambient plasma caused by the expansion of the CME core region; and (3) the dimmings are largely caused by the plasma rarefaction associated with the eruption.

## **INVESTIGATION OF THE FORMATION AND SEPARATION OF AN EXTREME-ULTRAVIOLET WAVE FROM THE EXPANSION OF A CORONAL MASS EJECTION**

X. Cheng<sup>1,2,3</sup>, J. Zhang<sup>2</sup>, O. Olmedo<sup>4</sup>, A. Vourlidas<sup>5</sup>, M. D. Ding<sup>1,3</sup>, and Y. Liu

2012 ApJ 745 L5, [File](#)

We address the nature of EUV waves through direct observations of the formation of a diffuse wave driven by the expansion of a coronal mass ejection (CME) and its subsequent separation from the CME front. The wave and the CME on **2011 June 7** were well observed by the Atmospheric Imaging Assembly on board the Solar Dynamics Observatory. Following the solar eruption onset, marked by the beginning of the rapid increasing of the CME velocity and the X-ray flux of accompanying flare, the CME exhibits a strong lateral expansion. During this impulsive expansion phase, the expansion speed of the CME bubble increases from  $100 \text{ km s}^{-1}$  to  $450 \text{ km s}^{-1}$  in only six minutes. An important finding is that a diffuse wave front starts to separate from the front of the expanding bubble shortly after the lateral expansion slows down. Also a type II burst is formed near the time of the separation. After the separation, two distinct fronts propagate with different kinematic properties. The diffuse front travels across the entire solar disk, while the sharp front rises up, forming the CME ejecta with the diffuse front ahead of it. These observations suggest that the previously termed EUV wave is a composite phenomenon and driven by the CME expansion. While the CME expansion is accelerating, the wave front is cospatial with the CME front, thus the two fronts are indiscernible. Following the end of the acceleration phase, the wave moves away from the CME front with a gradually increasing distance between them.

## **Observing Flux Rope Formation During the Impulsive Phase of a Solar Eruption**

X. Cheng, J. Zhang, Y. Liu, M. D. Ding

E-print, March 2011; ApJ Letters 2011 732 L25, [File](#)

Magnetic flux rope is believed to be an important structural component of coronal mass ejections (CMEs). While there exist much observational evidence of the flux rope after the eruption, e.g., as seen in remote-sensing coronagraph images or in-situ solar wind data, the direct observation of flux ropes during CME impulsive phase has been rare. In this Letter, we present an unambiguous observation of a flux rope still in the formation phase in the low corona. The CME of interest occurred above the east limb on **2010 November 03** with footpoints partially blocked. The flux rope was seen as a bright blob of hot plasma in AIA 131Å passband (peak temperature  $\sim 11$  MK) rising from the core of the source active region, rapidly moving outward and stretching upward the surrounding background magnetic field. The stretched magnetic field seemed to curve-in behind the core, similar to the classical magnetic reconnection scenario in eruptive flares. On the other hand, the flux rope appeared as a dark cavity in AIA 211Å passband (2.0 MK) and 171Å passband (0.6 MK); in these relatively cool temperature bands, a bright rim clearly enclosed the dark cavity. The bright rim likely represents the pile-up of the surrounding coronal plasma compressed by the expanding flux rope. The composite structure seen in AIA multiple temperature bands is very similar to that in the corresponding coronagraph images, which consists of a bright leading edge and a dark cavity, commonly believed to be a flux rope.

## **A Comparative Study of Confined and Eruptive Flares in NOAA AR 10720**

X. Cheng, J. Zhang, M. D. Ding, Y. Guo, and J. T. Su

E-print March 2011, ApJ

We investigate the distinct properties of two types of flares: eruptive flares associated with CMEs and confined flares without CMEs. Our sample of study includes nine M and X-class flares, all from the same active region (AR), six of which are confined and three others are eruptive. The confined flares tend to be more impulsive in the soft X-ray time profiles and show more slender shapes in the EIT 195 Å images, while the eruptive ones are of long-duration events and show much more extended brightening regions. The location of the confined flares are closer to the center of the AR, while the eruptive flares are at the outskirts. This difference is quantified by the displacement parameter, the distance between the AR center and the flare location: the average displacement of the six confined flares is 16 Mm, while that of eruptive ones is as large as 39 Mm. Further, through nonlinear force-free field extrapolation, we find that the decay index of the transverse magnetic field in the low corona ( $\sim 10$  Mm) have a larger value for eruptive flares than that for confined one. In addition, the strength of the transverse magnetic field over the eruptive flare sites is weaker than that over the confined ones. These results demonstrate that the strength and the decay index of background magnetic field may determine whether or not a flare be eruptive or confined. The implication of these results on CME models is discussed in the context of torus instability of flux rope.

14-17Jan 2005

## **Re-flaring of a Post-Flare Loop System Driven by Flux Rope Emergence and Twisting**

X. [Cheng](#), M. D. Ding, Y. Guo, J. Zhang, J. Jing, T. Wiegelmann

E-print, 11 May 2010, *ApJL*

In this letter, we study in detail the evolution of the post-flare loops on **2005 January 15** that occurred between two consecutive solar eruption events, both of which generated a fast halo CME and a major flare. The post-flare loop system, formed after the first CME/flare eruption, evolved rapidly, as manifested by the unusual accelerating rise motion of the loops. Through nonlinear force-free field (NLFFF) models, we obtain the magnetic structure over the active region. It clearly shows that the flux rope below the loops also kept rising accompanied with increasing twist and length. Finally, the post-flare magnetic configuration evolved to a state that resulted in the second CME/flare eruption. This is an event in which the post-flare loops can re-flare in a short period of  $\sim 16$  hr following the first CME/flare eruption. The observed re-flaring at the same location is likely driven by the rapid evolution of the flux rope caused by the magnetic flux emergence and the rotation of the sunspot. This observation provides valuable information on CME/flare models and their prediction.

## **A STATISTICAL STUDY OF THE POST-IMPULSIVE-PHASE ACCELERATION OF FLARE-ASSOCIATED CORONAL MASS EJECTIONS**

X. [Cheng](#)<sup>1</sup>, J. Zhang<sup>1,2</sup>, M. D. Ding<sup>1</sup>, and W. Poomvises<sup>2</sup>

*Astrophysical Journal*, 712:752–760, 2010 March, **File**

It is now generally accepted that the impulsive acceleration of a coronal mass ejection (CME) in the inner corona is closely correlated in time with the main energy release of the associated solar flare. In this paper, we examine in detail the post-impulsive-phase acceleration of a CME in the outer corona, which is the phase of evolution immediately following the main impulsive acceleration of the CME; this phase is believed to correspond to the decay phase of the associated flare. This observational study is based on a statistical sample of 247 CMEs that are associated with M- and X-class *GOES* soft X-ray flares from 1996 to 2006. We find that, from many examples of events, the CMEs associated with flares with long-decay time (or so-called long-duration flares) tend to have positive post-impulsive-phase acceleration, even though some of them have already obtained a high speed at the end of the impulsive acceleration but do not show a deceleration expected from the aerodynamic dragging of the background solar wind. On the other hand, the CMEs associated with flares of short-decay time tend to have significant deceleration. In the scattering plot of all events, there is a weak correlation between CME post-impulsive-phase acceleration and flare decay time. The CMEs deviated from the general trend are mostly slow or weak ones associated with flares of short-decay time; the deviation is caused by the relatively stronger solar wind dragging force for these events. The implications of our results on CME dynamics and CME–flare relations are discussed.

## **Large-Scale Activity Initiated BY Halo CMEs**

I. [Chertok](#)<sup>1</sup> and V. Grechnev<sup>2</sup>

*Coronal and Stellar Mass Ejections, Proceedings IAU Symposium No. 226, 2005, K. P. Dere, J. Wang & Y. Yan, eds, 2006.*

We summarize results of our recent studies of CME-associated EUV dimmings and coronal waves by ‘derotated’ fixed-difference SOHO/EIT heliograms at  $195^\circ\text{A}$  with 12-min intervals and at  $171, 195, 284, 304^\circ\text{A}$  with 6-h intervals. Correctness of the derotated fixed-difference technique is confirmed by the consideration of the Bastille Day 2000 event. We also demonstrate that long narrow channeled dimmings and anisotropic coronal waves are typical of the complex global solar magnetosphere near the solar cycle maximum. Homology of large-scale dimmings and coronal waves takes place in a series of recurrent eruptive events. Along with dimmings coinciding entirely or partially in all four EIT bands, there exist dimmings that appear different, mainly in the transition-region line of  $304^\circ\text{A}$  and high-temperature coronal line of  $284^\circ\text{A}$ .

## **Yohkoh data on CME-flare relationships and post-eruption magnetic reconnection in the corona.**

[Chertok](#), I.M.

*Astron. Soc. Pac. Conf. Ser.*, Vol. 111, p. 369 – 374, 1996

The consideration of various observations, in particular of microwave and Yohkoh X-ray data, brings us to the conclusion that, generally speaking, CMEs and flares are independent phenomena in the sense that they may occur one without the other. At the same time CMEs and flares may take place jointly, initiating each other in different cause-and-effect combinations. In any case, a CME, irrespective of its origin, is accompanied by some post-eruption magnetic reconnection and energy release high in the corona. The intensity and character of these processes may be different depending on magnetic structures (either above active regions, outside them, or in the vicinity of coronal holes) which are affected by a CME.

Current state-of-the-art spectrographs cannot resolve the fundamental spatial (sub-arcseconds) and temporal scales (less than a few tens of seconds) of the coronal dynamics of solar flares and eruptive phenomena. The highest resolution coronal data to date are based on imaging, which is blind to many of the processes that drive coronal energetics and dynamics. As shown by IRIS for the low solar atmosphere, we need high-resolution spectroscopic measurements with simultaneous imaging to understand the dominant processes. In this paper: (1) we introduce the Multi-slit Solar Explorer (MUSE), a spaceborne observatory to fill this observational gap by providing high-cadence (<20 s), sub-arcsecond resolution spectroscopic rasters over an active region size of the solar transition region and corona; (2) using advanced numerical models, we demonstrate the unique diagnostic capabilities of MUSE for exploring solar coronal dynamics, and for constraining and discriminating models of solar flares and eruptions; (3) we discuss the key contributions MUSE would make in addressing the science objectives of the Next Generation Solar Physics Mission (NGSPM), and how MUSE, the high-throughput EUV Solar Telescope (EUVST) and the Daniel K Inouye Solar Telescope (and other ground-based observatories) can operate as a distributed implementation of the NGSPM. This is a companion paper to De Pontieu et al. (2021a), which focuses on investigating coronal heating with MUSE. **2014 05 01**

## **Homologous Helical Jets: Observations by IRIS, SDO and Hinode and Magnetic Modeling with Data-Driven Simulations**

<http://arxiv.org/pdf/1501.01593v1.pdf>

We report on observations of recurrent jets by instruments onboard the Interface Region Imaging Spectrograph (IRIS), Solar Dynamics Observatory (SDO) and Hinode spacecrafts. Over a 4-hour period on **July 21st 2013**, recurrent coronal jets were observed to emanate from NOAA Active Region 11793. FUV spectra probing plasma at transition region temperatures show evidence of oppositely directed flows with components reaching Doppler velocities of +/- 100 km/s. Raster Doppler maps using a Si IV transition region line show all four jets to have helical motion of the same sense. Simultaneous observations of the region by SDO and Hinode show that the jets emanate from a source region comprising a pore embedded in the interior of a supergranule. The parasitic pore has opposite polarity flux compared to the surrounding network field. This leads to a spine-fan magnetic topology in the coronal field that is amenable to jet formation. Time-dependent data-driven simulations are used to investigate the underlying drivers for the jets. These numerical experiments show that the emergence of current-carrying magnetic field in the vicinity of the pore supplies the magnetic twist needed for recurrent helical jet formation.

## **Imaging Spectroscopy of CME-Associated Solar Radio Bursts**

**Sherry Chhabra**, **Dale E. Gary**, **Gregg Hallinan**, **Marin M. Anderso**, **Bin Chen**, **Lincoln J. Greenhill**, **Danny C. Price**

**2021** *ApJ* **906** 132

<https://arxiv.org/pdf/2011.06073.pdf>

<https://doi.org/10.3847/1538-4357/abc94b>

We present first results of a solar radio event observed with the Owens Valley Radio Observatory Long Wavelength Array (OVRO-LWA) at metric wavelengths. We examine a complex event consisting of multiple radio sources/bursts associated with a fast coronal mass ejection (CME) and an M2.1 GOES soft X-ray flare from **2015 September 20**. Images of 9--s cadence are used to analyze the event over a 120-minute period, and solar emission is observed out to a distance of  $\approx 3.5R_{\odot}$ , with an instantaneous bandwidth covering 22~MHz within the frequency range of 40--70~MHz. We present our results from the investigation of the radio event, focusing particularly on one burst source that exhibits outward motion, which we classify as a moving type IV burst. We image the event at multiple frequencies and use the source centroids to obtain the velocity for the outward motion. Spatial and temporal comparison with observations of the CME in white light from the LASCO(C2) coronagraph, indicates an association of the outward motion with the core of the CME. By performing graduated-cylindrical-shell (GCS) reconstruction of the CME, we constrain the density in the volume. The electron plasma frequency obtained from the density estimates do not allow us to completely dismiss plasma emission as the underlying mechanism. However, based on source height and smoothness of the emission in frequency and time, we argue that gyrosynchrotron is the more plausible mechanism. We use gyrosynchrotron spectral fitting techniques to estimate the evolving physical conditions during the outward motion of this burst source.

## **Observational Study of an Earth-affecting Problematic ICME from STEREO**

Yutian **Chi**<sup>1</sup>, Jie Zhang<sup>2,3</sup>, Chenglong Shen<sup>1,4</sup>, Phillip Hess<sup>5</sup>, Lijuan Liu<sup>6</sup>, Wageesh Mishra<sup>1</sup>, and Yuming Wang<sup>1,7</sup>

**2018 ApJ** 863 108

<http://sci-hub.tw/http://iopscience.iop.org/article/10.3847/1538-4357/aacf44/meta>

We present a study of the origin of one interplanetary coronal mass ejection (ICME) that lacked an easily identifiable signature of an associated progenitor coronal mass ejection (CME) near the Sun in the observations of SOHO/LASCO at the L1 point. We consider these kinds of ICMEs as problematic, as they pose the difficulty of understanding the Sun–Earth connection and providing space weather warnings; understanding the causes of problematic ICMEs is important for space weather forecasting. This study presents the first detailed analysis of a geoeffective problematic ICME that occurred on **2011 May 28**, whose progenitor CMEs are difficult to identify in LASCO images, but fortunately they were captured by SECCHI on board the STEREO spacecraft in the quadrature configuration. There are two progenitor CMEs launching from the Sun in succession of 8 hours. We apply the graduated cylindrical shell model to reconstruct the 3D geometry, propagating direction, velocity, and brightness of the two CMEs. The main cause of the first CME (CME-1) invisible in SOHO/LASCO is due to its low mass; that is, when the CME emerges above the occulter, its brightness is as faint as the noise. The second CME (CME-2) is small, including a narrow angular width and a small cross-section of the magnetic flux rope. Even though propagating toward the Earth, CME-2 appeared as a narrow CME instead of as a halo or partial halo CME in the LASCO field of view. We also show that CME-2 propagates faster than CME-1, and that they might have interacted in the interplanetary space. **2011-05-25**

## **First 4D Reconstruction of an Eruptive Prominence Using Three Simultaneous View Directions**

I. **Chifu**, B. Inhester, M. Mierla, V. Chifu, T. Wiegmann

*Solar Physics*, November **2012**, Volume 281, Issue 1, pp 121-135

Data from the STEREO (Solar Terrestrial Relations Observatory) mission are intensively used for 3D reconstruction of solar coronal structures. After the launch of the SDO (Solar Dynamic Observatory) satellite, its additional observations give the possibility to have a third eye for more accurate 3D reconstruction in the very low corona ( $< 1.5 R_{\odot}$ ). With our reconstruction code MBSR (Multi-view B-spline Stereoscopic Reconstruction), we use three view directions (STEREO A, B, and SDO) to perform the 3D reconstruction and evolution of a prominence which triggered a CME on **1 August 2010**. In the paper we present the reconstruction of this prominence from the moment it starts to erupt until it leaves the field of view of the coronagraph. We also determine the evolution of the leading edge of the CME. Based on the temporal evolution, we analyze some of its properties, such as velocity, acceleration, opening and rotation angles and evolution of the cavity.

## **On the three-dimensional relation between the coronal dimming, erupting filament and CME. Case study of the 28 October 2021 X1.0 event**

<https://arxiv.org/pdf/2308.09815.pdf>

<https://www.aanda.org/articles/aa/pdf/2023/10/aa47011-23.pdf>

We investigate the relation between the spatiotemporal evolution of the dimming region and the dominant direction of the filament eruption and CME propagation for the **28 October 2021** X1.0 flare/CME event observed from multiple viewpoints by Solar Orbiter, STEREO-A, SDO, and SOHO. We propose a method to estimate the dominant dimming direction by tracking its area evolution and emphasize its accurate estimation by calculating the surface area of a sphere for each pixel. To determine the early flux rope propagation direction, we perform 3D reconstruction of the CME via graduated cylindrical shell modeling (GCS) and tie-pointing of the filament. The dimming initially expands radially and

later shifts southeast. The orthogonal projections of the reconstructed height evolution of the erupting filament onto the solar surface are located in the sector of the dominant dimming growth, while the orthogonal projections of the inner part of GCS reconstruction align with the total dimming area. The filament reaches a maximum speed of  $\approx 250$  km/s at a height of about  $\approx 180$  Mm. The direction of its motion is strongly inclined from the radial ( $64^\circ$  to the East,  $32^\circ$  to the South). The  $50^\circ$  difference in the 3D direction between the CME and the filament leg closely corresponds to the CME half-width determined from reconstruction, suggesting a potential relation of the reconstructed filament to the associated leg of the CME body. Our findings highlight that the dominant propagation of the dimming growth reflects the direction of the erupting magnetic structure (filament) low in the solar atmosphere, though the filament evolution is not related directly to the direction of the global CME expansion. The overall dimming morphology closely resembles the inner part of the CME reconstruction, validating the use of dimming observations to obtain insight into the CME direction.

## **Magnetic Flux Rope Shredding by a Hyperbolic Flux Tube: The Detrimental Effects of Magnetic Topology on Solar Eruptions**

ApJ **843** 93 **2017**

<https://arxiv.org/pdf/1706.00057.pdf>

<http://sci-hub.cc/10.3847/1538-4357/aa77b2>

We present the analysis of an unusual failed eruption captured in high cadence and in many wavelengths during the observing campaign in support of the VAULT2.0 sounding rocket launch. The refurbished Very high Angular resolution Ultraviolet Telescope (VAULT2.0) is a  $\text{Ly}\alpha$  ( $\lambda$  1216 Å) spectroheliograph launched on **September 30, 2014**. The campaign targeted active region NOAA AR 12172 and was closely coordinated with the Hinode and IRIS missions and several ground-based observatories (NSO/IBIS, SOLIS, and BBSO). A filament eruption accompanied by a low level flaring event (at the GOES C-class level) occurred around the VAULT2.0 launch. No Coronal Mass Ejection (CME) was observed. The eruption and its source region, however, were recorded by the campaign instruments in many atmospheric heights ranging from the photosphere to the corona in high cadence and spatial resolution. This is a rare occasion which enables us to perform a comprehensive investigation on a failed eruption. We find that a rising Magnetic Flux Rope-like (MFR) structure was destroyed during its interaction with the ambient magnetic field creating downflows of cool plasma and diffuse hot coronal structures reminiscent of "cusps". We employ magnetofrictional simulations to show that the magnetic topology of the ambient field is responsible for the destruction of the MFR. Our unique observations suggest that the magnetic topology of the corona is a key ingredient for a successful eruption.

## **Formation of Magnetic Flux Ropes during Confined Flaring Well Before the Onset of a Pair of Major Coronal Mass Ejections**

Georgios [Chintzoglou](#), Spiros Patsourakos, Angelos Vourlidas

ApJ **809** 34 **2015**

<http://arxiv.org/pdf/1507.01165v1.pdf>

NOAA Active Region (AR) 11429 was the source of twin super-fast Coronal Mass Ejections (CMEs). The CMEs took place within a hour from each other, with the onset of the first taking place in the beginning of **March 7, 2012**. This AR fulfills all the requirements for a "super active region"; namely, Hale's law incompatibility and a  $\delta$ -spot magnetic configuration. One of the biggest storms of Solar Cycle 24 to date ( $\text{Dst} = -143$  nT) was associated with one of these events. Magnetic Flux Ropes (MFRs) are twisted magnetic structures in the corona, best seen in  $\sim 10$  MK hot plasma emission and are often considered the core of erupting structures. However, their "dormant" existence in the solar atmosphere (i.e. prior to eruptions), is an open question. Aided by multi-wavelength observations (SDO/HMI/AIA and STEREO EUVI B) and a Non-Linear Force-Free (NLFFF) model for the coronal magnetic field, our work uncovers two separate, weakly-twisted magnetic flux systems which suggest the existence of pre-eruption MFRs that eventually became the seeds of the two CMEs. The MFRs could have been formed during confined (i.e. not leading to major CMEs) flaring and sub-flaring events which took place the day before the two CMEs in the host AR 11429.

## **Capturing transient plasma flows and jets in the solar corona**

[L. P. Chitta](#), [S. K. Solanki](#), [H. Peter](#), [R. Aznar Cuadrado](#), [L. Teriaca](#), [U. Schühle](#), [F. Auchère](#), [D. Berghmans](#), [E. Kraaikamp](#), [S. Gissot](#), [C. Verbeecq](#)

A&A Letters **2021**

<https://arxiv.org/pdf/2109.15106.pdf>

Intensity bursts in ultraviolet (UV) to X-ray wavelengths, and plasma jets are typical signatures of magnetic reconnection and the associated impulsive heating of the solar atmospheric plasma. To gain new insights into the process, high-cadence observations are required to capture the rapid response of plasma to magnetic reconnection as well as the highly dynamic evolution of jets. Here we report 200 ms cadence extreme-UV observations recorded by the 174 Å High Resolution Imager of the Extreme Ultraviolet Imager onboard the **Solar Orbiter** mission. These observations, covering a quiet-Sun coronal region, reveal the onset signatures of magnetic reconnection as localized heating events. These localized sources then exhibit repeated plasma eruptions or jet activity. Our observations show that this spatial morphological change from localized sources to jet activity could occur rapidly on timescales of about 200 ms. The jets themselves are intermittent and are produced from the source region on timescales of about 200 ms. In the

initial phases of these events, plasma jets are observed to exhibit speeds, as inferred from propagating intensity disturbances, in the range of  $100\text{ km s}^{-1}$  to  $150\text{ km s}^{-1}$ . These jets then propagate to lengths of about  $5\text{ Mm}$ . We discuss examples of bidirectional and unidirectional jet activity observed to be initiated from the initially localized bursts in the corona. The transient nature of coronal bursts and plasma jets/flows and their dynamics could provide a benchmark for magnetic reconnection models of coronal bursts and jets. **2021 February 23**

### **A New Type of Jet in a Polar Limb of the Solar Coronal Hole**

Il-Hyun **Cho**<sup>1</sup>, Yong-Jae Moon<sup>1,2</sup>, Kyung-Suk Cho<sup>3,4</sup>, Valery M. Nakariakov<sup>2,5,6</sup>, Jin-Yi Lee<sup>1</sup>, and Yeon-Han Kim<sup>3</sup>

2019 ApJL 884 L38

<https://doi.org/10.3847/2041-8213/ab4799>

<https://arxiv.org/pdf/1910.09737.pdf>

A new type of chromospheric jet in a polar limb of a coronal hole is discovered in the Ca II filtergram of the Solar Optical Telescope on board the Hinode. We identify 30 jets in a filtered Ca II movie with a duration of 53 minutes. The average speed at their maximum heights is found to be  $132 \pm 44\text{ km s}^{-1}$  ranging from  $57$  to  $264\text{ km s}^{-1}$  along the propagation direction. The average lifetime is  $20 \pm 6$  ranging from 11 to 36 s. The speed and lifetime of the jets are located at end-tails of those parameters determined for type II spicules, hence implying a new type of jets. To confirm whether these jets are different from conventional spicules, we construct a time–height image averaged over a horizontal region of  $1''$ , and calculate lagged cross-correlations of intensity profiles at each height with the intensity at  $2\text{ Mm}$ . From this, we obtain a cross-correlation map as a function of lag and height. We find that the correlation curve as a function of lag time is well fitted into three different Gaussian functions whose standard deviations of the lag time are 193, 42, and 17 s. The corresponding propagation speeds are calculated to be  $9\text{ km s}^{-1}$ ,  $67\text{ km s}^{-1}$ , and  $121\text{ km s}^{-1}$ , respectively. The kinematic properties of the former two components seem to correspond to the 3-minute oscillations and type II spicules, while the latter component to the jets is addressed in this study.

### **A New Method to Determine the Temperature of CMEs Using a Coronagraph Filter System**

Kyuhyun **Cho**, Jongchul Chae, Eun-kyung Lim, Kyung-suk Cho, Su-Chan Bong, Heesu Yang

J. of Korean Astronomical Society (JKAS) 2016

<http://arxiv.org/pdf/1603.07047v1.pdf>

The coronagraph is an instrument enables the investigation of faint features in the vicinity of the Sun, particularly coronal mass ejections (CMEs). So far coronagraphic observations have been mainly used to determine the geometric and kinematic parameters of CMEs. Here, we introduce a new method for the determination of CME temperature using a two filter (4025 Å and 3934 Å) coronagraph system. The thermal motion of free electrons in CMEs broadens the absorption lines in the optical spectra that are produced by the Thomson scattering of visible light originating in the photosphere, which affects the intensity ratio at two different wavelengths. Thus the CME temperature can be inferred from the intensity ratio measured by the two filter coronagraph system. We demonstrate the method by invoking the graduated cylindrical shell (GCS) model for the 3 dimensional CME density distribution and discuss its significance. **2002 January 4**

### **Comparison of Helicity Signs in Interplanetary CMEs and Their Solar Source Regions**

K.-S. **Cho**, S.-H. Park, K. Marubashi, N. Gopalswamy, S. Akiyama, S. Yashiro, R.-S. Kim, E.-K. Lim

Solar Physics, May 2013, Volume 284, Issue 1, pp 105-127; **File**

If all coronal mass ejections (CMEs) have flux ropes, then the CMEs should keep their helicity signs from the Sun to the Earth according to the helicity conservation principle. This study presents an attempt to answer the question from the Coordinated Data Analysis Workshop (CDAW), “Do all CMEs have flux ropes?”, by using a qualitative helicity sign comparison between interplanetary CMEs (ICMEs) and their CME source regions. For this, we select 34 CME–ICME pairs whose source active regions (ARs) have continuous SOHO/MDI magnetogram data covering more than 24 hr without data gap during the passage of the ARs near the solar disk center. The helicity signs in the ARs are determined by estimation of cumulative magnetic helicity injected through the photosphere in the entire source ARs. The helicity signs in the ICMEs are estimated by applying the cylinder model developed by Marubashi (Adv. Space. Res., 26, 55, 2000) to 16 second resolution magnetic field data from the MAG instrument onboard the ACE spacecraft. It is found that 30 out of 34 events (88 %) are helicity sign-consistent events, while four events (12 %) are sign-inconsistent. Through a detailed investigation of the source ARs of the four sign-inconsistent events, we find that those events can be explained by the local helicity sign opposite to that of the entire AR helicity (**28 July 2000 ICME**), incorrectly reported solar source region in the CDAW list (**20 May 2005 ICME**), or the helicity sign of the pre-existing coronal magnetic field (**13 October 2000** and **20 November 2003 ICMEs**). We conclude that the helicity signs of the ICMEs are quite consistent with those of the injected helicities in the AR regions from where the CMEs erupted. **Table.**

### **A HIGH-FREQUENCY TYPE II SOLAR RADIO BURST ASSOCIATED WITH THE 2011 FEBRUARY 13 CORONAL MASS EJECTION**

K.-S. **Cho**<sup>1,2,3</sup>, N. Gopalswamy<sup>2</sup>, R.-Y. Kwon<sup>2,3</sup>, R.-S. Kim<sup>1,2,3</sup>, and S. Yashiro

2013 ApJ 765 148

We examine the relationship between the high-frequency (425 MHz) type II radio burst and the associated white-light coronal mass ejection (CME) that occurred on **2011 February 13**. The radio burst had a drift rate of 2.5 MHz s<sup>-1</sup>, indicating a relatively high shock speed. From SDO/AIA observations we find that a loop-like erupting front sweeps across high-density coronal loops near the start time of the burst (17:34:17 UT). The deduced distance of shock formation (0.06 Rs) from the flare center and speed of the shock (1100 km s<sup>-1</sup>) using the measured density from SDO/AIA observations are comparable to the height (0.05 Rs, from the solar surface) and speed (700 km s<sup>-1</sup>) of the CME leading edge observed by STEREO/EUVI. We conclude that the type II burst originates even in the low corona (<59 Mm or 0.08 Rs, above the solar surface) due to the fast CME shock passing through high-density loops.

### **Relationship between multiple type II solar radio bursts and CME observed by STEREO/SECCHI**

K.-S. **Cho**, S.-C. Bong, Y.-J. Moon, A. Shanmugaraju, R.-Y. Kwon and Y. D. Park  
A&A 530, A16 (2011), **File**

*Aims.* Two or more type II bursts are occasionally observed in close time sequence during solar eruptions, which are known as multiple type II bursts. The origin of the successive burst has been interpreted in terms of coronal mass ejections (CMEs) and/or flares. Detailed investigations of the relationship between CMEs and the bursts enable us to understand the nature of the multiple type II bursts. In this study, we examine multiple type II bursts and compare their kinematics with those of a CME occurring near the time of the bursts.

*Methods.* To do this, we selected multiple type II bursts observed by the Culgoora radiospectrographs and a limb CME detected in the low corona field of view (1.4–4 Rs) of a STEREO/SECCHI instrument on **December 31, 2007**. To determine the 3D kinematics of the CME, we applied the stereoscopic technique to the STEREO/SECCHI data.

*Results.* Our main results are as follows: (1) the multiple type II bursts occurred successively at ten minute intervals and displayed various emission structures and frequency drifting rates; (2) near the time of the bursts, the CME was observed by STEREO and SOHO simultaneously, but no evidence of other CMEs was detected; (3) inspection of the 3D kinematics of the CME using the stereoscopic observation by STEREO/SECCHI revealed that the CME propagated along the eastward radial direction as viewed from the Earth; (4) very close time and height associations were found between the CME nose and the first type II burst, and between CME-streamer interaction and the second type II burst.

*Conclusions.* On the basis of these results, we suggest that a single shock in the leading edge of the CME could be the source of the multiple type II bursts and support the notion that the CME nose and the CME-streamer interaction are the two main mechanisms able to generate the bursts.

### **A Coronal Mass Ejection and Hard X-Ray Emissions Associated with the Kink Instability**

Kyung-Suk **Cho**, Jeongwoo Lee, Su-Chan Bong, Yeon-Han Kim, Bhuwan Joshi and Young-Deuk Park  
BBSO preprint #1400, June 2009; ApJ, Volume 703, Number 1, p. 1-7, **2009**, **File**

We present a morphological study of the 2004 August 18 solar eruption that occurred in the active region NOAA 10656 near the west limb using (E)UV data from the Transition Region and Coronal Explorer (TRACE), H $\alpha$  filtergram of Big Bear Solar Observatory (BBSO), white light (WL) images of Mauna Loa Solar Observatory (MLSO), hard X-ray data of the Reuven Ramaty High Energy Solar Spectroscopic Imager (RHESSI), and microwave data of the Owens Valley Solar Array (OVSA). In this event, we have an excellent set of observations for tracing the early evolution of the coronal mass ejection (CME) from a flux rope emergence to its propagation into space as a well connected series of events thanks to the coronameter's field of view down to 1.1 solar radius in overlap with that of TRACE. This dataset reveals continuously evolving (E)UV, H $\alpha$ , and WL features that suggest the rise of a small, low-lying loop, its writhing motion, break of the kinked loop at its crossing point, and transformation of the ejecta to the CME. The hard X-ray and microwave sources are found in varying locations with a complicated temporal dependence, which, we interpret, is due to two successive flares in the event. The first flare appears to be associated with the rise of the small loop, which then triggers the second flare. During the second flare a hard X-ray coronal source is detected at the crossing point of the kinked loop, and more intriguingly, the kinked loop apparently breaks at the crossing point of the two legs, which indicates a magnetic reconnection at the X-point configuration. After the break of the kinked UV loop, a CME structure shows up in the MLSO field of view, and propagates away from the sun. It is concluded that this CME occurred due to the kink instability.

### **Low coronal observations of metric type II associated CMEs by MLSO coronameters:**

K.-S. **Cho**, S.-C. Bong, Y.-H. Kim, Y.-J. Moon, M. Dryer, A. Shanmugaraju, J. Lee and Y. D. Park  
A&A 491 (2008) 873-882, **File**

<http://www.aanda.org/10.1051/0004-6361:20079013>

*Aims.* We have investigated the relationship between coronal mass ejections (CMEs) and coronal type II radio bursts by using type II associated CMEs whose low coronal observations by MLSO MK coronameters (1.08-2.85 solar radii for MK4) were available.

*Methods.* For this we considered all type II burst data at 17:00 UT to 22:00 UT from 1996 to 2003, and then compared them with CME images that were obtained during the same MLSO (Mauna Loa Solar Observatory) observing periods. As a result, we selected 19 type II associated CMEs whose kinematics are well identified. A relationship between CMEs and type IIs has been examined in terms of spatial and temporal closeness without any extrapolation of

CME kinematics as well as in terms of CME-streamer interaction.

*Results.* We found that: (1) except one event, all the metric type II events occur simultaneously or after the CME appearance in MK field of view within 30 min, mostly within 10 min after; (2) the distribution of height difference between the CME front and type II formation shows that there are double peaks, one at the CME fronts and the other at about 1 solar radius behind the front; (3) about half of the events (9/19) are identified to have CME-streamer interaction (seven streamer deflection and two overlapping), and the interaction heights are very similar to those of type II formation as well as their interaction times are nearly coincident with those of type II starting; (4) for the other events (10/19), the CME front heights at the starting time of type IIs are comparable to the heights of type II formation. *Conclusions.* Our low coronal observations of type II associated CMEs suggest that CME front and/or CME-streamer interaction at CME flank are two main mechanisms to generate type II bursts.

## **Series of Small-scale Low Plasma $\beta$ Magnetic Flux Ropes Originating from the Same Longitudinal Region: Parker Solar Probe Observations**

Kyung-Eun **Choi**<sup>1</sup>, Dae-Young Lee<sup>2</sup>, Sung-Jun Noh<sup>3</sup>, and Oleksiy Agapitov

2024 ApJ 961 3

<https://iopscience.iop.org/article/10.3847/1538-4357/ad02f6/pdf>

In this study, we report on small-scale magnetic flux ropes (SMFRs) observed as a compact series in a narrow Carrington longitudinal range during three Parker Solar Probe (PSP) encounters. First, during  $\sim 1.5$  days of PSP's inbound part of Encounter 4, we identified a series of 11 SMFRs within  $1^{\circ}4$  in longitude over the radial distance of  $\sim 8.4 R_{\odot}$  (from  $\sim 44$  to  $35 R_{\odot}$ ). The identified SMFRs lasted from  $\sim 0.5$  to 1.8 hr, and adjacent events were separated mostly by a few hours and up to  $\sim 6.5$  hr at the longest, but some events were very closely spaced with intervals of a few  $\sim$  tens of minutes or less apart. Most of the identified SMFRs are successfully fitted to the force-free model. The SMFRs are clearly distinguished from the surroundings by a notable reduction in plasma  $\beta$ , which itself was comparably low (less than unity) in the background plasma. Furthermore, the magnetic field and plasma flow within the SMFRs fluctuated significantly less than the more turbulent surroundings. The fluctuations in the surrounding medium exhibited occasional Br polarity reversal (possibly switchbacks) and were Alfvénic to a large extent with far weaker compressional components. The majority of these key features with some differences have also been found in the series of SMFRs and their surroundings identified within  $1^{\circ}3$  or less in longitude during Encounters 1 and 5. We speculate that these SMFRs were repetitively generated by successive reconnection within a very narrow angular zone located close to the Sun but not necessarily at the same radial position. **2-3 Nov 2018, 3-4 Jun 2020, 2020-01-25-26**

## **Different Periodicities in the Sunspot Area and the Occurrence of Solar Flares and Coronal Mass Ejections in Solar Cycle 23 – 24**

D. P. **Choudhary**, J. K. Lawrence, M. Norris, A. C. Cadavid

Solar Physics, February 2014, Volume 289, Issue 2, pp 649-656

In order to investigate the relationship between magnetic-flux emergence, solar flares, and coronal mass ejections (CMEs), we study the periodicity in the time series of these quantities. It has been known that solar flares, sunspot area, and photospheric magnetic flux have a dominant periodicity of about 155 days, which is confined to a part of the phase of the solar cycle. These periodicities occur at different phases of the solar cycle during successive phases. We present a time-series analysis of sunspot area, flare and CME occurrence during Cycle 23 and the rising phase of Cycle 24 from 1996 to 2011. We find that the flux emergence, represented by sunspot area, has multiple periodicities. Flares and CMEs, however, do not occur with the same period as the flux emergence. Using the results of this study, we discuss the possible activity sources producing emerging flux.

## **Magnetic flux emergence and solar eruptions in partially ionized plasmas**

**Georgios Chouliaras, V. Archontis**

ApJ 2024

<https://arxiv.org/pdf/2412.10633>

We have performed 3D MHD simulations to study the effect of partial ionization in the process of magnetic flux emergence in the Sun. In fact, we continue previous work and we now focus: 1) on the emergence of the magnetic fields above the solar photosphere and 2) on the eruptive activity, which follows the emergence into the corona. We find that in the simulations with partial ionization (PI), the structure of the emerging field consists of arch-like fieldlines with very little twist since the axis of the initial rising field remains below the photosphere. The plasma inside the emerging volume is less dense and it is moving faster compared to the fully ionized (FI) simulation. In both cases, new flux ropes (FR) are formed due to reconnection between emerging fieldlines, and they eventually erupt in an ejective manner towards the outer solar atmosphere. We are witnessing three major eruptions in both simulations. At least for the first eruption, the formation of the eruptive FR occurs in the low atmosphere in the FI case and at coronal heights in the PI case. Also, in the first PI eruption, part of the eruptive FR carries neutrals in the high atmosphere, for a short period of time. Overall, the eruptions are relatively faster in the PI case, while a considerable amount of axial flux is found above the photosphere during the eruptions in both simulations.

## **H $\alpha$ and EUV observations of a partial CME**

Damian J. **Christian**, David B. Jess, Patrick Antolin, Mihalis Mathioudakis

ApJ, 804 147 2015

We have obtained H $\alpha$  high spatial and time resolution observations of the upper solar chromosphere and supplemented these with multi-wavelength observations from the Solar Dynamic Observatory (SDO) and the *Hinode* Extreme Ultraviolet Imaging Spectrometer (EIS). The H $\alpha$  observations were conducted on **11 February 2012** with the Hydrogen-Alpha Rapid Dynamics Camera (HARDcam) instrument at the National Solar Observatory's Dunn Solar Telescope. Our H $\alpha$  observations found large downflows of chromospheric material returning from coronal heights following a failed prominence eruption. We have detected several large condensations ("blobs") returning to the solar surface at velocities of  $\approx 200$  km s $^{-1}$  in both H $\alpha$  and several SDO AIA band passes. The average derived size of these "blobs" in H $\alpha$  is 500 by 3000 km $^2$  in the directions perpendicular and parallel to the direction of travel, respectively. A comparison of our "blob" widths to those found from coronal rain, indicate there are additional smaller, unresolved "blobs" in agreement with previous studies and recent numerical simulations. Our observed velocities and decelerations of the "blobs" in both H $\alpha$  and SDO bands are less than those expected for gravitational free-fall and imply additional magnetic or gas pressure impeding the flow. We derived a kinetic energy  $\approx 2$  orders of magnitude lower for the main eruption than a typical CME, which may explain its partial nature.

### **BRIGHT RAY-LIKE FEATURES IN THE AFTERMATH OF CORONAL MASS EJECTIONS: WHITE LIGHT VERSUS ULTRAVIOLET SPECTRA**

A. Ciaravella<sup>1</sup>, D. F. Webb<sup>2</sup>, S. Giordano<sup>3</sup>, and J. C. Raymond

2013 ApJ 766 65

Current sheets (CSs) are important signatures of magnetic reconnection in the eruption of confined solar magnetic structures. Models of coronal mass ejections (CMEs) involve formation of a CS connecting the ejected flux rope with the post-eruption magnetic loops. CSs have been identified in white light (WL) images of CMEs as narrow rays trailing the outward moving CME core, and in ultraviolet spectra as narrow bright features emitting the [Fe XVIII] line. In this work, samples of rays detected in WL images or in ultraviolet spectra have been analyzed. Temperatures, widths, and line intensities of the rays have been measured, and their correlation to the CME properties has been studied. The samples show a wide range of temperatures with hot, coronal, and cool rays. In some cases, the UV spectra support the identification of rays as CSs, but they show that some WL rays are cool material from the CME core. In many cases, both hot and cool material are present, but offset from each other along the Ultraviolet Coronagraph Spectrometer slit. We find that about 18% of the WL rays show very hot gas consistent with the CS interpretation, while about 23% show cold gas that we attribute to cool prominence material draining back from the CME core. The remaining events have ordinary coronal temperatures, perhaps because they have relaxed back to a quiescent state.

### **THE CURRENT SHEET ASSOCIATED WITH THE 2003 NOVEMBER 4 CORONAL MASS EJECTION: DENSITY, TEMPERATURE, THICKNESS, AND LINE WIDTH**

A. Ciaravella<sup>1, 2</sup> and J. C. Raymond<sup>2</sup>

Astrophysical Journal, 686:1372Y1382, 2008

<http://www.journals.uchicago.edu/doi/pdf/10.1086/590655>

In the wake of the **2003 November 4** coronal mass ejection associated with the largest solar flare of the last sunspot cycle, a current sheet (CS) was observed by the Ultraviolet Coronagraph Spectrometer (UVCS) as a narrow bright feature in the [Fe xviii] (106.8 K) line. This is the first UV observation in which the CS evolution is followed from its onset. UV spectra provide diagnostics of electron temperature, emission measure, Doppler shift, line width, and size of the CS as function of time. Since the UVCS slit was inside the Mark IV K-coronameter (MK4) field of view, the combination of UV spectra and MK4 white light data provides estimates of the electron density and depth along the line of sight of the CS. The thickness of the CS in the [Fe xviii] line is far larger than classical or anomalous resistivity would predict, and it might indicate an effective resistivity much larger than anomalous resistivity, such as that due to hyperdiffusion. The broad [Fe xviii] line profiles in the CS cannot be explained as thermal widths. They result from a combination of bulk motions and turbulence. The Petschek reconnection mechanism and turbulent reconnection may be consistent with the observations.

### **Ultraviolet Properties of Halo Coronal Mass Ejections: Doppler Shifts, Angles, Shocks, and Bulk Morphology**

A. Ciaravella, J. C. Raymond, and S. W. Kahler

### **Extreme solar events**

**Review**

[Edward W. Cliver](#), [Carolus J. Schrijver](#), [Kazunari Shibata](#) & [Ilya G. Usoskin](#)

[Living Reviews in Solar Physics](#) volume 19, Article number: 2 (2022)

<https://arxiv.org/ftp/arxiv/papers/2205/2205.09265.pdf>

<https://link.springer.com/content/pdf/10.1007/s41116-022-00033-8.pdf>

We trace the evolution of research on extreme solar and solar-terrestrial events from the 1859 Carrington event to the rapid development of the last twenty years. Our focus is on the largest observed/inferred/theoretical cases of sunspot groups, flares on the Sun and Sun-like stars, coronal mass ejections, solar proton events, and geomagnetic storms. The

reviewed studies are based on modern observations, historical or long-term data including the auroral and cosmogenic radionuclide record, and Kepler observations of Sun-like stars. We compile a table of 100- and 1000-year events based on occurrence frequency distributions for the space weather phenomena listed above. Questions considered include the Sun-like nature of superflare stars and the existence of impactful but unpredictable solar "black swans" and extreme "dragon king" solar phenomena that can involve different physics from that operating in events which are merely large. **774 AD, 17 Sep 1770, 1 September 1859, 4 Feb 1872, 14-15 May 1921, 28 Feb 1942, 5 April 1947, 23 May 1967, 2-11 August 1972, 29 Apr 1973, 21 Apr 2002, 28 October 2003; 6, 13, 14 Dec 2006, 9 Nov 2011, 28 Oct 2013, 4 Nov 2015**

### **Numerical simulation of the 12 May 1997 CME Event: The role of magnetic reconnection**

**Cohen**, O.; Attrill, G. D. R.; Schwadron, N. A.; Crooker, N. U.; Owens, M. J.; Downs, C.; Gombosi, T. I. *J. Geophys. Res.*, Vol. 115, No. A10, A10104, **2010**

We perform a numerical study of the evolution of a Coronal Mass Ejection (CME) and its interaction with the coronal magnetic field based on the **12 May 1997**, CME event using a global MagnetoHydroDynamic (MHD) model for the solar corona. The ambient solar wind steady-state solution is driven by photospheric magnetic field data, while the solar eruption is obtained by superimposing an unstable flux rope onto the steady-state solution. During the initial stage of CME expansion, the core flux rope reconnects with the neighboring field, which facilitates lateral expansion of the CME footprint in the low corona. The flux rope field also reconnects with the oppositely orientated overlying magnetic field in the manner of the breakout model. During this stage of the eruption, the simulated CME rotates counter-clockwise to achieve an orientation that is in agreement with the interplanetary flux rope observed at 1 AU. A significant component of the CME that expands into interplanetary space comprises one of the side lobes created mainly as a result of reconnection with the overlying field. Within 3 hours, reconnection effectively modifies the CME connectivity from the initial condition where both footpoints are rooted in the active region to a situation where one footpoint is displaced into the quiet Sun, at a significant distance ( $\approx 1R_{\odot}$ ) from the original source region. The expansion and rotation due to interaction with the overlying magnetic field stops when the CME reaches the outer edge of the helmet streamer belt, where the field is organized on a global scale. The simulation thus offers a new view of the role reconnection plays in rotating a CME flux rope and transporting its footpoints while preserving its core structure.

### **USING MULTIPLE-VIEWPOINT OBSERVATIONS TO DETERMINE THE INTERACTION OF THREE CORONAL MASS EJECTIONS OBSERVED ON 2012 MARCH 5**

Robin C. **Colaninno**<sup>1</sup> and Angelos Vourlidas

**2015** ApJ 815 70

We examine the interaction of three coronal mass ejections (CMEs) that took place on 2012 March 5 at heights less than  $20 R_{\odot}$  in the corona. We used a forward fitting model to reconstruct the three-dimensional trajectories and kinematics of the CMEs and determine their interaction in the observations from three viewpoints: Solar and Heliospheric Observatory (SOHO), STEREO-A, and STEREO-B. The first CME (CME-1), a slow-rising eruption near disk center, is already in progress at 02:45 UT when the second CME (CME-2) erupts from AR 11429 on the east limb. These two CMEs are present in the corona not interacting when a third CME (CME-3) erupts from AR 11429 at 03:34 UT. CME-3 has a constant velocity of  $1456[\pm 31]$  km s<sup>-1</sup> and drives a shock that is observed as a halo from all viewpoints. We find that the shock driven by CME-3 passed through CME-1 with no observable change in the geometry, trajectory, or velocity of CME-1. However, the elevated temperatures detected in situ when CME-1 reached Earth indicate that the plasma inside CME-1 may have been heated by the passage of the shock. CME-2 is accelerated by CME-3 to more than twice its initial velocity and remains a separate structure ahead of the CME-3 front. CME-2 is deflected 24° northward by CME-3 for a total deflection of 40° from its source region. These results suggest that the collision of CME-2 and CME-3 is superelastic. This work demonstrates the capability and utility of fitting forward models to complex and interacting CMEs observed in the corona from multiple viewpoints.

### **Update of the Photometric Calibration of the LASCO-C2 Coronagraph Using Stars**

R. C. **Colaninno**, R. A. Howard

*Solar Phys.* Volume 290, [Issue 3](#), pp 997-1009, **2015**

<http://link.springer.com/article/10.1007/s11207-014-0635-2/fulltext.html>

We present an update to the photometric calibration of the LASCO-C2 coronagraph onboard the [SOHO](#) spacecraft. We obtained the new calibration using data from the beginning of the mission in 1996 until 2013. We re-examined the LASCO-C2 photometric calibration by comparing the past three calibrations and the present calibration with the goal of validating an in-flight calibration. We find a photometric calibration factor (PCF) that is very similar to the factor recently published in Gardès, Lamy, and Llebaria (*Solar Phys.* 283, 667, 2013), which calculated a calibration between 1996 and 2009. The average of our PCF between 1999 and 2009 is the same, within our margin of error, as the average given by Gardès, Lamy, and Llebaria (*Solar Phys.* 283, 667, 2013) during the same time period. However, we find a different evolution of the calibration over the lifetime of the LASCO-C2 instrument compared with past results. We find that the sensitivity of the instrument is decreasing by a constant  $0.20 [\pm 0.03]$  % per year. We also find no significant difference in the signal degradation before and after the [SOHO](#) interruption. We discuss the effects of this new PCF on the calibrated data set and the potential impact on scientific results derived from the previous calibration.

21 March 2007

## **FIRST DETERMINATION OF THE TRUE MASS OF CORONAL MASS EJECTIONS: A NOVEL APPROACH TO USING THE TWO *STEREO* VIEWPOINTS**

Robin C. [Colaninno](#)<sup>1</sup> and Angelos Vourlidas<sup>2</sup>

*Astrophysical Journal*, 698:852–858, **2009**, [File](#)

The twin Sun Earth Connection Coronal and Heliospheric Investigation (SECCHI) COR2 coronagraphs of the *Solar Terrestrial Relations Observatory (STEREO)* provide images of the solar corona from two viewpoints in the solar system. Since their launch in late 2006, the *STEREO* Ahead (A) and Behind (B) spacecraft have been slowly separating from Earth at a rate of 22.5 per year. By the end of 2007, the two spacecraft were separated by more than 40° from each other. At that time, we began to see large-scale differences in the morphology and total intensity between coronal mass ejections (CMEs) observed with SECCHI-COR2 on *STEREO*-A and B. Due to the effects of the Thomson scattering geometry, the intensity of an observed CME is dependent on the angle it makes with the observed plane of the sky. From the intensity images, we can calculate the integrated line-of-sight electron density and mass. We demonstrate that it is possible to simultaneously derive the direction and true total mass of the CME if we make the simple assumption that the same mass should be observed in COR2-A and B.

## **Analysis of the Velocity Field of CMEs Using Optical Flow Methods**

Robin C. [Colaninno](#) and Angelos Vourlidas,

*The Astrophysical Journal*, 652:1747-1754, **2006**, [File](#)

we introduce an image-processing algorithm from the field of computer vision and demonstrate that the velocity field of a CME can be obtained reliably over most of the area, with certain assumptions and restrictions.

## **A statistical study of CME properties and of the correlation between flares and CMEs over the solar cycles 23 and 24**

A. [Compagnino](#), P. Romano, F. Zuccarello

*Solar Phys.* January **2017**, 292:5

<http://arxiv.org/pdf/1609.08943v1.pdf>

We investigated some properties of coronal mass ejections (CMEs), such as speed, acceleration, polar angle, angular width and mass, using data acquired by LASCO aboard of SOHO from July 31, 1997, to March 31, 2014, i.e., during the solar cycles 23 and 24. We used two CME catalogs: one provided by the CDAW Data Center and one obtained by the CACTus detection algorithm. For both dataset, we found that the number of CMEs observed during the peak of cycle 24 was higher or comparable to the one during cycle 23, although the photospheric activity during cycle 24 was weaker than during cycle 23. More precisely, using the CMEs detected by CACTus we noted that the number of events  $N$  is of the same order of magnitude during the peaks of the two cycles, but the peak of CME distribution during the cycle 24 is more extended in time ( $N > 1500$  during 2012 and 2013). We ascribe the discrepancy between CDAW and CACTus results to the observer bias for CME definition in the CDAW catalog (Robbrecht et al., 2009; Webb and Howard, 2012; Yashiro et al., 2008). We also used a dataset containing 19811 flares of C, M, and X class, observed by GOES during the same period. Using both dataset, we studied the relationship between the mass ejected by the CMEs and the flux emitted during the corresponding flares: we found 11441 flares that were temporally-correlated with CMEs for CDAW and 9120 for CACTus. Moreover, we found a log-linear relationship between the flux of the flares integrated from the start to end in the 0.1-0.8 nm range and the CME mass:  $\log(\text{CME mass})$  proportional to  $0.23 \times \log(\text{flare flux})$ . We also found some differences in the mean CMEs velocity and acceleration between the events associated with flares and those that were not. In particular, the CMEs associated with flares are on average 100 km/s faster than the ones not associated with flares.

## **Excitation Sources of Oscillations in Solar Coronal Loops: A Multi-wavelength Analysis**

Sandra M. [Conde](#)<sup>1,2</sup>, Rekha Jain<sup>3</sup>, and Vera Jatenco-Pereira<sup>1</sup>

**2020** *ApJL* 890 L21

<https://doi.org/10.3847/2041-8213/ab7348>

An investigation into the excitation sources of oscillations detected in a coronal loop structure is carried out using the images obtained with Interface Region Imaging Spectrometer (IRIS) and the Atmospheric Imaging Assembly (AIA) instrument on board the Solar Dynamics Observatory (SDO). A loop structure in the active region AR 11967 on **2014 January 28**, oscillating in the vicinity of a strong eruption and an M3.6 class flare site, is clearly noticeable in SDO/AIA 171 Å images. We study in detail, the oscillations with detected periods between 4 and 13 minutes and their connection in IRIS SJI 1330 Å and SDO/AIA 1700 Å images; both of these wavelengths sample the lower parts of the solar atmosphere. The simultaneous presence of many oscillations in the region of interest in all three wavelength passbands suggest that these oscillations were excited in the lower-chromosphere–photosphere plasma connected to the loop structure and then propagated at higher heights. We further investigate the Doppler velocity measurements from the spectrograph snapshots in IRIS C ii 1336 Å, Si iv 1403 Å and Mg ii k 2796 Å. These show signatures of upflows in

the vicinity of the loop structure's endpoints estimated from 171 Å images. We suggest that some of the oscillations observed in AIA 171 Å have been triggered by plasma ejections and perturbations seen in the lower layers of the solar atmosphere. Based on the estimated phase speeds, the oscillations are likely to be slow magnetoacoustic in nature.

## **SOLAR CYCLE VARIATIONS OF CORONAL NULL POINTS: IMPLICATIONS FOR THE MAGNETIC BREAKOUT MODEL OF CORONAL MASS EJECTIONS**

G. R. [Cook](#)<sup>1</sup>, D. H. [Mackay](#)<sup>1</sup>, and [Dibyendu Nandy](#)<sup>2</sup>

*Astrophysical Journal*, 704:1021–1035, **2009** October

In this paper, we investigate the solar cycle variation of coronal null points and magnetic breakout configurations in spherical geometry, using a combination of magnetic flux transport and potential field source surface models. Within the simulations, a total of 2843 coronal null points and breakout configurations are found over two solar cycles. It is found that the number of coronal nulls present at any time varies cyclically throughout the solar cycle, in phase with the flux emergence rate. At cycle maximum, peak values of 15–17 coronal nulls per day are found. No significant variation in the number of nulls is found from the rising to the declining phase. This indicates that the magnetic breakout model is applicable throughout both phases of the solar cycle. In addition, it is shown that when the simulations are used to construct synoptic data sets, such as those produced by Kitt Peak, the number of coronal nulls drops by a factor of 1/6. The vast majority of the coronal nulls are found to lie above the active latitudes and are the result of the complex nature of the underlying active region fields. Only 8% of the coronal nulls are found to be connected to the global dipole. Another interesting feature is that 18% of coronal nulls are found to lie above the equator due to cross-equatorial interactions between bipoles lying in the northern and southern hemispheres. As the majority of coronal nulls form above active latitudes, their average radial extent is found to be in the lowcorona below  $1.25 R_{\odot}$  (175,000 km above the photosphere). Through considering the underlying photospheric flux, it is found that 71% of coronal nulls are produced through quadrupolar flux distributions resulting from bipoles in the same hemisphere interacting. When the number of coronal nulls present in each rotation is compared to the number of bipoles emerging, a wide scatter is found. The ratio of coronal nulls to emerging bipoles is found to be approximately 1/3. Overall, the spatio-temporal evolution of coronal nulls is found to follow the typical solar butterfly diagram and is in qualitative agreement with the observed time dependence of coronal mass ejection source-region locations.

## **Designing a New Coronal Magnetic Field Energy Diagnostic**

Marcel F. [Corchado-Albelo](#)<sup>1</sup>, [Kévin Dalmasse](#)<sup>2</sup>, [Sarah Gibson](#)<sup>3</sup>, [Yuhong Fan](#)<sup>3</sup>, and [Anna Malanushenko](#)  
**2021** *ApJ* 907 23

<https://doi.org/10.3847/1538-4357/abc8f0>

In the solar corona, the free energy, i.e., the excess in magnetic energy over a ground-state potential field, forms the reservoir of energy that can be released during solar flares and coronal mass ejections. Such free energy provides a measure of the magnetic field nonpotentiality. Recent theoretical and observational studies indicate that the presence of nonpotential magnetic fields is imprinted into the structures of infrared, off-limb, coronal polarization. In this paper, we investigate the possibility of exploiting such observations for mapping and studying the accumulation and release of coronal free magnetic energy, with the goal of developing a new tool for identifying "hot spots" of coronal free energy such as those associated with twisted and/or sheared coronal magnetic fields. We applied forward modeling of infrared coronal polarimetry to three-dimensional models of nonpotential and potential magnetic fields. From these we defined a quantitative diagnostic of nonpotentiality that in the future could be calculated from a comparison of infrared, off-limb, coronal polarization observations from, e.g., the Coronal Multi-channel Polarimeter or the Daniel K. Inouye Solar Telescope, and the corresponding polarization signal forward-modeled from a potential field extrapolated from photospheric magnetograms. We considered the relative diagnostic potential of linear and circular polarization, and the sensitivities of these diagnostics to coronal density distributions and assumed boundary conditions of the potential field. Our work confirms the capacity of polarization measurements for diagnosing nonpotentiality and free energy in the solar corona.

## **A MODEL OF CORONAL STREAMERS WITH UNDERLYING FLUX ROPES**

M. [Cottaar](#)<sup>1</sup> and Y. Fan

*Astrophysical Journal*, 704:576–590, **2009** October

We present global two-dimensional axisymmetric isothermal MHD simulations of the dynamic evolution of a coronal helmet streamer, driven at the lower boundary by the emergence of a twisted flux rope. By varying both the detached toroidal and poloidal fluxes emerged into the corona, but fixing the normal flux distribution at the surface at the end of the emergence, we obtain solutions that either settle to a new steady state of a stable helmet streamer containing a flux rope, or result in a disruption of the helmet with the underlying flux rope being expelled in a coronal mass ejection (CME)-like eruption. In all of the cases studied, we find that the transition from a stable to an eruptive state takes place at a magnetic energy that is very close to the Aly open field energy. Furthermore, we find that the transition from a stable to an eruptive end state does not occur at a single critical value of the total relative magnetic helicity, but depends on the profile of the underlying flux rope. Cases where the detached flux rope contains a higher amount of self-helicity, i.e., higher internal twist or detached poloidal flux, are found to become eruptive at a significantly lower total helicity. For the eruptive cases, the detached flux rope after emergence first rises quasi-statically due to a gradual opening of the field lines at the edge of the streamer and a slow reconnection below the flux rope, which continues to slowly increase the amount of the detached flux. This decreases the downward magnetic tension on the flux rope. The dynamic eruption is initiated when the magnetic

pressure gradient no longer decreases fast enough to balance the decrease in the magnetic tension. Later rapid reconnections below the flux rope are important for accelerating the flux rope. For the stable helmets, we find that no cavities are formed due to the simplifying assumption of isothermal energetics and the uniform density lower boundary condition. However during the eruption we see the development of the 3-part structure of a CME.

### **Inward Propagating Plasma Parcels in the Solar Corona: Models with Aerodynamic Drag, Ablation, and Snowplow Accretion**

Steven R. **Cranmer** (CU Boulder), [Craig E. DeForest](#) (SwRI), [Sarah E. Gibson](#) (HAO/NCAR)

ApJ 2021

<https://arxiv.org/pdf/2103.12039.pdf>

Although the solar wind flows primarily outward from the Sun to interplanetary space, there are times when small-scale plasma inflows are observed. Inward-propagating density fluctuations in polar coronal holes were detected by the COR2 coronagraph on board the STEREO-A spacecraft at heliocentric distances of 7 to 12 solar radii, and these fluctuations appear to undergo substantial deceleration as they move closer to the Sun. Models of linear magnetohydrodynamic waves have not been able to explain these deceleration patterns, so they have been interpreted more recently as jets from coronal sites of magnetic reconnection. In this paper, we develop a range of dynamical models of discrete plasma parcels with the goal of better understanding the observed deceleration trend. We found that parcels with a constant mass do not behave like the observed flows, and neither do parcels undergoing ablative mass loss. However, parcels that accrete mass in a snowplow-like fashion can become decelerated as observed. We also extrapolated OMNI in situ data down to the so-called Alfvén surface and found that the initial launch-point for the observed parcels may often be above this critical radius. In other words, in order for the parcels to flow back down to the Sun, their initial speeds are probably somewhat nonlinear (i.e., supra-Alfvénic) and thus the parcels may be associated with structures such as shocks, jets, or shear instabilities.

### **Asymmetric expansion of coronal mass ejections in the low corona**

H. **Cremades**<sup>1,2</sup>, F. A. Iglesias<sup>1,2</sup> and L. A. Merenda

A&A 635, A100 (2020)

<https://doi.org/10.1051/0004-6361/201936664>

**Aims.** Understanding how magnetic fields are structured within coronal mass ejections (CMEs), and how they evolve from the low corona into the heliosphere, is a major challenge for space weather forecasting and for solar physics. The study of CME morphology is a particularly auspicious approach to this problem, given that it holds a close relationship with the CME magnetic field configuration. Although earlier studies have suggested an asymmetry in the width of CMEs in orthogonal directions, this has not been inspected using multi-viewpoint observations.

**Methods.** The improved spatial, temporal, and spectral resolution, added to the multiple vantage points offered by missions of the Heliophysics System Observatory, constitute a unique opportunity to gain insight into this regard. We inspect the early evolution (below ten solar radii) of the morphology of a dozen CMEs occurring under specific conditions of observing spacecraft location and CME trajectory, favorable to reduce uncertainties typically involved in the 3D reconstruction used here. These events are carefully reconstructed by means of a forward modeling tool using simultaneous observations of the Solar-Terrestrial Relations Observatory (STEREO) Extreme Ultraviolet Imager and the Solar Dynamics Observatory Atmospheric Imaging Assembly as input when originating low in the corona, and followed up in the outer fields of view of the STEREO and the Solar and Heliospheric Observatory coronagraphs. We then examine the height evolution of the morphological parameters arising from the reconstructions.

**Results.** The multi-viewpoint analysis of this set of CMEs revealed that their initial expansion – below three solar radii – is considerably asymmetric and non-self-similar. Both angular widths, namely along the main axes of CMEs (AWL) and in the orthogonal direction (AWD, representative of the flux rope diameter), exhibit much steeper change rates below this height, with the growth rate of AWL found to be larger than that of AWD, also below that height. Angular widths along the main axes of CMEs are on average  $\approx 1.8$  times larger than widths in the orthogonal direction AWD. The ratios of the two expansion speeds, namely in the directions of CMEs main axes and in their orthogonal, are nearly constant in time after  $\sim 4$  solar radii, with an average ratio  $\approx 1.6$ . Heights at which the width change rate is defined to stabilize are greater for AWL than for AWD.

### **Coronal mass ejections associated to a super-active region**

H. **Cremades** et al.

CESRA nugget #2080 2018

<http://www.astro.gla.ac.uk/users/eduard/cesra/?p=2080>

During its transit through central meridian, and along four consecutive days, from **13 to 16 February 2011**, NOAA active region (AR) 11158 generated coronal mass ejections (CMEs) in association with waves observed in the extreme ultraviolet (EUV) low corona, and even with a Moreton wave. On those dates, the spacecraft of the **STEREO** mission were located in quadrature with **SOHO** and **SDO**, enabling the exceptional observation of this series of Earth-directed events. Moreover, low-frequency radio emissions registered by the **WAVES** experiment aboard the **Wind** spacecraft allows tracking of the events in the interplanetary medium. These circumstances motivate a joint analysis of the four coronal wave events, their associated CMEs, and interplanetary radio counterparts, by means of observations from multiple viewpoints and at various wavelengths.

## Mass Loss Rates from Coronal Mass Ejections: A Predictive Theoretical Model for Solar-Type Stars

Steven R. [Cranmer](#) (CU Boulder)

ApJ 2017

<https://arxiv.org/pdf/1704.06689.pdf>

Coronal mass ejections (CMEs) are eruptive events that cause a solar-type star to shed mass and magnetic flux. CMEs tend to occur together with flares, radio storms, and bursts of energetic particles. On the Sun, CME-related mass loss is roughly an order of magnitude less intense than that of the background solar wind. However, on other types of stars, CMEs have been proposed to carry away much more mass and energy than the time-steady wind. Earlier papers have used observed correlations between solar CMEs and flare energies, in combination with stellar flare observations, to estimate stellar CME rates. This paper sidesteps flares and attempts to calibrate a more fundamental correlation between surface-averaged magnetic fluxes and CME properties. For the Sun, there exists a power-law relationship between the magnetic filling factor and the CME kinetic energy flux, and it is generalized for use on other stars. An example prediction of the time evolution of wind/CME mass-loss rates for a solar-mass star is given. A key result is that for ages younger than about 1 Gyr (i.e., activity levels only slightly higher than the present-day Sun), the CME mass loss exceeds that of the time-steady wind. At younger ages, CMEs carry 10 to 100 times more mass than the wind, and such high rates may be powerful enough to disperse circumstellar disks and affect the habitability of nearby planets. The cumulative CME mass lost by the young Sun may have been as much as 1% of a solar mass.

## Asymmetric expansion of coronal mass ejections in the low corona

Hebe [Cremades](#), [Francisco A. Iglesias](#), [Luciano A. Merenda](#)

A&A 2020

<https://arxiv.org/pdf/2001.10085.pdf>

**Aims.** The study of the morphology of coronal mass ejections (CMEs) is an auspicious approach to understanding how magnetic fields are structured within CMEs. Although earlier studies have suggested an asymmetry in the width of CMEs in orthogonal directions, this has not been inspected using multi-viewpoint observations.

**Methods.** We inspect the early evolution (below ten solar radii) of the morphology of a dozen CMEs occurring under specific conditions of observing spacecraft location and CME trajectory, favorable to reduce uncertainties typically involved in the 3D reconstruction used here. These events are carefully reconstructed by means of a forward modeling tool using simultaneous observations of STEREO EUVI and SDO/AIA as input when originating low in the corona, and followed up in the outer fields of view of the STEREO and the SOHO coronagraphs. We then examine the height evolution of the morphological parameters arising from the reconstructions.

**Results.** The multi-viewpoint analysis of this set of CMEs revealed that their initial expansion --below three solar radii-- is considerably asymmetric and non-self-similar. Both angular widths, namely along the main axes of CMEs (AWL) and in the orthogonal direction (AWD, representative of the flux rope diameter), exhibit much steeper change rates below this height, with the growth rate of AWL found to be larger than that of AWD, also below that height. Angular widths along the main axes of CMEs are on average  $\approx 1.8$  times larger than widths in the orthogonal direction AWD. The ratios of the two expansion speeds, namely in the directions of CMEs main axes and in their orthogonal, are nearly constant in time after  $\sim 4$  solar radii, with an average ratio  $\approx 1.6$ . Heights at which the width change rate is defined to stabilize are greater for AWL than for AWD. **14 December 2010**

## Coronal mass ejections from the same active region cluster: Two different perspectives

Hebe [Cremades](#), Cristina Hemilse Mandrini, Brigitte Schmieder, Alberto Maximiliano Crescitelli

Solar Phys Volume 290, Issue 6, pp 1671-1686 2015

<http://arxiv.org/pdf/1505.01384v1.pdf>

The cluster formed by active regions (ARs) NOAA 11121 and 11123, approximately located on the solar central meridian on **11 November 2010**, is of great scientific interest. This complex was the site of violent flux emergence and the source of a series of Earth-directed events on the same day. The onset of the events was nearly simultaneously observed by the Atmospheric Imaging Assembly (AIA) telescope aboard the Solar Dynamics Observatory (SDO) and the Extreme-Ultraviolet Imagers (EUVI) on the Sun-Earth Connection Coronal and Heliospheric Investigation (SECCHI) suite of telescopes onboard the Solar-Terrestrial Relations Observatory (STEREO) twin spacecraft. The progression of these events in the low corona was tracked by the Large Angle Spectroscopic Coronagraphs (LASCO) onboard the Solar and Heliospheric Observatory (SOHO) and the SECCHI/COR coronagraphs on STEREO. SDO and SOHO imagers provided data from the Earth's perspective, whilst the STEREO twin instruments procured images from the orthogonal directions. This spatial configuration of spacecraft allowed optimum simultaneous observations of the AR cluster and the coronal mass ejections that originated in it. Quadrature coronal observations provided by STEREO revealed a notably large amount of ejective events compared to those detected from Earth's perspective. Furthermore, joint observations by SDO/AIA and STEREO/SECCHI EUVI of the source region indicate that all events classified by GOES as X-ray flares had an ejective coronal counterpart in quadrature observations. These results have direct impact on current space weather forecasting because of the probable missing alarms when there is a lack of solar observations in a view direction perpendicular to the Sun-Earth line.

## Coronal Transient Events During Two Solar Minima: Their Solar Source Regions and Interplanetary Counterparts

H. [Cremades](#), C. H. Mandrini und S. Dasso

Solar Physics, Volume 274, Numbers 1-2, 233-249, **2011**, [File](#)

In the frame of two coordinated observational and research efforts, two full solar rotations were investigated in the times of two distinct solar minima. These two campaigns were dubbed Whole Sun Month (WSM; **10 August – 8 September 1996**) and Whole Heliosphere Interval (WHI; **20 March – 16 April 2008**). The nearly uninterrupted gathering of solar coronal data since the beginning of the Solar and Heliospheric Observatory (SOHO) era offers the exceptional possibility of comparing two solar minima for the first time, with regard to the coronal transient aspect. This study characterizes the variety of outward-traveling transients observed in the solar corona during both time intervals, from very narrow jet-like events to coronal mass ejections (CMEs). Their solar source regions and ensuing interplanetary structures were identified and characterized as well, toward a global-scale description of their role in determining the heliosphere's conditions. Multi-wavelength images provided by the space missions SOHO, Yokohoh (only WSM), and Solar-Terrestrial Relations Observatory (STEREO; only WHI) and ground-based observatories were analyzed for coronal ejecta and their solar sources, while data registered by the Advanced Composition Explorer (ACE) spacecraft were inspected for interplanetary CMEs and magnetic clouds. Notable differences arise from the analysis of the detailed survey of events: more (fewer) ejecta during WHI (WSM), 12% (40%) were produced by active regions during WHI (WSM), and nearly no (high) deflection from the radial direction was observed during WHI (WSM). Instrumental aspects such as dissimilar resolution, cadence, and fields of view are considered in order to discern instrumentally driven disparities from inherent differences between solar minima.

### **Coronal mass ejections: Solar cycle aspects**

Hebe [Cremades](#) and O.C. St. Cyr

[Advances in Space Research](#)

[Volume 40, Issue 7](#), Pages 1042-1048, **2007**, [File](#)

Research in the area of coronal mass ejections (CMEs) is now mature, since their discovery coincided with the first coronagraph that was flown in space in 1971. However, the continuity of space coronagraphs and similar instruments has allowed the detection and measurement of CMEs over almost three consecutive solar cycles. Their importance in the space weather field is well established, and some researchers believe the phenomenon may also be important for the longer-term space climate studies. In this review, we summarize the solar cycle variation of the main properties of CMEs detected by previous and ongoing missions. These include rate of detection, apparent angular width, detected mass, apparent speed, and apparent latitude. Their behavior in time is presented and discussed.

### **On the three-dimensional configuration of coronal mass ejections**

H. [Cremades](#) and V. Bothmer

A&A 422, 307–322 (**2004**); [File](#)

Coronal mass ejections (CMEs) are a direct consequence of the dynamic nature of the solar atmosphere. They represent fundamental processes in which energy is transferred from the Sun into interplanetary space, including geospace. Their origin, 3D structure and internal magnetic field configuration are to date not well understood. The SOHO spacecraft, launched by the end of 1995, has provided unprecedented data on CMEs since instruments switched on in 1996. From a detailed investigation of the full set of LASCO (Large Angle Spectroscopic Coronagraph) observations from 1996 to the end of 2002, a set of structured CME events has been identified, which exhibits white-light fine structures likely indicative of their internal magnetic field configuration and possible 3D structure. Their source regions in the low corona and photosphere have been inferred by means of complementary analyses of data from the Extreme-Ultraviolet Imaging Telescope (EIT) and Michelson Doppler Imager (MDI) on board SOHO, and ground-based H $\alpha$  measurements. According to the results of this study, structured CMEs arise in a self-similar manner from pre-existing small scale loop systems, overlying regions of opposite magnetic polarities. From the characteristic pattern of the CMEs' source regions in both solar hemispheres, a generic scheme is presented in which the projected white-light topology of a CME depends primarily on the orientation and position of the source region's neutral line on the solar disk. The paper also provides information about the white-light characteristics of the analysed CMEs, such as angular width and position angle, with respect to their source region properties, such as heliographic location, inclination and length, including the frequency and variation of these parameters over the investigated time period.

## Remote sensing of the solar site of interchange reconnection associated with the May 1997 magnetic cloud

Crooker N.U., Webb D.F.

Journal of Geophysical Research, Volume 111, Issue A8, CiteID A08108, 2006.

The direction of suprathermal electron flux on open magnetic field lines in the **15 May 1997** magnetic cloud is used to predict the solar location of the interchange reconnection that released one end of what presumably were doubly connected field lines in the coronal mass ejection (CME) of origin on **12 May**.

## Constraining Stellar Coronal Mass Ejections Through Multi-Wavelength Analysis of the Active M Dwarf EQ Peg

M. K. Crosley, R. A. Osten

2018 *ApJ* 856 39

<https://arxiv.org/pdf/1802.03440.pdf>

Stellar coronal mass ejections remain experimentally unconstrained, unlike their stellar flare counterparts which are observed ubiquitously across the electromagnetic spectrum. Low frequency radio bursts in the form of a type II burst offer the best means of identifying and constraining the rate and properties of stellar CMEs. CME properties can be further improved through the use of proposed solar-stellar scaling relations and multi-wavelength observations of CMEs through the use of type II bursts and the associated flare expected to occur alongside. We report on 20 hours of observation of the nearby, magnetically active, and well characterized M dwarf star EQ Peg. The observations are simultaneously observed with the Jansky Very Large Array at their P-band (230-470 MHz) and at the Apache Point observatory in the SDSS u' filter ( $\lambda = 3557 \text{ \AA}$ ). Dynamic spectra of the P band data, constructed to search for signals in the frequency-time domains, did not reveal evidence for drifting radio bursts that could be ascribed to type II bursts. Given the sensitivity of our observations, we are able to place limits on the brightness temperature and source size of any bursts which may have occurred. Using solar scaling relations on four observed stellar flares, we predict CME parameters. Given the constraints on coronal density and photospheric field strength, our models suggest that the observed flares would have been insufficient to produce detectable type II bursts at our observed frequencies. We consider the implications of these results, and other recent findings, on stellar mass loss.

## Transient Mass Loss Analysis of Solar Observations using Stellar Methods

M. K. Crosley, R. A. Osten, C. Norman

2017 *ApJ*, 845, 67

<https://arxiv.org/pdf/1707.01928.pdf>

Low frequency dynamic spectra of radio bursts from nearby stars offer the best chance to directly detect the stellar signature of transient mass loss on low mass stars. Crosley et al. (2016) proposes a multi-wavelength methodology to determine coronal mass ejection parameters, such as Coronal Mass Ejection (CME) speed, mass, and kinetic energy. We test the validity and accuracy of the results derived from the methodology by using Geostationary Operational Environmental Satellite X-ray observations and Bruny Island Radio Spectrometer radio observations. These are analogous observations to those which would be found in the stellar studies. Derived results from these observations are compared to direct white light measurements of the Large Angle and Spectrometric Coronagraph.

We find that, when a pre-event temperature can be determined, that the accuracy of CME speeds are within a few hundred km/s, and are reliable when specific criteria has been met. CME mass and kinetic energies are only useful in determining approximate order of magnitude measurements when considering the large errors associated to them. These results will be directly applicable to interpretation of any detected stellar events and derivation of stellar CME properties. **2011-01-28, 2011-02-13, 2012-03-17, 2012-06-03, 2012-07-06, 2013-05-02, 2013-10-24, 2013-11-08, 2014-01-08, 2014-02-20, 2014-03-20, 2014-04-25, 2014-11-03, 2014-12-17,**

## Statistical Study of Magnetic Topology for Eruptive and Confined Solar Flares

Yanmei Cui, Haimin Wang, Yan Xu, Siqing Liu

*JGR* 2018

<http://sci-hub.tw/http://onlinelibrary.wiley.com/doi/10.1002/2017JA024710/abstract;jsessionid=1B28DD312655626B6C73EE27929AA447.f03t01>

Large flares and halo CMEs can often cause strong space environment disturbances and sequentially a series of space environment effects. The X-class flares associated with halo CMEs are particularly prone to these effects. In this paper, 58 X-class flares were collected and studied with the source locations in 30 degrees from the disk center, which were observed from 1996 to 2015. Among these events, 48 flares were associated with CMEs and defined as “eruptive” events. The other 10 flares without CMEs were defined as “confined” flares. By comparing the properties of flares and associated magnetic fields for the two sets of samples, we found: (1) Magnetic free energy and overlying transverse fields play important roles in producing solar eruptions. Eruptive flares with high-speed CMEs tend to occur in active regions with more free energy and larger decay index. (2) CME speeds are affected by magnetic free energy, which are described by parameters of the unsigned magnetic flux, the area of polarity inversion region, and the strength of transverse fields in the low altitude. These parameters have moderate positive correlations with CME speeds.

**Table 1:** Selected X-Class Flares and the associated CMEs from 1996 to 2015

### **Shock wave driven by CME evidenced by metric type II burst and EUV wave**

R.D. **Cunha-Silva**, F.C.R. Fernandes, C.L. Selhorst

Advances in Space Research Volume 56, Issue 12, 15 December 2015, Pages 2804–2810

<http://www.sciencedirect.com/science/article/pii/S0273117715005311>

Solar type II radio bursts are produced by plasma oscillations in the solar corona as a result of shock waves. The relationship between type II bursts and coronal shocks is well evidenced by observations since the 1960s. However, the drivers of the shocks associated with type II events at metric wavelengths remain as a controversial issue among solar physicists. The flares and the coronal mass ejections (CMEs) are considered as potential drivers of these shocks. In this article, we present an analysis of a metric type II burst observed on **May 17, 2013**, using data provided by spectrometers from e-CALLISTO (extended-Compound Astronomical Low-cost Low-frequency Instrument for Spectroscopy and Transportable Observatories) and EUV images from the Extreme Ultraviolet Imager (EUVI), aboard the Solar Terrestrial Relations Observatory (STEREO). The event was associated with an M3.2 SXR flare and a halo CME. The EUV wave produced by the expansion of the CME was clear from the EUV images. The heights of the EUV wave fronts proved to be consistent with the heights of the radio source obtained with the  $2-4 \times$  Newkirk density model, which provided a clue to an oblique propagation of the type-II-emitting shock segment. The results for the magnetic field in the regions of the shock also revealed to be consistent with the heights of the radio source obtained using the  $2-4 \times$  Newkirk density model. Exponential fit on the intensity maxima of the harmonic emission provided a shock speed of  $\sim 580-990 \text{ km s}^{-1}$ , consistent with the average speed of the associated EUV wave front of  $626 \text{ km s}^{-1}$ .

### **Explosive Events: Swirling Transition Region Jets**

W. **Curdt**, H. Tian, S. Kamio

Solar Physics, October 2012, Volume 280, Issue 2, pp 417-424

In this paper, we extend our earlier work to provide additional evidence for an alternative scenario to explain the nature of events called ‘explosive events’. The bidirectional, fast Doppler motion of explosive events observed spectroscopically in the transition region emission is classically interpreted as a pair of bidirectional jets moving upward and downward from a reconnection site. We discuss the problems of this model. In our previous work, we focused basically on the discrepancy of fast Doppler motion without detectable motion in the image plane. We now suggest an alternative scenario for the explosive events, based on our observations of spectral line tilts and bifurcated structure in some events. Both features are indicative of rotational motion in narrow structures. We explain the bifurcation as the result of rotation of hollow cylindrical structures and demonstrate that this kind of sheath model can also be applied to explain the nature of the puzzling ‘explosive events’. We find that the spectral tilt, the lack of apparent motion, the bifurcation, and a rapidly growing number of direct observations support an alternative scenario of linear, spicular-sized jets with a strong spinning motion.

### **MLSO Mark III K-Coronameter Observations of the CME Rate from 1989 – 1996**

O. C. St. **Cyr**, Q. A. Flint, H. Xie, D. F. Webb, J. T. Burkepile, A. R. Lecinski, C. Quirk, A. L. Stanger

Solar Phys. Volume 290, Issue 10, pp 2951-2962 2015

We report here an attempt to fill the 1990 – 1995 gap in the CME rate using the Mauna Loa Solar Observatory’s Mark III (Mk3) K-coronameter. The Mk3 instrument observed routinely several hours most days beginning in 1980 until it was upgraded to Mk4 in 1999. We describe the statistical properties of the CMEs detected during 1989 – 1996, and we determine a CME rate for each of those years. Since spaceborne coronagraphs have more complete duty cycles than a

ground-based instrument at a single location, we compare the Mk3-derived CME rate from 1989 with the rate from the SMM C/P coronagraph, and from 1996 with the rate from the SOHO LASCO coronagraphs.

### **Nanodust dynamics during a coronal mass ejection**

Andrzej [Czechowski](#) and Jens Kleimann

Ann. Geophys., 35, 1033-1049, 2017

<https://www.ann-geophys.net/35/1033/2017/angeo-35-1033-2017.pdf>

Short Summary: Interplanetary dust also includes very small (nanometer-sized) particles. The dynamics of nanodust is determined by electromagnetic forces, which accelerate the dust to velocities on the order of 500 km/s or, in the vicinity of the Sun, trap them in bound orbits. We investigate the behavior of nanodust during a coronal mass ejection. We find a new population of extremely fast (1000 km/s) nanodust. We also study the effect of the ion drag force.

### **Centre-to-limb properties of small, photospheric quiet Sun jets**

F. Rubio [da Costa](#), S. K. Solanki, S. Danilovic, J. Hizberger, V. Martínez-Pillet

A&A 574, A95 (2015)

<http://arxiv.org/pdf/1412.1620v1.pdf>

Strongly Doppler-shifted Stokes V profiles have been detected in the quiet Sun with the IMAx instrument on-board the SUNRISE stratospheric balloon-borne telescope. High velocities are required in order to produce such signals, hence these events have been interpreted as jets, although other sources are also possible. We aim to characterize the variation of the main properties of these events (occurrence rate, lifetime, size and velocities) with their position on the solar disk between disk centre and the solar limb. These events have been identified in Sunrise/IMaX data according to the same objective criteria at all available positions on the solar disk. Their properties were determined using standard techniques. Our study yielded a number of new insights into this phenomenon. Most importantly, the number density of these events is independent of the heliocentric angle, i.e. the investigated supersonic flows are nearly isotropically distributed. Size and lifetime are also nearly independent of the heliocentric angle, while their intensity contrast increases towards the solar limb. The Stokes V jets are associated with upflow velocities deduced from Stokes I, which are stronger towards the limb. Their intensity decreases with time, while their line-of-sight (LOS) velocity does not display a clear temporal evolution. Their association with linear polarization signals decreases towards the limb. The density of events appears to be independent of heliocentric angle, establishing that they are directed nearly randomly. If these events are jets triggered by magnetic reconnection between emerging magnetic flux and the ambient field, then our results suggest that there is no preferred geometry for the reconnection process. **10th and**

### **The role of filament activation in a solar eruption**

F. Rubio [da Costa](#)<sup>1,2</sup>, F. Zuccarello<sup>1</sup>, L. Fletcher<sup>2</sup>, P. Romano<sup>3</sup> and N. Labrosse

A&A 539, A27 (2012), **File**

<http://arxiv.org/pdf/1412.1858v1.pdf>

Context. Observations show that the mutual relationship between filament eruptions and solar flares cannot be described in terms of a unique scenario. In some cases, the eruption of a filament appears to trigger a flare, while in others the observations are more consistent with magnetic reconnection that produces both the flare observational signatures (e.g., ribbons, plasma jets, post-flare loops, etc.) and later the destabilization and eruption of a filament. Aims. Contributing to a better comprehension of the role played by filament eruptions in solar flares, we study an event which occurred in NOAA 8471, where a flare and the activation of (at least) two filaments were observed on **28**

**February 1999.**

Methods. By using imaging data acquired in the 1216, 1600, 171 and 195 Å TRACE channels and by BBSO in the continuum and in the H $\alpha$  line, a morphological study of the event is carried out. Moreover, using TRACE 1216 and 1600 Å data, an estimate of the “pure” Ly $\alpha$  power is obtained. The extrapolation of the magnetic field lines is done using the SOHO/MDI magnetograms and assuming a potential field.

Results. Initially an area hosting a filament located over a  $\delta$  spot becomes brighter than the surroundings, both in the chromosphere and in the corona. This area increases in brightness and extension, eventually assuming a two-ribbon morphology, until it reaches the eastern part of the active region. Here a second filament becomes activated and the brightening propagates to the south, passing over a large supergranular cell. The potential magnetic field extrapolation indicates that the field line connectivity changes after the flare.

Conclusions. The event is triggered by the destabilization of a filament located between the two polarities of a  $\delta$  spot. This destabilization involves the magnetic arcades of the active region and causes the eruption of a second filament, that gives rise to a CME and to plasma motions over a supergranular cell. We conclude that in this event the two filaments play an active and decisive role, albeit in different stages of the phenomenon, in fact the destabilization of one filament causes brightenings, reconnection and ribbons, while the second one, whose eruption is caused by the field reconfiguration resulting from the previous reconnection, undergoes the greatest changes and causes the CME.

### **Sequential eruptions triggered by flux emergence - observations and modeling**

Sally [Dacie](#), [Tibor Torok](#), [Pascal Demoulin](#), [Mark Linton](#), [Cooper Downs](#), [Lidia van Driel-Gesztelyi](#), [David Long](#), [James Leake](#)

ApJ **862** 117 **2018**

<https://arxiv.org/pdf/1807.00020.pdf>

<http://sci-hub.tw/http://iopscience.iop.org/article/10.3847/1538-4357/aacce3/meta>

We describe and analyze observations by the Solar Dynamics Observatory of the emergence of a small, bipolar active region within an area of unipolar magnetic flux that was surrounded by a circular, quiescent filament. Within only eight hours of the start of the emergence, a partial splitting of the filament and two consecutive coronal mass ejections took place. We argue that all three dynamic events occurred as a result of particular magnetic-reconnection episodes between the emerging bipole and the pre-existing coronal magnetic field. In order to substantiate our interpretation, we consider three-dimensional magnetohydrodynamic simulations that model the emergence of magnetic flux in the vicinity of a large-scale coronal flux rope. The simulations qualitatively reproduce most of the reconnection episodes suggested by the observations; as well as the filament-splitting, the first eruption, and the formation of sheared/twisted fields that may have played a role in the second eruption. Our results suggest that the position of emerging flux with respect to the background magnetic configuration is a crucial factor for the resulting evolution, while previous results suggest that parameters such as the orientation or the amount of emerging flux are important as well. This poses a challenge for predicting the onset of eruptions that are triggered by flux emergence, and it calls for a detailed survey of the relevant parameter space by means of numerical simulations. **18 July 2014**

### **Modeling the formation and eruption of coronal structures by linking data-driven magnetofrictional and MHD simulations for AR 12673★**

F. Daei<sup>1</sup>, J. Pomoell<sup>1</sup>, D. J. Price<sup>1</sup>, A. Kumari<sup>1,2</sup>, S. Good<sup>1</sup> and E. K. J. Kilpua<sup>1</sup>

A&A 676, A141 (2023)

<https://www.aanda.org/articles/aa/pdf/2023/08/aa46183-23.pdf>

**Context.** The data-driven and time-dependent modeling of coronal magnetic fields is crucial for understanding solar eruptions. These efforts are complicated by the challenges of finding a balance between physical realism and computing efficiency. One possible technique is to couple two modeling approaches.

**Aims.** Our aim here is to showcase our progress in using time-dependent magnetofrictional model (TMFM) results as input to dynamical magnetohydrodynamic (MHD) simulations. However, due to the different evolution processes in these two models, using TMFM snapshots in an MHD simulation is nontrivial. We address these issues, both physically and numerically, discuss the incompatibility of the TMFM output to serve as the initial condition in MHD simulations, and show our methods of mitigating this. The evolution of the flux systems and the cause of the eruption are investigated.

**Methods.** TMFM is a prevalent approach that has proven to be a very useful tool in the study of the formation of unstable structures in the solar corona. In particular, it is capable of incorporating observational data as initial and boundary conditions and requires shorter computational time compared to MHD simulations. To leverage the efficiency of data-driven TMFM and also to simulate eruptive events in the MHD framework, one can apply TMFM up to a certain time before the expected eruption(s) and then proceed with the simulation in the full or ideal MHD regime in order to more accurately capture the eruption process.

**Results.** We show the results of a benchmark test case with a linked TMFM and MHD simulation to study the evolution of NOAA active region 12673. A rise of a twisted flux bundle through the MHD simulation domain is observed, but we find that the rate of the rise and the altitude reached depends on the time of the TMFM snapshot that was used to initialize the MHD simulation and the helicity injected into the system. The analysis suggested that torus instability and slip-running reconnection could play an important role in the eruption.

**Conclusions.** The results show that the linkage of TMFM and zero- $\beta$  MHD models can be successfully used to model the eruptive coronal magnetic fields. **3-6 Sep 2017**

### **Effect of the Heliospheric State on CME Evolution**

[Fithanegest Kassa Dagnev](#), [Nat Gopalswamy](#), [Solomon Belay Tessema](#), [Sachiko Akiyama](#), [Seiji Yashiro](#)  
2022 ApJ 936 122

<https://arxiv.org/ftp/arxiv/papers/2208/2208.03536.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac8744/pdf>

The culmination of solar cycle 24 by the end of 2019 has created the opportunity to compare the differing properties of coronal mass ejections (CMEs) between two whole solar cycles: Solar cycle 23 (SC 23) and Solar cycle 24 (SC 24). We report on the width evolution of limb CMEs in SC 23 and 24 in order to test the suggestion by Gopalswamy et al.

(2015a) that CME flux ropes attain pressure balance at larger heliocentric distances in SC 24. We measure CME width as a function of heliocentric distance for a significantly large number of limb CMEs (~1000) and determine the distances where the CMEs reach constant width in each cycle. We introduced a new parameter: the transition height ( $h_c$ ) of a CME defined as the critical heliocentric distance beyond which the CME width stabilizes to a quasi-constant value. Cycle and phase-to-phase comparisons are based on this new parameter. We find that the average value of  $h_c$  in SC 24 is 62% higher than in SC 23. SC 24 CMEs attain their peak width at larger distances from the Sun as compared to SC 23 CMEs. The enhanced transition height in SC 24 is new observational ratification of the anomalous expansion. The anomalous expansion of SC 24 CMEs which is caused by the weak state of the heliosphere, accounts for the larger heliocentric distance where the pressure balance between CME flux rope and the ambient medium is attained. **2014**

ApJ **903** 118 **2020**

<https://arxiv.org/ftp/arxiv/papers/2009/2009.06033.pdf>

<https://doi.org/10.3847/1538-4357/abb887>

We report on the properties of halo coronal mass ejections (HCMEs) in solar cycles 23 and 24. We compare the HCMEs properties between the corresponding phases (rise, maximum, and declining) in cycles 23 and 24 in addition to comparing those between the whole cycles. Despite the significant decline in the sunspot number (SSN) in cycle 24, which dropped by 46% with respect to cycle 23, the abundance of HCMEs is similar in the two cycles. The HCME rate per SSN is 44% higher in cycle 24. In the maximum phase, cycle-24 rate normalized to SSN increased by 127% while the SSN dropped by 43%. The source longitudes of cycle-24 HCMEs are more uniformly distributed than those in cycle 23. We found that the average sky-plane speed in cycle 23 is ~16% higher than that in cycle 24. The size distributions of the associated flares between the two cycles and the corresponding phases are similar. The average speed at a central meridian distance (CMD) = 600 for cycle 23 is ~28% higher than that of cycle 24. We discuss the unusual bump in HCME activity in the declining phase of cycle 23 as due to exceptional active regions that produced many CMEs during October 2003 to October 2005. The differing HCME properties in the two cycles can be attributed to the anomalous expansion of cycle-24 CMEs. Considering the HCMEs in the rise, maximum and declining phases, we find that the maximum phase shows the highest contrast between the two cycles.

## A comparison of CME expansion speeds between solar cycles 23 and 24

Fithanegest Kassa [Dagnev](#), [Nat Gopalswamy](#), [Solomon Belay Tessema](#)

Journal of Physics Conference Series, to appear in the Proc. 19th International Astrophysics Conference held in Santa Fe, New Mexico, March 9 - 13, **2020**

<https://arxiv.org/ftp/arxiv/papers/2007/2007.13204.pdf>

We report on a comparison of the expansion speeds of limb coronal mass ejections (CMEs) between solar cycles 23 and 24. We selected a large number of limb CME events associated with soft X-ray flare size greater than or equal to M1.0 from both cycles. We used data and measurement tools available at the online CME catalog ([this https URL](#)) that consists of the properties of all CMEs detected by the Solar and Heliospheric Observatory's (SOHO) Large Angle and Spectrometric Coronagraph (LASCO). We found that the expansion speeds in cycle 24 are higher than those in cycle 23. We also found that the relation between radial and expansion speeds has different slopes in cycles 23 and 24. The cycle 24 slope is 45% higher than that in cycle 23. The expansion speed is also higher for a given radial speed. The difference increases with speed. For a 2000 km/s radial speed, the expansion speed in cycle 24 is ~48% higher. These results present additional evidence for the anomalous expansion of cycle 24-CMEs, which is due to the reduced total pressure in the heliosphere. **2001 April 02**

## The shock driving capability of a CME inferred from multiwavelength observations

Fithanegest Kassa [Dagnev](#), [Nat Gopalswamy](#), [Solomon Belay Tessema](#), [Ange Cynthia Umuhire](#), [Seiji Yashiro](#), [Pertti Mäkelä](#), [Hong Xie](#)

Sun and Geosphere, **Vol.14, No. 2, 2019** p. 105-110

<https://arxiv.org/ftp/arxiv/papers/2002/2002.04056.pdf>

[http://newserver.stil.bas.bg/SUNGEO/00SGArhiv/SG\\_v14\\_No2\\_2019-pp105-110.pdf](http://newserver.stil.bas.bg/SUNGEO/00SGArhiv/SG_v14_No2_2019-pp105-110.pdf)

The radial speed of a coronal mass ejection (CME) determines the shock-driving capability of a CME as indicated by the presence of a type II radio burst. Here we report on the **April 18, 2014** CME that was associated with a type II radio burst in the metric and interplanetary domains. We used the radio-burst data provided by the San Vito Solar Observatory of the Radio Solar Telescope Network and data from the Wind spacecraft. The CME is a full halo in the field of view of the coronagraphs on board the Solar and Heliospheric Observatory (SOHO). The CME was also observed by the coronagraphs on board the Solar Terrestrial Relations Observatory (STEREO). We computed the CME shock and flux rope speeds based on the multi-view observations by the different coronagraphs and by EUV instruments. We determined the shock speed from metric and interplanetary radio observations and found them to be consistent with white-light observations, provided the metric type II burst and its continuation into the decameter-hectometric domain are produced at the shock flanks, where the speed is still high enough to accelerate electrons that produce the type II bursts. Interestingly, there was an interplanetary type II burst segment consistent with an origin at the shock nose suggesting that the curved shock was crossing plasma levels separated by a few solar radii. We conclude that the CME speed is high enough to produce the interplanetary Type II burst and a solar energetic particle (SEP) event. However, the speed is not high enough to produce a ground level enhancement (GLE) event, which requires the shock to form at a height of ~1.5 Rs.

## STITCH: A Subgrid-Scale Model for Energy Buildup in the Solar Corona

[Joel T. Dahlin](#), [C. Richard DeVore](#), [Spiro K. Antiochos](#)

ApJ **941** 79 **2022**

<https://arxiv.org/pdf/2112.00641.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac9e5a/pdf>

The solar corona routinely exhibits explosive activity, in particular coronal mass ejections and their accompanying eruptive flares, that have global-scale consequences. These events and their smaller counterparts, coronal jets, originate in narrow, sinuous filament channels. The key processes that form and evolve the channels operate on still smaller spatial scales and much longer time scales, culminating in a vast separation of characteristic lengths and times that govern these explosive phenomena. In this article, we describe implementation and tests of an efficient subgrid-scale model for generating eruptive structures in magnetohydrodynamics (MHD) coronal simulations. *STITCH -- Statistical Injection of Condensed Helicity* -- is a physics-based, reduced representation of helicity condensation: a process wherein small-scale vortical surface convection forms ubiquitous current sheets, and pervasive reconnection across the sheets mediates an inverse cascade of magnetic helicity and free energy, thereby forming the filament channels. STITCH abstracts these complex processes into a single new term, in the MHD Ohm's law and induction equation, which directly injects tangential magnetic flux into the low corona. We show that this approach is in very good agreement with a full helicity-condensation calculation that treats all of the dynamics explicitly, while enabling substantial reductions in temporal duration especially, but also in spatial resolution. In addition, we illustrate the flexibility of STITCH at forming localized filament channels and at energizing complex surface flux distributions that have sinuous boundaries. STITCH is simple to implement and computationally efficient, making it a powerful new technique for event-based, data-driven modeling of solar eruptions.

## **A Model for Energy Buildup and Eruption Onset in Coronal Mass Ejections**

Joel T. [Dahlin](#), [Spiro K. Antiochos](#), [C. Richard DeVore](#)

ApJ **879** 96 **2019**

<https://arxiv.org/pdf/1905.13218.pdf>

[sci-hub.se/10.3847/1538-4357/ab262a](https://sci-hub.se/10.3847/1538-4357/ab262a)

Coronal mass ejections (CMEs) and eruptive flares (EFs) are the most energetic explosions in the solar system. Their underlying origin is the free energy that builds up slowly in the sheared magnetic field of a filament channel. We report the first end-to-end numerical simulation of a CME/EF, from zero-free-energy initial state through filament-channel formation to violent eruption, driven solely by the magnetic-helicity condensation process. Helicity is the topological measure of linkages between magnetic flux systems, and is conserved in the corona, building up inexorably until it is ejected into interplanetary space. Numerous investigations have demonstrated that helicity injected by small-scale vortical motions, such as those observed in the photosphere, undergoes an inverse cascade from small scales to large, 'condensing' at magnetic-polarity boundaries. Our new results verify that this process forms a filament channel within a compact bipolar region embedded in a background dipole field, and show for the first time that a fast CME eventually occurs via the magnetic-breakout mechanism. We further show that the trigger for explosive eruption is reconnection onset in the flare current sheet that develops above the polarity inversion line: this reconnection forms flare loops below the sheet and a CME flux rope above, and initiates high-speed outward flow of the CME. Our findings have important implications for magnetic self-organization and explosive behavior in solar and other astrophysical plasmas, and for understanding and predicting explosive solar activity.

## **A partial filament eruption in three steps induced by external magnetic reconnection**

[Jun Dai](#), [Zhentong Li](#), [Ya Wang](#), [Zhe Xu](#), [Yanjie Zhang](#), [Leping Li](#), [Qingmin Zhang](#), [Yingna Su](#), [Haisheng Ji](#)

**2022** ApJ **929** 85

<https://arxiv.org/ftp/arxiv/papers/2201/2201.11314.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac4fbc/pdf>

We present an investigation of partial filament eruption on **2012 June 17** in the active region NOAA 11504. For the first time, we observed the vertical splitting process during the partial eruption with high resolution narrow band images at 10830 Å. The active filament was rooted in a small sunspot of the active region. Particularly, it underwent the partial eruption in three steps, i.e. the precursor, the first eruption, and the second eruption, while the later two were associated with a C1.0 flare and a C3.9 flare, respectively. During the precursor, slow magnetic reconnection took place between the filament and the adjoining loops that also rooted in the sunspot. The continuous reconnection not only caused the filament to split into three groups of threads vertically but also formed a new filament, which was growing and accompanied brightening took place around the site. Subsequently, the growing filament erupted together with one group splitted threads, resulted in the first eruption. At the beginning of the first eruption, a subsequent magnetic reconnection occurred between the erupting splitted threads and another ambient magnetic loop. After about three minutes, the second eruption occurred as a result of the eruption of two larger unstable filaments induced by the magnetic reconnection. The high-resolution observation provides a direct evidence that magnetic reconnection between filament and its ambient magnetic fields could induce the vertical splitting of the filament, resulting in partial eruption.

## **A Time-dependent Self-similar Reconstruction of Solar Coronal Mass Ejections Based on the Gibson–Low Model**

Xinghua [Dai](#)

**2022** ApJ **925** 24

<https://iopscience.iop.org/article/10.3847/1538-4357/ac3eda/pdf>

The analytic Gibson–Low (GL) model, a time-dependent self-similar solution of the magnetohydrodynamics, is first used to directly reconstruct a coronal mass ejection (CME) through the method of forward modeling in this study. A systematic description of the GL model is presented at the beginning, and a set of parameters is introduced to define the

model. Then a CME on **2011 March 7** is reconstructed by fitting of GL (FGL) of the multi-viewpoint and time series observations. The first step of FGL is the initialization of the location and orientation of the GL using the information of the CME source region. The second step is to fit the parameters of size, shape, velocity, and strength of the magnetic field of the GL to the observations of coronagraphs at 20:24 and 20:39. The GL at 20:54 and 3 R<sub>☉</sub> is generated through the theory of self-similar expansion respectively. Comparisons between the synthetic images of the GL and the real observations of the CME prove the performance of FGL that the reconstructions well match the observations.

### **Oscillations and mass-draining that lead to a sympathetic eruption of a quiescent filament**

[Jun Dai](#), [Qingmin Zhang](#), [Yanjie Zhang](#), [Zhe Xu](#), [Yingna Su](#), [Haisheng Ji](#)

ApJ **923** 74 **2021**

<https://arxiv.org/pdf/2110.04695.pdf>

<https://doi.org/10.3847/1538-4357/ac2d97>

In this paper, we present a multi-wavelength analysis to mass-draining and oscillations in a large quiescent filament prior to its successful eruption on **2015 April 28**. The eruption of a smaller filament that was parallel and in close, 350 proximity was observed to induce longitudinal oscillations and enhance mass-draining within the filament of interest. The longitudinal oscillation with an amplitude of 25 Mm and 23 km underwent no damping during its observable cycle. Subsequently the slightly enhanced draining may have excited a eruption behind the limb, leading to a feedback that further enhanced the draining and induced simultaneous oscillations within the filament of interest. We find significant damping for these simultaneous oscillations, where the transverse oscillations proceeded with the amplitudes of 15 Mm and 14 km, while the longitudinal oscillations involved a larger displacement and velocity amplitude (57 Mm, 43 km). The second grouping of oscillation lasted for 2 cycles and had the similar period of 2 hours. From this, the curvature radius and transverse magnetic field strength of the magnetic dips supporting the filaments can be estimated to be 355 Mm and 34 G. The mass-draining within the filament of interest lasted for 14 hours. The apparent velocity grew from 35 km to 85 km, with the transition being coincident with the occurrence of the oscillations. We conclude that two filament eruptions are sympathetic, i.e. the eruption of the quiescent filament was triggered by the eruption of the nearby smaller filament.

### **The Formation and Eruption of A Sigmoidal Filament Driven by Rotating Network Magnetic Fields**

[Jun Dai](#), [Haisheng Ji](#), [Leping Li](#), [Jun Zhang](#), [Huadong Chen](#)

**2021** ApJ **906** 66

<https://arxiv.org/pdf/2012.06775.pdf>

<https://doi.org/10.3847/1538-4357/abcaf4>

We present the formation and eruption of a sigmoidal filament driven by rotating network magnetic fields (RNFs) near the center of the solar disk, which was observed by the one-meter aperture New Vacuum Solar Telescope (NVST) at Fuxian Solar Observatory (FSO) on **2018 July 12**. Counterclockwise RNFs twist two small-scale filaments at their northeastern foot-point region, giving a rotation of nearly 200 degree within about 140 minutes. The motion of the RNF has a tendency to accelerate at first and then decelerate obviously, as the average rotation speed increased from 10 to 150 ,and then slowed down to 50 . Coalescence then occurs between filaments F1 and F2. Meanwhile the fine structures in the southwestern region of the filament was involved in another interaction of coalescence. The subsequent EUV brightening due to plasma heating is observed in the two interaction regions. These interacting structures, including F1, F2 and the fine structures in the southwestern region, eventually evolve into a larger-scale sigmoidal filament twisted in the same direction as the RNFs gave. The twist of the sigmoidal filament has exceeded  $4\{\pi\}$  and the filament erupted finally. The motion of the sigmoidal filament keeps uniform until a nearby jet collides, causing the filament to erupt faster. These results provide evidence that RNF plays an important role in the formation and eruption of the sigmoidal filament. The phenomena also suggests that the kink instability is the trigger mechanism for the filament eruption.

### **Electron Density Reconstruction of Solar Coronal Mass Ejections Based on Genetic Algorithm: Method and Application**

Xinghua [Dai](#), [Huaning Wang](#)

**2020** ApJ **896** 155

<https://arxiv.org/pdf/1902.06953.pdf>

<https://doi.org/10.3847/1538-4357/ab963a>

We present a new method to reconstruct three dimensional density of Coronal Mass Ejection (CME) based on genetic algorithm (GA), namely genetic reconstruction method (GRM). At first, a model "CME" is constructed to produce synthetic CME images for the genetic reconstruction. Then the method is applied to coronagraph data from SOHO, STEREO-A and B on **September 30th, 2013**. In comparison with the existing methods for density reconstruction, GRM obtain global optimization of CME electron distribution. On the other hand, GRM decreases the difficulty of reconstruction by calculating electron number of every CME pixel in one of the view angles. Then the electrons are randomly redistributed along each line of sight (LOS) of CME pixel. Genetic operators named "crossover" and "mutation" are employed to optimize the electron distribution. Brightness of each pixel are recalculated through mechanism of Thomson scattering in multiple view angles. Genetic operator named "selection" is then employed to hold better distributions and eliminate the worse distributions according to fitness of recalculated brightness to the observed brightness. Such process may iterate through hundreds of times to obtain globally optimized electron

distributions. We compare the reconstructed brightness with observation to show the availability of GRM. Results of GRM are also compared with those of polarimetric reconstruction and forward modeling for the method availability. We further apply the reconstructed CME into Space Weather Modeling Framework (SWMF) to obtain evolution of interplanetary CME and its geo-effectiveness. Time difference of the CME arrival between ACE measurement and SWMF simulation is less than 5 hours.

### **Current sheets in the wake of an eruption of two crossing filaments**

Jun [Dai](#), [Jiayan Yang](#), [Leping Li](#), [Jun Zhang](#)

ApJ **869** 118 **2018**

<https://arxiv.org/pdf/1811.08563.pdf>

[sci-hub.tw/10.3847/1538-4357/aaedbb](http://sci-hub.tw/10.3847/1538-4357/aaedbb)

Employing Solar Dynamic Observatory/Atmospheric Imaging Assembly (AIA) multi-wavelength images, we study an eruption of two crossing filaments, and firstly report the current sheets (CSs) connecting the lower flare ribbons and the upper erupting filaments. On **July 8, 2014**, two crossing filaments are observed in the NOAA active region (AR) 12113. The lower-lying filament rises first, and then meets the higher-lying one. Thereafter, both of them erupt together. The filament eruption draws the overlying magnetic field lines upward, leading to the approach of two legs, with opposite magnetic polarities, of the overlying field lines. Two sets of bright CSs form at the interface of these two legs, and magnetic reconnection takes place in the CSs producing the underneath flare ribbons and post-flare loops. Several bright plasmoids appear in the CSs, and propagate along the CSs bi-directionally. The CSs and plasmoids are observed in AIA multi-wavelength channels, indicating that both of them have been heated during the reconnection process, with hot and warm components. Employing the differential emission measure (EM) analysis, we find that both the temperature and EM of the CSs decrease from the flare arcades outward to the erupting filaments, and those of the plasmoids are significantly larger than the regions where no plasmoid is detected.

### **Improvement on Mass Calculations of Solar CMEs**

Xinghua [Dai](#)<sup>1,2</sup>, Huaning Wang<sup>1</sup>, Xin Huang<sup>1</sup>, Zhanle Du<sup>1</sup>, and Han He

**2015** ApJ 801 39

The mass of a coronal mass ejection (CME) is calculated from the measured brightness and assumed geometry of Thomson scattering. The simplest geometry for mass calculations is to assume that all of the electrons are in the plane of the sky (POS). With additional information like source region or multiviewpoint observations, the mass can be calculated more precisely under the assumption that the entire CME is in a plane defined by its trajectory. Polarization measurements provide information on the average angle of the CME electrons along the line of sight of each CCD pixel from the POS, and this can further improve the mass calculations as discussed here. A CME event initiating on **2012 July 23** at 2:20 UT observed by the Solar Terrestrial Relations Observatory is employed to validate our method.

### **The Classification of Ambiguity in Polarimetric Reconstruction of Coronal Mass Ejection**

Xinghua [Dai](#)<sup>1,2</sup>, Huaning Wang<sup>1</sup>, Xin Huang<sup>1</sup>, Zhanle Du<sup>1</sup>, and Han He

**2014** ApJ 780 141

The Thomson scattering theory indicates that there exist explicit and implicit ambiguities in polarimetric analyses of coronal mass ejection (CME) observations. We suggest a classification for these ambiguities in CME reconstruction. Three samples, including double explicit, mixed, and double implicit ambiguity, are shown with the polarimetric analyses of STEREO CME observations. These samples demonstrate that this classification is helpful for improving polarimetric reconstruction.

### **EVOLUTION OF PILED-UP COMPRESSIONS IN MODELED CORONAL MASS EJECTION SHEATHS AND THE RESULTING SHEATH STRUCTURES**

Indrajit [Das](#)<sup>1</sup>, Merav Opher<sup>1,2</sup>, Rebekah Evans<sup>1</sup>, Cristiane Loesch<sup>3</sup>, and Tamas I. Gombosi<sup>4</sup>

Astrophysical Journal, 729:112 (7pp), **2011** March, **File**

We study coronal mass ejection (CME)-driven shocks and the resulting post-shock structures in the lower corona (2–7R<sub>⊙</sub>). Two CMEs are erupted by modified Titov–D’emoulin (TD) and Gibson–Low (GL) type flux ropes (FRs) with the Space Weather Modeling Framework. We observe a substantial pile-up of density compression and a narrow region of plasma depletion layer (PDL) in the simulations. As the CME/FR moves and expands in the solar wind medium, it pushes the magnetized material lying ahead of it. Hence, the magnetic field lines draping around the CME front are compressed in the sheath just ahead of the CME. These compressed field lines squeeze out the plasma sideways, forming PDL in the region. Solar plasma being pushed and displaced from behind forms a strong piled-up compression (PUC) of density downstream of the PDL. Both CMEs have comparable propagation speeds, while GL has larger expansion speed than TD due to its higher initial magnetic pressure. We argue that high CME expansion speed along with high solar wind density in the region is responsible for the large PUC found in the lower corona. In case of GL, the PUC is much wider, although the density compression ratio for both the cases is comparable. Although these simulations artificially initiate out-of-equilibrium CMEs and drive them in an artificial solar wind solution, we predict that PUCs, in general, will be large in the lower corona. This should affect the ion profiles of the accelerated solar energetic particles.

## Study of Interplanetary and Geomagnetic Response of Filament Associated CMEs

Kunjai Dave, Wageesh Mishra, Nandita Srivastava, R. M. Jadhav

Proceedings IAU Symposium No. 340, 2018

<https://arxiv.org/pdf/1807.00809.pdf>

It has been established that Coronal Mass Ejections (CMEs) may have significant impact on terrestrial magnetic field and lead to space weather events. In the present study, we selected several CMEs which are associated with filament eruptions on the Sun. We attempt to identify the presence of filament material within ICME at 1AU. We discuss how different ICMEs associated with filaments lead to moderate or major geomagnetic activity on their arrival at the Earth. Our study also highlights the difficulties in identifying the filament material at 1AU within isolated and in interacting CMEs. 23 May 2010, 6 Oct 2010, 23 Sep 2012

## A SELF-SIMILAR EXPANSION MODEL FOR USE IN SOLAR WIND TRANSIENT PROPAGATION STUDIES

J. A. Davies<sup>1</sup>, R. A. Harrison<sup>1</sup>, C. H. Perry<sup>1</sup>, C. Möstl<sup>2,3,4</sup>, N. Lugaz<sup>5</sup>, T. Rollett<sup>2</sup>, C. J. Davis<sup>1,6</sup>, S. R. Crothers<sup>1</sup>, M. Temmer<sup>2</sup>, C. J. Eyles<sup>1,7</sup>, and N. P. Savani

2012 ApJ 750 23

Since the advent of wide-angle imaging of the inner heliosphere, a plethora of techniques have been developed to investigate the three-dimensional structure and kinematics of solar wind transients, such as coronal mass ejections, from their signatures in single- and multi-spacecraft imaging observations. These techniques, which range from the highly complex and computationally intensive to methods based on simple curve fitting, all have their inherent advantages and limitations. In the analysis of single-spacecraft imaging observations, much use has been made of the fixed fitting (FPF) and harmonic mean fitting (HMF) techniques, in which the solar wind transient is considered to be a radially propagating point source (fixed, FP, model) and a radially expanding circle anchored at Sun centre (harmonic mean, HM, model), respectively. Initially, we compare the radial speeds and propagation directions derived from application of the FPF and HMF techniques to a large set of STEREO/Heliospheric Imager (HI) observations. As the geometries on which these two techniques are founded constitute extreme descriptions of solar wind transients in terms of their extent along the line of sight, we describe a single-spacecraft fitting technique based on a more generalized model for which the FP and HM geometries form the limiting cases. In addition to providing estimates of a transient's speed and propagation direction, the self-similar expansion fitting (SSEF) technique provides, in theory, the capability to estimate the transient's angular extent in the plane orthogonal to the field of view. Using the HI observations, and also by performing a Monte Carlo simulation, we assess the potential of the SSEF technique.

## Assessing the Accuracy of CME Speed and Trajectory Estimates from STEREO Observations Through a Comparison of Independent Methods

C.J. Davis · J. Kennedy · J.A. Davies

Solar Phys (2010) 263: 209–222, DOI 10.1007/s11207-010-9535-2; File

We have estimated the speed and direction of propagation of a number of Coronal Mass Ejections (CMEs) using single-spacecraft data from the STEREO Heliospheric Imager (HI) wide-field cameras. In general, these values are in good agreement with those predicted by Thernisien, Vourlidas, and Howard in *Solar Phys.* **256**, 111 – 130 (2009) using a forward modelling method to fit CMEs imaged by the STEREO COR2 coronagraphs. The directions of the CMEs predicted by both techniques are in good agreement despite the fact that many of the CMEs under study travel in directions that cause them to fade rapidly in the HI images. The velocities estimated from both techniques are in general agreement although there are some interesting differences that may provide evidence for the influence of the ambient solar wind on the speed of CMEs. The majority of CMEs with a velocity estimated to be below 400 km s<sup>-1</sup> in the COR2 field of view have higher estimated velocities in the HI field of view, while, conversely, those with COR2 velocities estimated to be above 400 km s<sup>-1</sup> have lower estimated HI velocities. We interpret this as evidence for the deceleration of fast CMEs and the acceleration of slower CMEs by interaction with the ambient solar wind beyond the COR2 field of view. We also show that the uncertainties in our derived parameters are influenced by the range of elongations over which each CME can be tracked. In order to reduce the uncertainty in the predicted arrival time of a CME at 1 Astronomical Unit (AU) to within six hours, the CME needs to be tracked out to at least 30 degrees elongation. This is in good agreement with predictions of the accuracy of our technique based on Monte Carlo simulations.

Within the set of studied CMEs, there are two clear events that were predicted from the HI data to travel over another spacecraft; *in-situ* measurements at these other spacecraft confirm the accuracy of these predictions. The ability of the HI cameras to image Corotating Interaction Region (CIR)-entrained transients as well as CMEs can result in some ambiguity

when trying to distinguishing individual signatures.

## **How a Strong Solar Coronal Mass Ejection can Eject Dust from the Moon's Surface to the Earth's Atmosphere**

Fran [De Aquino](#)

2014?

<https://hal.archives-ouvertes.fr/hal-01081735>

A solar coronal mass ejection (CME) is a massive ejection of plasma from the Sun to the space. In this article it is shown how a strong solar coronal mass ejection can eject dust from the Moon's Surface to the space. If this ejection occurs when the Moon is in specific regions of its trajectory around the Earth, then this lunar dust can be gravitationally attracted to the Earth, forming a dust shell at the Earth's atmosphere, which can block the sunlight for some days.

## **Properties of Streamer Wave Events Observed During the STEREO Era**

Bieke [Decraemer](#), [Andrei N. Zhukov](#), [Tom Van Doorselaere](#)

ApJ **893** 78 **2020**

<https://arxiv.org/pdf/2003.12350.pdf>

<https://doi.org/10.3847/1538-4357/ab8194>

Transverse waves are sometimes observed in solar helmet streamers, typically after the passage of a coronal mass ejection (CME). The CME-driven shock wave moves the streamer sideways, and a decaying oscillation of the streamer is observed after the CME passage. Previous works generally reported observations of streamer oscillations taken from a single vantage point (typically the SOHO spacecraft). We conduct a data survey searching for streamer wave events observed by the COR2 coronagraphs onboard the STEREO spacecraft. For the first time, we report observations of streamer wave events from multiple vantage points, by using the COR2 instrument on both STEREO A and B, as well as the SOHO/LASCO C2+C3 coronagraphs. We investigate the properties of streamer waves by comparing the different events and performing a statistical analysis. Common observational features give us additional insight on the physical nature of streamer wave events. The most important conclusion is that there appears to be no relation between the speed of the CME and the phase speed of the resulting streamer wave, indicating that the streamer wave speed is determined by the physical properties of the streamer rather than the properties of the CME. This result makes streamer waves events excellent candidates for coronal seismology studies. From a comparison between the measured phase speeds and the phase speeds calculated from the measured periods and wavelengths, we could determine that the speed of the post-shock solar wind flow in our streamers is around  $300 \text{ km s}^{-1}$ . **2013-02-06**

**Table 1.** Summary of the physical parameters measured for the 22 streamer wave events identified with STEREO/COR2.

## **3D Polarized Imaging of Coronal Mass Ejections: Chirality of a CME**

C. E. [DeForest](#)<sup>1</sup>, C. A. de Koning<sup>2</sup>, and H. A. Elliott<sup>1</sup>

2017 ApJ 850 130

<http://iopscience.iop.org/article/10.3847/1538-4357/aa94ca/pdf>

We report on a direct polarimetric determination of the chirality of a coronal mass ejection (CME), using the physics of Thomson scattering applied to synoptic polarized images from the Solar Terrestrial Relations Observatories/COR2 coronagraph. We confirmed the determination using in situ magnetic field measurements of the same CME with the ACE spacecraft. CME chirality is related to the helicity ejected from the solar corona along with the mass and field entrained in the CME. It is also important to prediction of the space-weather-relevant Z component of the CME magnetic field. Hence, remote measurement of CME chirality is an important step toward both understanding CME physics and predicting geoeffectiveness of individual CMEs. The polarimetric properties of Thomson scattering are well known and can, in principle, be used to measure the 3D structure of imaged objects in the solar corona and inner heliosphere. However, reduction of that principle to practice has been limited by the twin difficulties of background subtraction and the signal-to-noise ratio in coronagraph data. Useful measurements of the 3D structure require relative photometry at a few percent precision level in each linear polarization component of the K corona. This corresponds to a relative photometric precision of order  $10^{-4}$  in direct images of the sky before subtraction of the F corona and related signal. Our measurement was enabled by recent developments in signal processing, which enable a better separation of the photometric signal from noise in the synoptic COR2 data. We discuss the relevance of this demonstration measurement to future instrument requirements, and to the future measurements of 3D structures in CMEs and other solar wind features. **2010 Apr 3**

## **ERRATUM: "FEASIBILITY OF HELIOSPHERIC IMAGING FROM NEAR EARTH"**

## **TRACKING CORONAL FEATURES FROM THE LOW CORONA TO EARTH: A QUANTITATIVE ANALYSIS OF THE 2008 DECEMBER 12 CORONAL MASS EJECTION**

C. E. [DeForest](#)<sup>1</sup>, T. A. Howard<sup>1</sup>, and D. J. McComas

2013 ApJ 769 43

We have tracked a slow magnetic cloud associated coronal mass ejection (CME) continuously from its origin as a flux rope structure in the low solar corona over a four-day passage to impact with spacecraft located near Earth. Combining measurements from the STEREO, ACE, and Wind space missions, we are able to follow major elements with enough specificity to relate pre-CME coronal structure in the low corona to the corresponding elements seen in the near-Earth in situ data. Combining extreme ultraviolet imaging, quantitative Thomson scattering data throughout the flight of the CME, and "ground-truth" in situ measurements, we: (1) identify the plasma observed by ACE and Wind with specific features in the solar corona (a segment of a long flux rope); (2) determine the onset mechanism of the CME (destabilization of a filament channel following flare reconnection, coupled with the mass draining instability) and demonstrate that it is consistent with the in situ measurements; (3) identify the origin of different layers of the sheath material around the central magnetic cloud (closed field lifted from the base of the corona, closed field entrained during passage through the corona, and solar wind entrained by the front of the CME); (4) measure mass accretion of the system via snowplow effects in the solar wind as the CME crossed the solar system; and (5) quantify the kinetic energy budget of the system in interplanetary space, and determine that it is consistent with no long-term driving force on the CME.

### DISCONNECTING OPEN SOLAR MAGNETIC FLUX

C. E. DeForest<sup>1</sup>, T. A. Howard<sup>1</sup>, and D. J. McComas<sup>1,2</sup>

Astrophysical Journal, 745:36 (9pp), 2012

[http://www.boulder.swri.edu/~howard/Papers/2012\\_Disconnection.pdf](http://www.boulder.swri.edu/~howard/Papers/2012_Disconnection.pdf) - File

Disconnection of open magnetic flux by reconnection is required to balance the injection of open flux by coronal mass ejections and other eruptive events. Making use of recent advances in heliospheric background subtraction, we have imaged many abrupt disconnection events. These events produce dense plasma clouds whose distinctive shape can now be traced from the corona across the inner solar system via heliospheric imaging. The morphology of each initial event is characteristic of magnetic reconnection across a current sheet, and the newly disconnected flux takes the form of a "U"-shaped loop that moves outward, accreting coronal and solar wind material. We analyzed one such event on 2008 December 18 as it formed and accelerated at  $20 \text{ m s}^{-2}$  to  $320 \text{ km s}^{-1}$ , thereafter expanding self-similarly until it exited our field of view 1.2 AU from the Sun. From acceleration and photometric mass estimates we derive the coronal magnetic field strength to be  $8 \mu\text{T}$ ,  $6R_{\odot}$  above the photosphere, and the entrained flux to be  $1.6 \times 10^{11} \text{ Wb}$  ( $1.6 \times 10^{19} \text{ Mx}$ ). We model the feature's propagation by balancing inferred magnetic tension force against accretion drag. This model is consistent with the feature's behavior and accepted solar wind parameters. By counting events over a 36 day window, we estimate a global event rate of  $1 \text{ day}^{-1}$  and a global solar minimum unsigned flux disconnection rate of  $6 \times 10^{13} \text{ Wbyr}^{-1}$  ( $6 \times 10^{21} \text{ Mxyr}^{-1}$ ) by this mechanism. That rate corresponds to  $\sim -0.2 \text{ nTyr}^{-1}$  change in the radial heliospheric field at 1 AU, indicating that the mechanism is important to the heliospheric flux balance.

### Lessons Learned from the Three-view Determination of CME Mass

Curt A. de Koning

2017 ApJ 844 61

<http://sci-hub.cc/10.3847/1538-4357/aa7a09>

If two viewpoints are available, it has been suggested that total-brightness images might be used to simultaneously derive the CME deprojected mass and propagation direction. Exploiting all available data provided by SOHO, STEREO-A, and STEREO-B supplies three combinations of spacecraft pairs for double-viewpoint analysis. We show that, if only aleatory variation is reckoned, then the CME deprojected mass can vary by as much as 100% between different pairs of spacecraft. Going beyond multiple double-viewpoint analyses, we also utilize these spacecraft to simultaneously estimate the CME deprojected mass and propagation direction with triple-viewpoint analysis. However, once again, if only aleatory variation is reckoned, then, for many events, there is no common mass value estimated by the three viewpoints. This indicates that epistemic uncertainty is significant and must be reckoned also. We consider in detail the mass in the coronagraph field of view, from one, two, and three viewpoints, for the CME observed on **2007 December 31**, focusing especially on the approximations used and uncertainties in this process. Altogether, we use triple-viewpoint analysis to estimate the mass of eight CMEs. When simultaneously estimating the CME deprojected mass and propagation direction using total-brightness images, the single degree of freedom provided by a third, independent viewpoint clarifies the calculation of, and reduces ambiguity in, the deprojected mass; however, the deprojected mass should not be confused with the true mass.

### Geometric Localization of CMEs in 3D Space Using STEREO Beacon Data: First Results

Curt A. de Koning · V.J. Pizzo · D.A. Biesecker

Solar Phys (2009) 256: 167–181, DOI 10.1007/s11207-009-9344-7, 2009, File

#### STEREO SCIENCE RESULTS AT SOLAR MINIMUM

The geometric localization technique (Pizzo and Biesecker, *Geophys. Res. Lett.* **31**, 21802, 2004) can readily be used with *Solar Terrestrial Relations Observatory* (STEREO) Space Weather Beacon data to observe coronal mass ejection (CME) propagation within three-dimensional space in near-real time. This technique is based upon simple triangulation concepts and utilizes a series of lines of sight from two space-based observatories to determine gross characteristics of CMEs, such as location and velocity. Since this work is aimed at space weather applications, the emphasis is on use of COR2 coronagraph

data, which has a field of view from  $2.5R_{\odot}$  to  $15R_{\odot}$ ; this spatial coverage allows us to observe the early temporal development of a CME, and hence to calculate its velocity, even for very fast CMEs. We apply this technique to highly-compressed COR2 beacon images for several CMEs at various spacecraft separation angles: 21 August 2007, when the separation angle between the two spacecraft was  $26^{\circ}$ ; 31 December 2007 and 2 January 2008, when the separation angle was  $44^{\circ}$ ; and 17 October 2008, when the spacecraft separation was  $79^{\circ}$ . We present results on the speed and direction of propagation for these events and discuss the error associated with this technique. We also compare our results to the two-dimensional plane-of-sky speeds calculated from STEREO and SOHO.

### **In-flight radiometric calibration of the Metis Visible Light channel using stars and comparison with STEREO-A/COR2 data**

Y. De Leo<sup>1,2</sup>, A. Burtovoi<sup>3</sup>, L. Teriaca<sup>1</sup>, M. Romoli<sup>3,4</sup>, + + +  
A&A 676, A45 (2023)

<https://www.aanda.org/articles/aa/pdf/2023/08/aa45979-23.pdf>

Context. We present the results for the in-flight radiometric calibration performed for the Visible Light (VL) channel of the Metis coronagraph on board Solar Orbiter.

Aims. The radiometric calibration is a fundamental step in building the official pipeline of the instrument, devoted to producing the calibrated data in physical units (L2 data).

Methods. To obtain the radiometric calibration factor ( $\epsilon_{VL}$ ), we used stellar targets transiting the Metis field of view. We derived  $\epsilon_{VL}$  by determining the signal of each calibration star by means of the aperture photometry and calculating its expected flux in the Metis band pass. The analyzed data set covers the time range from the beginning of the Cruise Phase of the mission (June 2020) until March 2021.

Results. Considering the uncertainties, the estimated factor  $\epsilon_{VL}$  is in a good agreement with that obtained during the on-ground calibration campaign. This implies that up to March 2021 there was no measurable reduction in the VL channel throughput. Finally, we compared the total and polarized brightness visible light images of the solar corona acquired with Metis and STEREO-A/COR2 during the November 2020 superior conjunction of these instruments. A general good agreement was obtained between the images of these instruments for both the total and polarized brightness. **18 November 2020**

### **Initiation and Development of the white-light and radio CME on 15 April 2001**

P. Demoulin, A. Vourlidas, M. Pick, A. Bouteille

E-print, 9 March 2012, File; 2012 ApJ 750 147

The 2001 April 15 event was one of the largest of the last solar cycle. A former study (Maia et al., 2007) established that this event was associated with a coronal mass ejection (CME) observed both at white light and radio frequencies. This radio CME is illuminated by synchrotron emission from relativistic electrons. In this paper, we investigate the relation of the radio CME to its extreme ultraviolet (EUV) and white light counterpart and reach four main conclusions. i) The radio CME corresponds to the white light flux rope cavity. ii) The presence of a reconnecting current sheet behind the erupting flux rope is framed, both from below and above, by bursty radio sources. This reconnection is the source of relativistic radiating electrons which are injected down along the reconnected coronal arches and up along the flux rope border forming the radio CME. iii) Radio imaging reveals an important lateral over expansion in the low corona; this over expansion is at the origin of compression regions where type II and III bursts are imaged. iv) Already in the initiation phase, radio images reveal large scale interactions of the source active region with its surroundings, including another active region and open magnetic fields. Thus, these complementary radio, EUV, white light data validate the flux rope eruption model of CMEs.

ERRATUM: 2012 ApJ 754 156

### **Criteria for Flux Rope Eruption: Non Equilibrium versus Torus Instability**

P. Demoulin and G. Aulanier

E-print, June 2010, ApJ, 718(2), 1388-1399; File

The coronal magnetic configuration of an active region typically evolves quietly during few days before becoming suddenly eruptive and launching a coronal mass ejection (CME). The precise origin of the eruption is still debated. Among several mechanisms, it has been proposed that a loss of equilibrium, or an ideal magneto-hydrodynamic (MHD) instability such as the torus instability, could be responsible for the sudden eruptivity. Distinct approaches have also been formulated for limit cases having circular or translation symmetry. We revisit the previous theoretical approaches, setting them in the same analytical framework. The coronal field results from the contribution of a non-neutralized current channel added to a background magnetic field, which in our model is the potential field generated by two photospheric flux concentrations. The evolution on short Alfvénic time scale is governed by ideal MHD. We show analytically first that the loss of equilibrium and the stability analysis are two different views of the same physical mechanism. Second, we identify that the same physics is involved in the instability of circular and straight current

channels. Indeed, they are just two particular limiting case of more general current paths. A global instability of the magnetic configuration is present when the current channel is located at a coronal height,  $h$ , large enough so that the decay index of the potential field,  $(d \ln |B_p|) / (d \ln h)$  is larger than a critical value. At the limit of very thin current channels, previous analysis found a critical decay index of 1.5 and 1 for circular and straight current channels, respectively. However, with current channels being deformable and as thick as expected in the corona, we show that this critical index has similar values for circular and straight current channels, typically in the range [1.1,1.3].

## **Interaction of ICMEs with the Solar Wind (Review)**

**Demoulin P.**

E-print, Sept 2009, SW12 proceedings; **File**

Interplanetary Coronal Mass Ejections (ICMEs) are formed of plasma and magnetic field launched from the Sun into the Solar Wind (SW). These coherent magnetic structures, frequently formed by a flux rope, interact strongly with the SW. Such interaction is reviewed by comparing the results obtained from in situ observations and with numerical simulations. Like fast ships in the ocean, fast ICMEs drive an extended shock in front. However, their interaction with the SW is much more complex than that of the ship analogy. For example, as they expand in all directions while traveling away from the Sun, a sheath of SW plasma and magnetic field accumulates in front, which partially reconnects with the ICME magnetic field. Furthermore, not only ICMEs have a profound impact on the heliosphere, but the type of SW encountered by an ICME has an important impact on its evolution (e.g. increase of mass, global deceleration, lost of magnetic flux and helicity, distortion of the configuration).

## **Quantitative links between CMEs and magnetic clouds**

**P. Démoulin**

E-print, Sept. 2007, Ann. Geophys., 2008, 26, 3113, **File**

Magnetic clouds (MCs), and more generally interplanetary coronal mass ejections (ICMEs), are believed to be the interplanetary counterparts of CMEs. The link has usually been shown by taking into account the CME launch position on the Sun, the expected time delay and by comparing the orientation of the coronal and interplanetary magnetic field. Making such a link more quantitative is challenging since it requires the relation of very different kinds of magnetic field measurements: (i) photospheric magnetic maps, which are observed from a distant vantage point (remote sensing) and (ii) in situ measurements of MCs, which provide precise, directly measured, magnetic field data merely from one-dimensional linear samples. The association between events in these different domains can be made using adequate coronal and MC models. Then, global quantities like magnetic fluxes and helicity can be derived and compared. All the associations criteria are reviewed, with a description of the general trends found. A special focus is given on the cases which do not follow the earlier derived mean laws since interesting physics is usually associated to them.

## **Recent theoretical and observational developments in magnetic helicity studies**

Adv. Space Res. 39(11), Pages 1674-1693, 2007 **Обзор**

**P. Démoulin**

Magnetic helicity quantifies how the magnetic field is sheared and twisted compared to its lowest energy state (potential field). Such stressed magnetic fields are usually observed in association with flares, eruptive filaments, and coronal mass ejections (CMEs). Magnetic helicity plays a key role in magnetohydrodynamics because it is almost preserved on a timescale less than the global diffusion time scale. Its conservation defines a constraint to the magnetic field evolution.

Only relatively recently, scientists have realized that magnetic helicity can be computed from observations, and methods have been derived to bridge the gap between theory and observations. At the photospheric level, the rate (or flux) of magnetic helicity can be computed from the evolution of longitudinal magnetograms. The coronal helicity is estimated from magnetic extrapolation, while the helicity ejected in magnetic clouds (interplanetary counter-part of CMEs) is derived through modelling of in situ magnetic field measurements. Using its conserved property, a quantitative link between phenomena observed in the corona and then in the interplanetary medium has been achieved.

## **The Roles of Reconnected Flux and Overlying Fields in CME Speeds**

**Minda Deng**, Brian T. Welsch

Solar Phys. January 2017, 292:17

<http://arxiv.org/pdf/1504.02905v1.pdf>

The standard model of eruptive, two-ribbon flares involves reconnection of over-lying magnetic fields beneath a rising ejection. Numerous observers have reported evidence linking this reconnection, indicated by photospheric flux swept out by flare ribbons, to coronal mass ejection (CME) acceleration. This acceleration might be caused by reconnected fields that wrap around the ejection producing an increased outward hoop force. Other observations have linked stronger over-lying fields, measured by the power-law index of the fitted decay rate of field strength overlying eruption sites, to slower CME speeds. This might be caused by greater downward magnetic tension in stronger overlying fields. So overlying fields might both help and hinder the acceleration of CMEs: reconnection that converts overlying fields into flux winding about the ejection might help, but unreconnected overlying fields might hurt. Here, we investigate the roles of both ribbon fluxes and the decay rates of overlying fields in a set of 16 eruptive events. We confirm previous

results that higher CME speeds are associated with both larger ribbon fluxes and more rapidly decaying overlying fields. We find the association with ribbon fluxes to be weaker than a previous report, but stronger than the dependence on the decay rate of overlying fields. **1998 Apr 29, 1998 Nov 05, 2000 Jan 18, 2000 Jul 25, 2000 Aug 09, 2000 Nov 24, 2001 Apr 10, 2001 Apr 26, 2001 Sep 28, 2002 Mar 20, 2002 July 26, 2003 Oct 28, 2003 Oct 29, 2003 Nov 18, 2004 Nov 07, 2005 May 13**

## LASCO AND EIT OBSERVATIONS OF HELICAL STRUCTURE IN CORONAL MASS EJECTIONS

K. P. **DERE**,<sup>1</sup> G. E. BRUECKNER,<sup>2</sup> R. A. HOWARD, D. J. MICHELS, AND J. P. DELABOUDINIÈRE  
ASTROPHYSICAL JOURNAL, 516:465-474, **1999**; **File**

Observations of coronal mass ejections (CMEs) by the Large Angle Spectrometric Coronagraph (LASCO) on the Solar and Heliospheric Observatory (SOHO) show a significant fraction with circular intensity patterns. In the past, these would have been called .. disconnection II events, but we suggest that these are evidence of CMEs containing helical magnetic flux ropes that are often central to many theoretical models of CMEs and have been observed in magnetic clouds near 1 AU. Three examples are examined in detail with the LASCO and Extreme-Ultraviolet Imaging Telescope (EIT) data sets, which provide observations from their initiation through 30 R<sub>☉</sub>.

## EIT and LASCO Observations of the Initiation of a Coronal Mass Ejection. Solar

**Dere**, K.P., Brueckner, G.E., Howard, R.A., Koomen, M.J., Korendyke, C.M., Kreplin, R.W., Michels, D.J., Moses, J.D., Moulton, N.E., Socker, D.G., St. Cyr, O.C., Delaboudinière, J.P., Artzner, G.E., Brunaud, J., Gabriel, A.H., Hochedez, J.F., Millier, F., Song, X.Y., Chauvineau, J.P., Marioge, J.P., Defise, J.M., Jamar, C., Rochus, P., Catura, R.C., Lemen, J.R., Gurman, J.B., Neupert, W., Clette, F., Cugnon, P., van Dessel, E.L., Lamy, P.L., Llebaria, A., Schwenn, R., Simnett, G.M.,  
**1997**. Solar Phys. 175, 601–612.

<https://link.springer.com/content/pdf/10.1023/A:1004907307376.pdf>

We present the first observations of the initiation of a coronal mass ejection (CME) seen on the disk of the Sun. Observations with the EIT experiment on SOHO show that the CME began in a small volume and was initially associated with slow motions of prominence material and a small brightening at one end of the prominence. Shortly afterward, the prominence was accelerated to about 100 km s<sup>-1</sup> and was preceded by a bright loop-like structure, which surrounded an emission void, that traveled out into the corona at a velocity of 200–400 km s<sup>-1</sup>. These three components, the prominence, the dark void, and the bright loops are typical of CMEs when seen at distance in the corona and here are shown to be present at the earliest stages of the CME. The event was later observed to traverse the LASCO coronagraphs fields of view from 1.1 to 30 R<sub>☉</sub>. Of particular interest is the fact that this large-scale event, spanning as much as 70 deg in latitude, originated in a volume with dimensions of roughly 35" (2.5 x 104 km). Further, a disturbance that propagated across the disk and a chain of activity near the limb may also be associated with this event as well as a considerable degree of activity near the west limb. **23 December 1996**

## Does Nearby Open Flux Affect the Eruptivity of Solar Active Regions?

Marc L. **DeRosa**, [Graham Barnes](#)

ApJ **861** 131 **2018** DOI [10.3847/1538-4357/aac77a](https://doi.org/10.3847/1538-4357/aac77a)

<https://arxiv.org/pdf/1802.01199.pdf>

The most energetic solar flares are typically associated with the ejection of a cloud of coronal material into the heliosphere in the form of a coronal mass ejection (CME). However, there exist large flares which are not accompanied by a CME. The existence of these non-eruptive flares raises the question of whether such flares suffer from a lack of access to nearby open fields in the vicinity above the flare (reconnection) site. In this study, we use a sample of 56 flares from Sunspot Cycles 23 and 24 to test whether active regions that produce eruptive X-class flares are preferentially located near coronal magnetic field domains that are open to the heliosphere, as inferred from a potential field source surface model. The study shows that X-class flares having access to open fields are eruptive at a higher rate than those for which access is lacking. The significance of this result should be moderated due to the small number of non-eruptive X-class flares in the sample, based on the associated Bayes factor. **2001-04-15, 2002-08-21, 2013-11-10, 2014-12-20, 2017-09-06**

Current operational forecasts of solar eruptions are made by human experts using a combination of qualitative shape-based classification systems and historical data about flaring frequencies. In the past decade, there has been a great deal of interest in crafting machine-learning (ML) flare-prediction methods to extract underlying patterns from a training set --e.g., a set of solar magnetogram images, each characterized by features derived from the magnetic field and labeled as to whether it was an eruption precursor. These patterns, captured by various methods (neural nets, support vector machines, etc.), can then be used to classify new images. A major challenge with any ML method is the featurization of the data: pre-processing the raw images to extract higher-level properties, such as characteristics of the magnetic field, that can streamline the training and use of these methods. It is key to choose features that are informative, from the standpoint of the task at hand. To date, the majority of ML-based solar eruption methods have used physics-based magnetic and electric field features such as the total unsigned magnetic flux, the gradients of the fields, the vertical current density, etc. In this paper, we extend the relevant feature set to include characteristics of the magnetic field that are based purely on the geometry and topology of 2D magnetogram images and show that this improves the prediction accuracy of a neural-net based flare-prediction method. **2017 Sept 1-7**

### **Observations of a prominence eruption and loop contraction**

[Pooja Devi](#), [Pascal Démoulin](#), [Ramesh Chandra](#), [Reetika Joshi](#), [Brigitte Schmieder](#), [Bhuwan Joshi](#)

A&A 647, A85 2021

<https://arxiv.org/pdf/2101.07682.pdf>

<https://www.aanda.org/articles/aa/pdf/2021/03/aa40042-20.pdf>

Context. Prominence eruptions provide key observations to understand the launch of coronal mass ejections as their cold plasma traces a part of the unstable magnetic configuration.

Aims. We select a well observed case to derive observational constraints for eruption models.

Methods. We analyze the prominence eruption and loop expansion and contraction observed on **02 March 2015** associated with a GOES M3.7 class flare (SOL2015-03-02T15:27) using the data from Atmospheric Imaging Assembly (AIA) and the Reuven Ramaty High Energy Solar Spectroscopic Imager (RHESSI). We study the prominence eruption and the evolution of loops using the time-distance techniques.

Results. The source region is a decaying bipolar active region where magnetic flux cancellation is present for several days before the eruption. AIA observations locate the erupting prominence within a flux rope viewed along its local axis direction. We identify and quantify the motion of loops in contraction and expansion located on the side of the erupting flux rope. Finally, RHESSI hard X-ray observations identify the loop top and two foot-point sources.

Conclusions. Both AIA and RHESSI observations support the standard model of eruptive flares. The contraction occurs 19 minutes after the start of the prominence eruption indicating that this contraction is not associated with the eruption driver. Rather, this prominence eruption is compatible with an unstable flux rope where the contraction and expansion of the lateral loop is the consequence of a side vortex developing after the flux rope is launched.

### **Spinning solar jets explained through the interplay between plasma sheets and vortex columns**

[Sahel Dey](#), [Piyali Chatterjee](#), [Robertus Erdelyi](#)

2024

<https://arxiv.org/pdf/2404.16096>

Bunches of swaying and spinning plasma jets in the solar atmosphere - the spicules - exhibit a variety of complex dynamics that are clearly observed in the images of the solar limb. Utilizing three-dimensional radiative magnetohydrodynamics (rMHD) simulation data, we uncover another facet of a forest of spicules that turns out to be a manifestation of the two-dimensional plasma drapery, instead of one-dimensional conical spikes. This fluted morphology is observed in other contexts like molecular clouds, auroras, and coronal loops. Further, using a sequence of high-cadence line-of-sight integrated images, generated from our simulation, we obtain multiple episodes of spinning amongst clusters of synthetic spicules, also reported in observations near the solar limb. This perception of rotation, according to our findings, is associated with hot swirling plasma columns, extending to coronal heights - that we label as coronal swirling conduits (CoSCo).

### **Recurring Homologous Solar Eruptions in NOAA AR 11429**

[Suman K. Dhakal](#), [Jie Zhang](#), [Panditi Vemareddy](#), [Nishu Karna](#)

ApJ 901 40 2020

<https://arxiv.org/pdf/2008.03447.pdf>

<https://doi.org/10.3847/1538-4357/abacbc>

[https://ui.adsabs.harvard.edu/link\\_gateway/2020ApJ...901...40D/PUB\\_PDF](https://ui.adsabs.harvard.edu/link_gateway/2020ApJ...901...40D/PUB_PDF)

We present the study of three homologous solar eruptions from NOAA active region (AR) 11429 over four days. This large and complex AR divided into two relatively simple sub-regions: northeast (NE) and southwest (SW). Recurrent eruptions occurred from the SW sub-region over different evolutionary phases, which provided a unique opportunity to isolate the physical processes responsible for solar eruptions. Persistent shearing and convergence of opposite magnetic polarities led to continuous flux cancellation along the SW polarity inversion line (PIL). A filament persistently lying along the SW-PIL was observed to survive each eruption, which suggests the partial eruption of the magnetic system. Further, following the first and second eruptions, a sigmoidal magnetic structure of similar morphology was reformed

along the SW-PIL. The photospheric motion of magnetic flux continuously injected and stored the negative helicity in the partially erupted magnetic system and built up the magnetic free energy for the successive eruptions. These results suggest that the shearing motion and magnetic flux cancellation of opposite fluxes were: (1) the dominant factor, irrespective of the evolutionary phase, that contributed to the recurrent homologous eruption, and (2) the key processes of forming the erupting structure, likely a magnetic flux rope, and its long-lasting continuation results in reformation of identical erupting structure. The study also finds that similar magnetic topology could result in the magnetic reconnection at the same location, and such flares during the precursor phase would help in the eruption by decreasing the constraint of overlying magnetic field. **2012/03/07, 2012/03/09, 2012/03/10**

We report a study of a compound solar eruption that was associated with two consecutively erupting magnetic structures and correspondingly two distinct peaks, during impulsive phase, of an M-class flare (M8.5). Simultaneous multi-viewpoint observations from SDO, GOES and STEREO-A show that this compound eruption originated from two pre-existing sigmoidal magnetic structures lying along the same polarity inversion line. Observations of the associated pre-existing filaments further show that these magnetic structures are lying one on top of the other, separated by 12 Mm in height, in a so-called "double-decker" configuration. The high-lying magnetic structure became unstable and erupted first, appearing as an expanding hot channel seen at extreme ultraviolet wavelengths. About 12 minutes later, the low-lying structure also started to erupt and moved at an even faster speed compared to the high-lying one. As a result, the two erupting structures interacted and merged with each other, appearing as a single coronal mass ejection in the outer corona. We find that the double-decker configuration is likely caused by the persistent shearing motion and flux cancellation along the source active region's strong-gradient polarity inversion line. The successive destabilization of these two separate but closely spaced magnetic structures, possibly in the form of magnetic flux ropes, led to a compound solar eruption. The study of the compound eruption provides a unique opportunity to reveal the formation process, initiation, and evolution of complex eruptive structures in solar active regions. **March 10, 2012**

## **Trigger of successive filament eruptions observed by SDO and STEREO**

Solar Physics 292:145 **2017**

<https://arxiv.org/pdf/1706.07385.pdf>

Using multi-wavelength observation from SDO and STEREO, we investigated the mechanism of two successive eruptions (F1 & F2) of a filament in active region NOAA 11444 on 27 March, 2012. The filament was inverse 'J' shaped and lying along a quasi-circular polarity inversion line (PIL). The first part of the filament (F1) erupted at ~2:30UT on **27 March 2012**, the second part of the filament (F2) erupted at around 4:20 UT on the same day. A precursor/pre-flare brightening was observed below filament's main axis about 30 min prior to F1. The brightening was followed by a jet-like ejection below filament, which triggered the eruption. Before the eruption of F2, the filament seems to be trapped within the overlying arcade loops almost for ~1.5-hr before its successful eruption. Interestingly, we observed simultaneously contraction (~12km/s) and expansion (~20km/s) of arcade loops in the active region before F2. HMI magnetograms show the converging motion of the opposite polarities resulting in flux cancellation near PIL. We suggest that flux cancellation at PIL resulted jet-like ejection below filament's main axis, which triggered the eruption F1 similar to tether-cutting process. The eruption F2 was triggered by removal of the overlying arcade loops via reconnection process. Both filament eruptions produced high speed (~1000km/s) CMEs.

## **Observations of Photospheric Vortical Motions During the Early Stage of Filament Eruption**

Sajal Kumar [Dhara](#), B. Ravindra, Ravinder Kumar Banyal

Solar Phys. **2014**

<http://arxiv.org/pdf/1410.3592v1.pdf>

Solar filaments/prominences exhibit rotational motion during different phases of their evolution from their formation to eruption. We have observed the rotational/vortical motion in the photosphere near the ends of ten filaments during their initial phase of eruption, at the onset of the fast rise phase. All the filaments were associated with active regions. The photospheric vortical motions we observed lasted for 4–20 minutes. In the vicinity of the conjugate ends of the filament the direction of rotation was opposite, except for two cases, where rotational motion was observed at only one end point. The sudden onset of a large photospheric vortex motion could have played a role in destabilizing the filament by transporting axial flux into the activated filament thereby increasing the outward magnetic pressure in it. The outward magnetic pressure may have pushed the filament/flux rope to the height where the torus instability criterion was satisfied, and hence it could have caused the filament instability and eruption. **07–Jun–2011, 07–Sep–2011, 02–Jul–2012, 02–Sep–2012, 07–Apr–2012, 31–Dec–2013, 01–Jan–2014, 01–Jan–2014, 04–Apr–2014, 15–Apr–2014**

## **Solar signatures and eruption mechanism of the 2010 August 14 CME**

Elke **D'Huys**, Daniel B. Seaton, Anik De Groof, David Berghmans, Stefaan Poedts

Journal of Space Weather and Space Climate 7 A7 2017

<https://arxiv.org/pdf/1701.08814v1.pdf>

<http://www.swsc-journal.org/articles/swsc/pdf/2017/01/swsc160031.pdf>

On **2010 August 14**, a wide-angled coronal mass ejection (CME) was observed. This solar eruption originated from a destabilized filament that connected two active regions and the unwinding of this filament gave the eruption an untwisting motion that drew the attention of many observers. In addition to the erupting filament and the associated CME, several other low-coronal signatures that typically indicate the occurrence of a solar eruption were associated to this event. However, contrary to what is expected, the fast CME ( $v > 900 \text{ km s}^{-1}$ ) was accompanied by only a weak C4.4 flare.

We investigate the various eruption signatures that were observed for this event and focus on the kinematic evolution of the filament in order to determine its eruption mechanism. Had this solar eruption occurred just a few days earlier, it could have been a significant event for space weather. The risk to underestimate the strength of this eruption based solely on the C4.4 flare illustrates the need to include all eruption signatures in event analyses in order to obtain a complete picture of a solar eruption and assess its possible space weather impact.

## **The Effect of Limited Sample Sizes on the Accuracy of the Estimated Scaling Parameter for Power-Law-Distributed Solar Data**

Elke **D'Huys**, David Berghmans, Daniel B. Seaton, Stefaan Poedts

Solar Phys. 2016

<http://arxiv.org/pdf/1605.06972v1.pdf>

Many natural processes exhibit power-law behavior. The power-law exponent is linked to the underlying physical process and therefore its precise value is of interest. With respect to the energy content of nanoflares, for example, a power-law exponent steeper than 2 is believed to be a necessary condition to solve the enigmatic coronal heating problem. Studying power-law distributions over several orders of magnitudes requires sufficient data and appropriate methodology. In this paper we demonstrate the shortcomings of some popular methods in solar physics that are applied to data of typical sample sizes. We use synthetic data to study the effect of the sample size on the performance of different estimation methods and show that vast amounts of data are needed to obtain a reliable result with graphical methods (where the power-law exponent is estimated by a linear fit on a log-transformed histogram of the data). We **revisit published results on power laws for the angular width of solar coronal mass ejections and the radiative losses of nanoflares**. We demonstrate the benefits of the maximum likelihood estimator and advocate its use.

## **Observational Characteristics of CMEs without Low Coronal Signatures**

E. **D'Huys**, D.B. Seaton, S. Poedts, D. Berghmans

2014 ApJ 795 49

<http://arxiv.org/pdf/1409.1422v1.pdf>, File

Solar eruptions are usually associated with a variety of phenomena occurring in the low corona before, during, and after onset of eruption. Though easily visible in coronagraph observations, so-called stealth coronal mass ejections (CMEs) do not obviously exhibit any of these low-coronal signatures. The presence or absence of distinct low coronal signatures can be linked to different theoretical models to establish the mechanisms by which the eruption is initiated and driven. In this study, **40 CMEs without low coronal signatures, occurring in 2012**, are identified. Their observational and kinematic properties are analyzed and compared to those of regular CMEs. Solar eruptions without clear on-disk or low coronal signatures can lead to unexpected space weather impacts, since many early warning signs for significant space weather activity are not present in these events. A better understanding of their initiation mechanism(s) will considerably improve the ability to predict such space weather events.

**Table 3. CACTus detection parameters for the CMEs without low coronal signatures observed in 2012.**

## **Influence of the magnetic field topology in the evolution of small-scale two-fluid jets in the solar atmosphere**

E. E. **Díaz-Figueroa**, [G. Ares de Parga](#), [J. J. González-Avilés](#)

2023

<https://arxiv.org/pdf/2302.00147.pdf>

We perform a series of numerical simulations to recreate small-scale two-fluid jets using the JOANNA code, considering the magnetohydrodynamics of two fluids (ions + electrons and neutral particles). We first excite the jets in a uniform magnetic field by using velocity pulse perturbations located at  $y_0 = 1.3, 1.5, \text{ and } 1.8 \text{ Mm}$ , considering the base of the photosphere at  $y = 0 \text{ Mm}$ . Then, we repeat the excitation of the jets in a magnetic field that mimics a flux tube. Mainly, the jets excited at the upper chromosphere ( $y \sim 1.8 \text{ Mm}$ ) reach lower heights than those excited at the lower chromosphere ( $y \sim 1.3 \text{ Mm}$ ); this is due to the higher initial vertical location because of the lesser amount of plasma dragging. In both scenarios, the dynamics of the neutral particles and ions show similar behavior; however, we can still identify some differences in the velocity drift, which in our simulations is of the order of  $10\text{--}3 \text{ km s}^{-1}$  at the tips of the jets once they reached their maximum heights. Also, we estimate the heat generation due to the friction between ions

and neutrals (Qini,n), which is of the order of  $0.002\text{--}0.06\text{ W m}^{-3}$ ; however it is small to contribute to the heating of the surroundings of the solar corona. The jets in the two magnetic environments do not show substantial differences other than a slight variation in the maximum heights reached, particularly in the uniform magnetic field scenario. Finally, the maximum heights reached by the three different jets are in the range of some morphological parameters corresponding to macrospicules, Type I spicules, and Type II spicules.

### **Comparative analysis of solar radio bursts before and during CME propagation**

G.**Dididze**, [B.M. Shergelashvili](#), [V.N. Melnik](#), [V.V. Dorovskyy](#), [A.I. Brazhenko](#), [S. Poedts](#), [T.V.](#)

[Zaqarashvili](#), [M. Khodachenko](#)

A&A **2019**

<https://arxiv.org/pdf/1903.12279.pdf>

Context. As is well known, CME propagation often results in the fragmentation of the solar atmosphere on smaller regions of density (magnetic field) enhancement (depletion). It is expected that this type of fragmentation may have radio signatures.

Aims. The general aim of the present paper is to perform a comparative analysis of type III solar and narrow-band type-III-like radio burst properties before and during CME events, respectively. The main goal is to analyze radio observational signatures of the dynamical processes in solar corona. In particular, we aim to perform a comparison of local plasma parameters without and with CME propagation, based on the analysis of decameter radio emission data. Methods. In order to examine this intuitive expectation, we performed a comparison of usual type III bursts before the CME with narrow-band type-III-like bursts, which are observationally detectable on top of the background type IV radio bursts associated with CME propagation. We focused on the analysis of in total 429 type III and 129 narrow-band type-III-like bursts. We studied their main characteristic parameters such as frequency drift rate, duration, and instantaneous frequency bandwidth using standard statistical methods. Furthermore, we inferred local plasma parameters (e.g., density scale height, emission source radial sizes) using known definitions of frequency drift, duration, and instantaneous frequency bandwidth.

Results. The analysis reveals that the physical parameters of coronal plasma before CMEs considerably differ from those during the propagation of CMEs (the observational periods 2 and 4 with type IV radio bursts associated with CMEs). Local density radial profiles and the characteristic spatial scales of radio emission sources vary with radial distance more drastically during the CME propagation compared to the cases of quasistatic solar atmosphere without CME(s) (observational periods 1 and 3).

Conclusions. The results of the work enable us to distinguish different regimes of plasma state in the solar corona. Our results create a solid perspective from which to develop novel tools for coronal plasma studies using radio dynamic spectra. **2014-06-13**

### **Are the Magnetic Field Directions of Surrounding Loops a Key Parameter for Confining a Solar Filament Eruption?**

Tao **Ding**<sup>1</sup>, Jun Zhang<sup>1</sup>, and Junchao Hong<sup>2</sup>

**2022** ApJL 933 L38

<https://iopscience.iop.org/article/10.3847/2041-8213/ac7c73/pdf>

Using high-resolution H $\alpha$  data from the 1 m New Vacuum Solar Telescope, combined with multiband Atmospheric Imaging Assembly extreme ultraviolet observations and Helioseismic and Magnetic Imager light-of-sight magnetograms from the Solar Dynamical Observatory, we study a quiet-Sun filament eruption on **2019 November 1**. During the erupting process, the filament was blocked by at least three sets of surrounding loops (L1–L3). The magnetic field direction of L2 is opposite to that of the top segment of the erupting filament. While the top segment contacted L2, a current sheet formed between L2 and the top segment. Then, magnetic reconnection took place, resulting in the destruction of L2 and the filament. On the other hand, the magnetic field direction of L1 is the same as that of the left leg of the erupting filament, and that of L3 is the same as that of the right leg. The left leg expanded eastward and met L1, then it stopped. The right leg expanded westward and collided with L3. It rebounded and finally stopped at the interaction region. These observations imply that the magnetic field directions of the surrounding magnetic structures are a key parameter for confining a filament eruption. While the field direction of a surrounding structure is the same as that of an eruptive filament, the filament is confined.

### **First Detection of Prominence Material Embedded within a $2 \times 10^6$ K CME Front Streaming away at $100\text{--}1500\text{ km s}^{-1}$ in the Solar Corona**

Adalbert **Ding**<sup>1,2</sup> and Shadia Rifai Habbal

**2017** ApJL 842 L7

<http://iopscience.iop.org/sci-hub.cc/2041-8205/842/1/L7/>

Coronal mass ejections (CMEs) are the largest and most dynamic explosions detected in the million degree solar corona, with speeds reaching up to  $3000\text{ km s}^{-1}$  at Earth's orbit. Triggered by the eruption of prominences, in most cases, one of the outstanding questions pertaining to the dynamic CME-prominence system is the fate of the cool  $10^4\text{--}10^5\text{ K}$  ejected filaments. We present spectroscopic observations acquired during the **2015 March 20** total solar eclipse, which captured a plethora of redshifted plasmoids from Fe xiv emission at  $2 \times 10^6\text{ K}$ . Approximately 10% of these plasmoids enshrouded the same neutral and singly ionized plasma below  $2 \times 10^5\text{ K}$ , observed in prominences anchored at the Sun at that time. This discovery was enabled by the novel design of a dual-channel spectrometer and the

exceptionally clear sky conditions on the island of Svalbard during totality. The Doppler redshifts corresponded to speeds ranging from under 100 to over 1500 km s<sup>-1</sup>. These are the first comprehensive spectroscopic observations to unambiguously detect a  $2 \times 10^6$  K filamentary CME front with inclusions of cool prominence material. The CME front covered a projected area of  $2.5 \times 1.5 R_s^2$  starting from the solar surface. These observations imply that cool prominence inclusions within a CME front maintain their ionic composition during expansion away from the Sun.

## Interaction between Two Coronal Mass Ejections in the 2013 May 22 Large Solar Energetic Particle Event

Liu-Guan [Ding](#)<sup>1,2</sup>, Gang Li<sup>2</sup>, Yong Jiang<sup>3</sup>, Gui-Ming Le<sup>4</sup>, Cheng-Long Shen<sup>5</sup>, Yu-Ming Wang<sup>5</sup>, Yao Chen<sup>6</sup>, Fei Xu<sup>1</sup>, Bin Gu<sup>1</sup>, and Ya-Nan Zhang  
2014 ApJ 793 L35.

We investigate the eruption and interaction of two coronal mass ejections (CMEs) during the large **2013 May 22** solar energetic particle event using multiple spacecraft observations. Two CMEs, having similar propagation directions, were found to erupt from two nearby active regions (ARs), AR11748 and AR11745, at ~08:48 UT and ~13:25 UT, respectively. The second CME was faster than the first CME. Using the graduated cylindrical shell model, we reconstructed the propagation of these two CMEs and found that the leading edge of the second CME caught up with the trailing edge of the first CME at a height of ~6 solar radii. After about two hours, the leading edges of the two CMEs merged at a height of ~20 solar radii. Type II solar radio bursts showed strong enhancement during this two hour period. Using the velocity dispersion method, we obtained the solar particle release (SPR) time and the path length for energetic electrons. Further assuming that energetic protons propagated along the same interplanetary magnetic field, we also obtained the SPR time for energetic protons, which were close to that of electrons. These release times agreed with the time when the second CME caught up with the trailing edge of the first CME, indicating that the CME-CME interaction (and shock-CME interaction) plays an important role in the process of particle acceleration in this event.

## THE "TWIN-CME" SCENARIO AND LARGE SOLAR ENERGETIC PARTICLE EVENTS IN SOLAR CYCLE 23

Liuguan [Ding](#)<sup>1,2</sup>, Yong Jiang<sup>1</sup>, Lulu Zhao<sup>2</sup>, and Gang Li  
2013 ApJ 763 30, [File](#)

Energetic particles in large solar energetic particle (SEP) events are a major concern for space weather. Recently, Li et al. proposed a "twin-CME" scenario for ground-level events. Here we extend that study to large SEP events in solar cycle 23. Depending on whether preceding coronal mass ejections (CMEs) within 9 hr exist and whether ions >10 MeV nucleon<sup>-1</sup> exceed 10 pfu, we categorize fast CMEs with speed >900 km s<sup>-1</sup> and width >60° from the western hemisphere source regions into four groups: groups I and II are "twin" and single CMEs that lead to large SEPs; groups III and IV are "twin" and single CMEs that do not lead to large SEPs. The major findings of this paper are: first, large SEP events tend to be "twin-CME" events. Of 59 western large SEP events in solar cycle 23, 43 are "twin-CME" (group I) events and 16 are single-CME (group II) events. Second, not all "twin CMEs" produced large SEPs: 28 twin CMEs did not produce large SEPs (group III events). Some of them produced excesses of particles up to a few MeV nucleon<sup>-1</sup>. Third, there were 39 single fast CMEs that did not produce SEPs (group IV events). Some of these also showed an excess of particles up to a few MeV nucleon<sup>-1</sup>. For all four groups of events, we perform statistical analyses on properties such as the angular width, the speed, the existence of accompanying metric type II radio bursts, and the associated flare class for the main CMEs and the preceding CMEs.

## Statistics of coronal dimmings associated with coronal mass ejections.

### II. Relationship between coronal dimmings and their associated CMEs

Karin [Dissauer](#), [Astrid M. Veronig](#), [Manuela Temmer](#), [Tatiana Podladchikova](#)

ApJ 874 123 2018

<https://arxiv.org/pdf/1810.01589.pdf>

[sci-hub.se/10.3847/1538-4357/ab0962](https://sci-hub.se/10.3847/1538-4357/ab0962)

We present a statistical study of 62 coronal dimming events associated with Earth-directed CMEs during the quasi-quadrature period of STEREO and SDO. This unique setting allows us to study both phenomena in great detail and compare characteristic quantities statistically. Coronal dimmings are observed on-disk by SDO/AIA and HMI, while the CME kinematics during the impulsive acceleration phase is studied close to the limb with STEREO/EUVI and COR, minimizing projection effects. The dimming area, its total unsigned magnetic flux and its total brightness, reflecting properties of the total dimming region at its final extent, show the highest correlations with the CME mass ( $c \sim 0.6-0.7$ ). Their corresponding time derivatives, describing the dynamics of the dimming evolution, show the strongest correlations with the CME peak velocity ( $c \sim 0.6$ ). The highest correlation of  $c = 0.68 \pm 0.08$  is found with the mean intensity of dimmings, indicating that the lower the CME starts in the corona, the faster it propagates. No significant correlation between dimming parameters and the CME acceleration was found. However, for events where high-cadence STEREO observations were available, the mean unsigned magnetic field density in the dimming regions tends to be positively correlated with the CME peak acceleration ( $c = 0.42 \pm 0.20$ ). This suggests that stronger magnetic fields result in higher Lorentz forces providing stronger driving force for the CME acceleration. Specific coronal dimming parameters correlate with both, CME and flare quantities providing further evidence for the flare-CME feedback

relationship. For events in which the CME occurs together with a flare, coronal dimmings statistically reflect the properties of both phenomena. **2011 February 13, 2011-06-02, 2011 October 2, 2012-06-14, 2012-09-28**

## Statistics of coronal dimmings associated with coronal mass ejections.

### I. Characteristic dimming properties and flare association

Karin [Dissauer](#), [Astrid M. Veronig](#), [Manuela Temmer](#), [Tatiana Podladchikova](#), [Kamalam Vanninathan](#)  
ApJ **863** 169 **2018**

<https://arxiv.org/pdf/1807.05056.pdf>

<http://iopscience.iop.org/article/10.3847/1538-4357/aad3c6/pdf>

Coronal dimmings, localized regions of reduced emission in the EUV and soft X-rays, are interpreted as density depletions due to mass loss during the CME expansion. They contain crucial information on the early evolution of CMEs low in the corona. For 62 dimming events, characteristic parameters are derived, statistically analyzed and compared with basic flare quantities. On average, coronal dimmings have a size of  $2.15 \times 10^{10}$  km<sup>2</sup>, contain a total unsigned magnetic flux of  $1.75 \times 10^{21}$  Mx, and show a total brightness decrease of  $-1.91 \times 10^6$  DN, which results in a relative decrease of  $\sim 60\%$  compared to the pre-eruption intensity level. Their main evacuation phase lasts for  $\sim 50$  minutes. The dimming area, the total dimming brightness, and the total unsigned magnetic flux show the highest correlation with the flare SXR fluence ( $c \geq 0.7$ ). Their corresponding time derivatives, describing the dimming dynamics, strongly correlate with the GOES flare class ( $c \geq 0.6$ ). For 60% of the events we identified core dimmings, i.e. signatures of an erupting flux rope. They contain 20% of the magnetic flux covering only 5% of the total dimming area. Secondary dimmings map overlying fields that are stretched during the eruption and closed down by magnetic reconnection, thus adding flux to the erupting flux rope via magnetic reconnection. This interpretation is supported by the strong correlation between the magnetic fluxes of secondary dimmings and flare reconnection fluxes ( $c = 0.63 \pm 0.08$ ), the balance between positive and negative magnetic fluxes ( $c = 0.83 \pm 0.04$ ) within the total dimmings and the fact that for strong flares ( $> M1.0$ ) the reconnection and secondary dimming fluxes are roughly equal. **2011 June 21, 13 Dec 2011, 9 March 2012, 10 March 2012, 11 May 2012, 2012 June 6**

**Table 1.** Overview of the events under study 2010-2012

### On the detection of coronal dimmings and the extraction of their characteristic properties

Karin [Dissauer](#), [Astrid M. Veronig](#), [Manuela Temmer](#), [Tatiana Podladchikova](#), [Kamalam Vanninathan](#)  
ApJ **2018**

<https://arxiv.org/pdf/1802.03185.pdf>

Coronal dimmings are distinct phenomena associated to coronal mass ejections (CMEs). The study of coronal dimmings and the extraction of their characteristic parameters helps us to obtain additional information of CMEs, especially on the initiation and early evolution of Earth-directed CMEs. We present a new approach to detect coronal dimming regions based on a thresholding technique applied on logarithmic base-ratio images. Characteristic dimming parameters describing the dynamics, morphology, magnetic properties and the brightness of coronal dimming regions are extracted by cumulatively summing newly dimmed pixels over time. It is also demonstrated how core dimming regions are identified as a subset of the overall identified dimming region. We successfully apply our method to two well-observed coronal dimming events. For both events the core dimming regions are identified and the spatial evolution of the dimming area reveals the expansion of the dimming region around these footpoints. We also show that in the early impulsive phase of the dimming expansion the total unsigned magnetic flux involved in the dimming regions is balanced and that up to 30% of this flux results from the localized core dimming regions. Furthermore, the onset in the profile of the area growth rate is co-temporal with the start of the associated flares and in one case also with the fast rise of the CME, indicating a strong relationship of coronal dimmings with both flare and CMEs. **6 September, 2011, October 1, 2011, 26 December 2011**

### Stereoscopic observations of the effects of a halo CME on the solar coronal structure\*

S. [Dolei](#), P. Romano, D. Spadaro and R. Ventura

A&A 567, A9 (2014)

We investigated the substantial restructuring of the outer solar corona in the aftermath of the halo CME that occurred on **9 March 2012**. To perform our analysis, we used SOHO/LASCO, STEREO/COR1 and SDO/AIA data, which provide observations from different viewpoints. In particular, we applied the polarization ratio technique to the COR1 calibrated images to derive the three-dimensional structure of the CME and determine its direction and speed of propagation. We also estimated the CME mass from a sequence of four observations of the event and obtained values of up to  $2.2 \times 10^{16}$  g. The COR1 images show a brightness decrease in the coronal sector where the CME propagates. We verified that this intensity reduction is due to a plasma depletion. Moreover, the combined analysis performed by the two STEREO satellites allowed us to deduce that a preexisting streamer is located along the propagation direction of the CME and disappears after the passage of the event. The coronal mass loss associated with the plasma depletion is much lower than the mass expelled from the Sun in the COR1-B data. Conversely, the COR1-A observations allowed us to infer that the mass of the streamer carried away from the outer corona corresponds to about half of the CME mass. The results

highlight the importance of stereoscopic observations in the study of corona restructuring in the aftermath of a CME event.

### **Measurements with STEREO/COR1 data of drag forces acting on small-scale blobs falling in the intermediate corona**

S. [Dolei](#)<sup>1</sup>, A. Bemporad<sup>2</sup> and D. Spadaro  
A&A 562, A74 (2014)

In this work we study the kinematics of three small-scale ( $0.01 R_{\odot}$ ) blobs of chromospheric plasma falling back to the Sun after the huge eruptive event of **June 7, 2011**. From a study of 3D trajectories of blobs made with the Solar TERrestrial RELations Observatory (STEREO) data, we demonstrate the existence of a significant drag force acting on the blobs and calculate two drag coefficients, in the radial and tangential directions. The resulting drag coefficients  $CD$  are between 0 and 5, comparable in the two directions, making the drag force only a factor of 0.45–0.75 smaller than the gravitational force. To obtain a correct determination of electron densities in the blobs, we also demonstrate how, by combining measurements of total and polarized brightness, the  $H\alpha$  contribution to the white-light emission observed by the COR1 telescopes can be estimated. This component is significant for chromospheric plasma, being between 95 and 98% of the total white-light emission. Moreover, we demonstrate that the COR1 data can be employed even to estimate the  $H\alpha$  polarized component, which turns out to be in the order of a few percent of  $H\alpha$  total emission from the blobs. If the drag forces acting on small-scale blobs reported here are similar to those that play a role during the CME propagation, our results suggest that the magnetic drag should be considered even in the CME initiation modelling.

### **A ring of polarized light: evidence for twisted coronal magnetism in cavities.**

[Dove](#), J.B., Gibson, S.E., Rachmeler, L.A., Tomczyk, S., Judge, P.:  
2011, *Astrophys. J. Lett.* **731**, L1

Coronal prominence cavities may be manifestations of twisted or sheared magnetic fields capable of storing the energy required to drive solar eruptions. The Coronal Multi-Channel Polarimeter (CoMP), recently installed at Mauna Loa Solar Observatory, can measure polarimetric signatures of current-carrying magnetohydrodynamic (MHD) systems. For the first time, this instrument offers the capability of daily full-Sun observations of the forbidden lines of Fe XIII with high enough spatial resolution and throughput to measure polarimetric signatures of current-carrying MHD systems. By forward-calculating CoMP observables from analytic MHD models of **spheromak**-type magnetic flux ropes, we show that a predicted observable for such flux ropes oriented along the line of sight is a bright ring of linear polarization surrounding a region where the linear polarization strength is relatively depleted. We present CoMP observations of a coronal cavity possessing such a polarization ring.

### **Magnetohydrodynamic Simulations of Spicular Jet Propagation Applied to Lower Solar Atmosphere Model. II. Case Studies with Tilted Jets**

Fionnlagh Mackenzie [Dover](#)<sup>1</sup>, Rahul Sharma<sup>2</sup>, and Robertus Erdélyi<sup>1,3,4</sup>  
2022 ApJ 929 88

<https://iopscience.iop.org/article/10.3847/1538-4357/ac5aa9/pdf>

We report on numerical simulations of a propagating momentum pulse, representing an inclined jet structure in a stratified lower solar atmosphere model. Here, the numerical jets were generated via injection of a momentum pulse misaligned with the radial magnetic field, which resulted in a collimated structure that mimicked the observed inclined jet features in the chromosphere. The influence of inclination angle was examined for a variety of initial driver conditions (amplitude, period) and magnetic field magnitudes to identify their potential role in determining the morphological and dynamical characteristics of chromospheric jets. The numerical jets in our computational domain were consistent with the observed magnitudes of apex height and cross-sectional width for average inclination of chromospheric features. Furthermore, with an increasing misalignment between the momentum pulse and ambient magnetic field, the simulated structures showed a drop in the maximum apex height and length, while an increase in cross-sectional width magnitudes. Our numerical experiments also revealed the development of a pulse-like transverse motions in jets along with high density edges/nodes in the direction of jet displacement. It is postulated that dynamic kink instability might be responsible for the observed kinematic behavior of the inclined jet structures in the solar chromosphere.

### **Are switchbacks signatures of magnetic flux ropes generated by interchange reconnection in the corona?**

The structure of magnetic flux ropes injected into the solar wind during reconnection in the coronal atmosphere is explored with particle-in-cell simulations and compared with  $\{it\}$  in situ measurements of magnetic "switchbacks" from the Parker Solar Probe. We suggest that multi-x-line reconnection between open and closed flux in the corona will inject flux ropes into the solar wind and that these flux ropes can convect outward over long distances before disintegrating. Simulations that explore the magnetic structure of flux ropes in the solar wind reproduce key features of the "switchback" observations: a rapid rotation of the radial magnetic field into the transverse direction (a consequence

of reconnection with a strong guide field); and the potential to reverse the radial field component. The potential implication of the injection of large numbers of flux ropes in the coronal atmosphere for understanding the generation of the solar wind is discussed. **Nov. 5, 2018**

## **Magnetohydrodynamic Simulations of Spicular Jet Propagation Applied to Lower Solar Atmosphere Model**

**2021 ApJ 913 19**

<https://doi.org/10.3847/1538-4357/abefd1>

We report a series of numerical experiments for the propagation of a momentum pulse representing a chromospheric jet, simulated using an idealized magnetohydrodynamic model. The jet in a stratified lower solar atmosphere is subjected to a varied initial driver (amplitude, period) and magnetic field conditions to examine the parameter influence over jet morphology and kinematics. The simulated jet captured key observed spicule characteristics including maximum heights, field-aligned mass motions/trajectories, and cross-sectional width deformations. Next, the jet features also show a prominent bright, bulb-like apex, similar to reported observed chromospheric jets, formed due to the higher density of plasma and/or waves. Furthermore, the simulations highlight the presence of not yet observed internal crisscross/knots substructures generated by shock waves reflected within the jet structure. Therefore we suggest verifying these predicted fine-scale structures in highly localized lower solar atmospheric jets, e.g., in spicules or fibrils by high-resolution observations, offered by the Daniel K. Inoyue Solar Telescope or otherwise.

## **Observations and 3D MHD Modeling of a Confined Helical Jet Launched by a Filament Eruption**

<https://arxiv.org/pdf/1912.02133.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ab5d39/pdf>

We present a detailed analysis of a confined filament eruption and jet associated with a C1.5 class solar flare. Multi-wavelength observations from GONG and SDO reveal the filament forming over several days following the emergence and then partial cancellation of a minority polarity spot within a decaying bipolar active region. The emergence is also associated with the formation of a 3D null point separatrix that surrounds the minority polarity. The filament eruption occurs concurrent with brightenings adjacent to and below the filament, suggestive of breakout and flare reconnection, respectively. The erupting filament material becomes partially transferred into a strong outflow jet (~ 60 km/s) along coronal loops, becoming guided back towards the surface. Utilising high resolution H $\alpha$  observations from SST/CRISP, we construct velocity maps of the outflows demonstrating their highly structured but broadly helical nature. We contrast the observations with a 3D MHD simulation of a breakout jet in a closed-field background and find close qualitative agreement. We conclude that the suggested model provides an intuitive mechanism for transferring twist/helicity in confined filament eruptions, thus validating the applicability of the breakout model not only to jets and coronal mass ejections but also to confined eruptions and flares. **30 June 2013**

## **IMPLICATIONS OF MASS AND ENERGY LOSS DUE TO CORONAL MASS EJECTIONS ON MAGNETICALLY ACTIVE STARS**

Jeremy J. [Drake](#)<sup>1</sup>, Ofer Cohen<sup>1</sup>, Seiji Yashiro<sup>2,3</sup>, and Nat Gopalswamy  
**2013 ApJ 764 170**

<http://arxiv.org/pdf/1302.1136.pdf>

Analysis of a database of solar coronal mass ejections (CMEs) and associated flares over the period 1996-2007 finds well-behaved power-law relationships between the 1-8 Å flare X-ray fluence and CME mass and kinetic energy. We extrapolate these relationships to lower and higher flare energies to estimate the mass and energy loss due to CMEs from stellar coronae, assuming that the observed X-ray emission of the latter is dominated by flares with a frequency as a function of energy  $dn/dE = kE^{-\alpha}$ . For solar-like stars at saturated levels of X-ray activity, the implied losses depend fairly weakly on the assumed value of  $\alpha$  and are very large:  $\text{yr}^{-1}$  and . In order to avoid such large energy requirements, either the relationships between CME mass and speed and flare energy must flatten for X-ray fluence 1031 erg, or the flare-CME association must drop significantly below 1 for more energetic events. If active coronae are dominated by flares, then the total coronal energy budget is likely to be up to an order of magnitude larger than the canonical 10–3 L bol X-ray saturation threshold. This raises the question of what is the maximum energy a magnetic dynamo can extract from a star? For an energy budget of 1% of L bol, the CME mass loss rate is about  $5 \times 10^{-11} M_{\odot} \text{yr}^{-1}$ .

## **Tethered Prominence-CME Systems Captured during the 2012 November 13 and 2013 November 3 Total Solar Eclipses**

Miloslav [Druckmüller](#)<sup>1</sup>, Shadia R. Habbal<sup>2</sup>, Nathalia Alzate<sup>3</sup>, and Constantinos Emmanouilidis<sup>4</sup>  
**2017 ApJL 851 L41**

<http://sci-hub.tw/10.3847/2041-8213/aa9ed5>

We report on white light observations of high latitude tethered prominences acquired during the total solar eclipses of **2012 November 13 and 2013 November 3**, at solar maximum, with a field of view spanning several solar radii. Distinguished by their pinkish hue, characteristic of emission from neutral hydrogen and helium, the four tethered prominences were akin to twisted flux ropes, stretching out to the limit of the field of view, while remaining anchored at the Sun. Cotemporal observations in the extreme ultraviolet from the Solar Dynamics Observatory (SDO/AIA) clearly showed that the pinkish emission from the cool ( $\approx 10^4 - 10^5$  K) filamentary prominences was cospatial with the 30.4 nm He II emission, and was directly linked to filamentary structures emitting at coronal temperatures  $\geq 10^6$  K in 17.1 and 19.3 nm. The tethered prominences evolved from typical tornado types. Each one formed the core of different types of coronal mass ejections (CMEs), as inferred from coordinated LASCO C2, C3, and STEREO A and B coronagraph observations. Two of them evolved into a series of faint, unstructured puffs. One was a normal CME. The most striking one was a "light-bulb" type CME, whose three-dimensional structure was confirmed from all four coronagraphs. These first uninterrupted detections of prominence-CME systems anchored at the Sun, and stretching out to at least the edge of the field of view of LASCO C3, provide the first observational confirmation for the source of counter-streaming electron fluxes measured in interplanetary CMEs, or ICMEs.

### **Variations in the Correlations of Acceleration and Force of Slow and Fast CMEs with Solar Activity during Solar Cycles 23 – 24**

**Zhanle Du**

**Solar Physics** volume 296, Article number: 34 (2021)

<https://link.springer.com/content/pdf/10.1007/s11207-021-01778-5.pdf>

Studying the behavior of coronal mass ejections (CMEs) is important for both solar physics and space weather. The correlations of smoothed monthly mean daily integrated CME acceleration [a], mass [M], and the force [Ma] to drive CMEs with sunspot activity [RI] are analyzed for both slow and fast CMEs and for both Solar Cycles 23 and 24 separately. It is found that aa is inversely related to both RI and M. The correlation between Ma and RI for both slow and fast CMEs is negative at the rising phase of Solar Cycle 23 and positive otherwise. There is a sharp peak in  $\gamma = Ma/RI$  near the solar minimum (December 2008) for both slow and fast CMEs. However, for fast CMEs, there is a sharp negative peak near the previous solar minimum (August 1996) and another positive peak near the current solar minimum (2019). The positive (negative) peak tends to be related to the solar minimum from a stronger (weaker) to a weaker (stronger) solar cycle. These results suggest that the CME acceleration depends more on the strength of solar activity than on the CME's speed. Stronger magnetic activity may slow down the CMEs that are too massive or too fast and weaker activity may speed up the CMEs that are less massive or too slow. During a few years' period of magnetic-field polarity reversal around the solar minimum, the force provided by large-scale magnetic-field structures may not be strong enough to constrain CME motions, leading to the "escape" of CMEs with large  $|\gamma|$ .

### **Plasma Energization in Colliding Magnetic Flux Ropes**

Senbei **Du**<sup>1,2</sup>, Fan Guo<sup>2,3</sup>, Gary P. Zank<sup>1,4</sup>, Xiaocan Li<sup>3</sup>, and Adam Stanier

**2018** ApJ 867 16

[sci-hub.tw/10.3847/1538-4357/aae30e](https://arxiv.org/abs/1808.03301)

Magnetic flux ropes are commonly observed throughout the heliosphere, and recent studies suggest that interacting flux ropes are associated with some energetic particle events. In this work, we carry out 2D particle-in-cell (PIC) simulations to study the coalescence of two magnetic flux ropes (or magnetic islands), and the subsequent plasma energization processes. The simulations are initialized with two magnetic islands embedded in a reconnecting current sheet. The two islands collide and eventually merge into a single island. Particles are accelerated during this process as the magnetic energy is released and converted to the plasma energy, including bulk kinetic energy increase by the ideal electric field, and thermal energy increase by the fluid compression and the nonideal electric field. We find that contributions from these different energization mechanisms are all important and comparable with each other. Fluid shear and a nongyrotropic pressure tensor also contribute to the energy conversion process. For simulations with different box sizes ranging from  $L_x \sim 25-100d_i$  and ion-to-electron mass ratios  $m_i/m_e = 25, 100, \text{ and } 400$ , we find that the general evolution is qualitatively the same for all runs, and the energization depends only weakly on either the system size or the mass ratio. The results may help us understand plasma energization in solar and heliospheric environments.

### **Correlations Between CME Parameters and Sunspot Activity**

**Zhanle Du**

**Solar Physics**, Volume 278, Number 1 (2012), 203-215

<http://arxiv.org/abs/1112.5560v1>

Smoothed monthly mean coronal mass ejection (CME) parameters (speed, acceleration, central position angle, angular width, mass, and kinetic energy) for Cycle 23 are cross-analyzed, showing that there is a high correlation between most of them. The CME acceleration (a) is highly correlated with the reciprocal of its mass (M), with a correlation coefficient  $r=0.899$ . The force (Ma) to drive a CME is found to be well anti-correlated with the sunspot number (Rz),  $r=-0.750$ .

The relationships between CME parameters and  $R_z$  can be well described by an integral response model with a decay time scale of about 11 months. The correlation coefficients of CME parameters with the reconstructed series based on this model ( $r_1=0.886$ ) are higher than the linear correlation coefficients of the parameters with  $R_z$  ( $r_0=0.830$ ). If a double decay integral response model is used (with two decay time scales of about 6 and 60 months), the correlations between CME parameters and  $R_z$  improve ( $r_2=0.906$ ). The time delays between CME parameters with respect to  $R_z$  are also well predicted by this model ( $19/22=86\%$ ); the average time delays are 19 months for the reconstructed and 22 months for the original time series. The model implies that CMEs are related to the accumulation of solar magnetic energy. These relationships can help in understanding the mechanisms at work during the solar cycle.

## **On the Determining Physical Factor of Jet-Related Coronal Mass Ejection's Morphology in the High Corona**

[Yadan Duan](#), [Yuandeng Shen](#), [Zehao Tang](#), [Chenrui Zhou](#), [Song Tan](#)

ApJ 968 110 2024

<https://arxiv.org/pdf/2404.19179>

<https://iopscience.iop.org/article/10.3847/1538-4357/ad445c/pdf>

A solar jet can often cause coronal mass ejections (CMEs) with different morphologies in the high corona, for example, jet-like CMEs, bubble-like CMEs, and so-called twin CMEs that include a pair of simultaneous jet-like and bubble-like CMEs. However, what determines the morphology of a jet-related CME is still an open question. Using high spatiotemporal resolution stereoscopic observations taken by the Solar Dynamics Observatory (SDO) and the Solar Terrestrial Relations Observatory (STEREO) from October 2010 to December 2012, we performed a statistical study of jet-related CMEs to study the potential physical factors that determine the morphology of CMEs in the outer corona. Our statistical sample includes 16 jet-related CME events of which 7 are twin CME events and 9 are jet-like narrow CMEs. We find that all CMEs in our sample were accompanied by filament-driven blowout jets and Type III radio bursts during their initial formation and involved magnetic reconnection between filament channels and the surrounding magnetic fields. Most of our cases occurred in a fan-spine magnetic configuration. Our study suggests that the bubble-like components of twin CMEs lacking an obvious core are related to the expansion of the closed-loop systems next to the fan-spine topology, while the jet-like component is from the coronal extension of the jet plasma along open fields. Based on the statistical results, we conclude that the morphology of jet-related CMEs in the high corona may be related to the filament length and the initial magnetic null point height of the fan-spine structures. **2011 August 28, 2012 January 20, 2012 August 9, 2012 August 31**

## **The Initiation Mechanism of the First On-disk X-Class Flare of Solar Cycle 25**

[Aiyang Duan](#), [Chaowei Jiang](#), [ZhenJun Zhou](#), [Xueshang Feng](#)

A&A 674, A192 2023

<https://arxiv.org/pdf/2304.13241.pdf>

<https://www.aanda.org/articles/aa/pdf/2023/06/aa45583-22.pdf>

In this paper we study the initiation mechanism of the first on-disk X-class eruptive flare in solar cycle 25. Coronal magnetic field reconstructions reveal a magnetic flux rope (MFR) with configuration highly consistent with a filament existing for a long period before the flare, and the eruption of the whole filament indicates that the MFR erupted during the flare. However, quantitative analysis shows that the pre-flare MFR resides in a height too low to trigger a torus instability (TI). The filament experienced a slow rise before the flare onset, for which we estimate evolution of the filament height using a triangulation method by combining the SDO and STEREO observations, and find it is also much lower than the critical height for triggering TI. On the other hand, the pre-flare evolution of the current density shows progressive thinning of a vertical current layer on top of the flare PIL, which suggests that a vertical current sheet forms before the eruption. Meanwhile, there is continuously shearing motion along the PIL under the main branch of the filament, which can drive the coronal field to form such a current sheet. As such, we suggest that the event follows a reconnection-based initiation mechanism as recently established using a high-accuracy MHD simulation, in which an eruption is initiated by reconnection in a current sheet that forms gradually within continuously-sheared magnetic arcade. The eruption should be further driven by TI as the filament quickly rises into the TI domain during the eruption. **28 Oct 2021**

## **Macrospicules and Their Connection to Magnetic Reconnection in the Lower Atmosphere**

[Yadan Duan](#), [Yuandeng Shen](#), [Hechao Chen](#), [Zehao Tang](#), [Chenrui Zhou](#), [Xinping Zhou](#), [Song Tan](#)

ApJL 942 L22 2022

<https://arxiv.org/pdf/2212.03425.pdf>

<https://iopscience.iop.org/article/10.3847/2041-8213/acac2b/pdf>

Solar macrospicules are beam-like cool plasma ejections of size in-between spicules and coronal jets, which can elucidate potential connections between plasma jetting activity at different scales. With high-resolution observations from the *New Vacuum Solar Telescope* and Solar Dynamic Observatory, we investigate the origin of five groups of recurrent active-region macrospicules. Before the launch of each macrospicule, we detect a compact bright patch (BP) at its base where a newly emerging dipole contacts and cancel with the pre-existing ambient field. The spectral diagnosis from the *Interface Region Imaging Spectrograph* at one of BPs reveals signatures of reconnection at

the lower atmosphere. Multiwavelength imaging of these BPs show that they mainly occur at the rising phase of the flux emergence and slowly ascend from the lower to the upper chromosphere. Remarkable macrospicules occur and fade out once the BPs appear and decay from the AIA 304 Å images, respectively. We suggest that these macrospicules and related BPs form in a common reconnection process, in which the increasing reconnection height between the emerging dipole and the ambient field results in the observed variations from BPs to macrospicules. Interestingly, most macrospicules show similar characteristics to larger-scale coronal jets and/or smaller-scale spicules, i.e., the rotating motions, the presence of minifilaments and BPs before the eruptions, and magnetic flux emergence and cancellation. We conclude that the formation mechanism of macrospicules should be the same as spicules and coronal jets, i.e., solar jetting phenomena at different scales share the same physical mechanism in association with magnetic reconnection. **November 11, 2020**

## **Homologous Accelerated Electron Beams, Quasi-periodic fast-propagating Wave and CME Observed in one Fan-spine Jet**

[Yadan Duan](#), [Yuandeng Shen](#), [Xinping Zhou](#), [Zehao Tang](#), [Chengrui Zhou](#), [Song Tan](#)

ApJ **926** L39 **2022**

<https://arxiv.org/pdf/2201.08982.pdf>

<https://iopscience.iop.org/article/10.3847/2041-8213/ac4df2/pdf>

Using imaging and radio multi-wavelength observations, we studied the origin of two homologous accelerated electron beams and a quasi-periodic fast-propagating (QFP) wave train associated with a solar jet on **2012 July 14**. The jet occurred in a small-scale fan-spine magnetic system embedding in a large-scale pseudostreamer, which associated with a GOES C1.4 flare, a jet-like coronal mass ejection (CME), a type II radio burst, and a type III radio burst. During the initial stage, a QFP wave train and a fast moving on-disk radio source were detected in succession ahead of the jet along the outer spine of the fan-spine system. When the jet reached a height of about 1.3 solar radii, it underwent a bifurcation into two branches. Based on our analysis results, all the observed phenomena in association with the jet can be explained by using a fan-spine magnetic system. We propose that both the type III radio burst and the on-disk fast moving radio source were caused by the same physical process, i.e., the energetic electrons accelerated by the magnetic reconnection at the null point, and they were along the open field lines of the pseudostreamer and the closed outer spine of the fan-spine structure, respectively. Due to the bifurcation of the jet body, the lower branch along the closed outer spine of the fan-spine structure fell back to the solar surface, while the upper branch along the open field lines of the pseudostreamer caused the jet-like CME in the outer corona.

## **Structural evolution of a magnetic flux rope associated with a major flare in the solar active region 12205**

A. Y. [Duan](#), C. W. Jiang, Y. Guo, X. S. Feng, J. Cui

A&A, **659**, A25 **2022**

<https://doi.org/10.1051/0004-6361/202142061>

<https://www.aanda.org/articles/aa/pdf/2022/03/aa42061-21.pdf>

Solar eruptions are often generated as a result of the complex magnetic environment in solar active regions (ARs). Unravelling the relevant structure and evolution is vital to disclosing the underlying mechanisms that initiate such eruptions. In this work, we conduct a comprehensive study of the magnetic field structure and evolution responsible for a major flare eruption in a complex AR: NOAA 12205. The study is based on a detailed analysis of observations from the SDO and a time sequence of coronal magnetic field extrapolations. The AR is characterized by a long sequence of sunspots, harboring two groups of  $\delta$  type that evolved dynamically via continual rotation, shearing, colliding, and flux cancellation. Our study suggests that the joint effect of the sunspot motions along a large-scale magnetic flux rope (MFR) supporting a filament was gradually built up along the main polarity inversion line. A quantitative analysis of the coronal magnetic evolution strongly indicates that an ideal instability of the MFR finally led to the major eruption of the X1.6 flare, although it was preceded by episodes of localized reconnections. These localized reconnections should play a key role in building up the unstable MFR by, for example, tether-cutting reconnection low near the photosphere, as driven by the shearing and flux cancellation. Through these reconnections, the MF gains a significant amount of twisted flux and is lifted up to a height above the torus unstable threshold, at which the background restraining force decreases fast enough with the height. **7 Nov 2014**

## **Structure and Evolution of an Inter-Active Region Large-scale Magnetic Flux Rope**

Aiying [Duan](#)<sup>1</sup>, Chaowei Jiang<sup>2</sup>, Peng Zou<sup>2</sup>, Xueshang Feng<sup>2</sup>, and Jun Cui<sup>1</sup>

**2021** ApJ **906** 45

<https://doi.org/10.3847/1538-4357/abc701>

Magnetic flux rope (MFR) has been recognized as the key magnetic configuration of solar eruptions. While pre-eruption MFRs within the core of solar active regions (ARs) have been widely studied, those existing between two ARs, i.e., the intermediate ones in weak-field regions, were rarely studied. There are also major eruptions that occurred in such intermediate regions and study of the MFR there will help us understand the physics mechanism underlying the eruptions. Here, with a nonlinear force-free field reconstruction of solar coronal magnetic fields, we tracked the five-day evolution covering the full life of a large-scale inter-AR MFR forming between ARs NOAA 11943 and 11944, which is closely cospatial with a long sigmoidal filament channel and an eruptive X1.2 flare occurring on **2014 January 7**. Through topological analysis of the reconstructed 3D magnetic field, it is found that the MFR begins to

form early on **2014 January 6**; then with its magnetic twist degree continuously increasing for over 30 hr, it becomes highly twisted with field lines winding numbers approaching six turns, which might be the highest twisting degree in extrapolated MFRs that have been reported in the literature. The formation and strength of the MFR are attributed to a continuous sunspot rotation of AR 11944 and flux cancellation between the two ARs. The MFR and its associated filaments exhibit no significant change across the flare time, indicating it is not responsible for the flare eruption. After the flare, the MFR slowly disappears, possibly due to the disturbance by the eruption.

## Variation of Magnetic Flux Ropes Through Major Solar Flares

Aiying Duan, Chaowei Jiang, Zhenjun Zhou, Xueshang Feng, Jun Cui

ApJL **907** L23 **2021**

<https://arxiv.org/pdf/2012.14588.pdf>

<https://doi.org/10.3847/2041-8213/abd638>

It remains unclear how solar flares are triggered and in what conditions they can be eruptive with coronal mass ejections. Magnetic flux ropes (MFRs) has been suggested as the central magnetic structure of solar eruptions, and their ideal instabilities including mainly the kink instability (KI) and torus instability (TI) provide important candidates for triggering mechanisms. Here using magnetic field extrapolations from observed photospheric magnetograms, we systematically studied the variation of coronal magnetic fields, focusing on MFRs, through major flares including 29 eruptive and 16 confined events. We found that nearly 90% events possess MFR before flare and 70% have MFR even after flare. We calculated the controlling parameters of KI and TI, including the MFR's maximum twist number and the decay index of its strapping field. Using the KI and TI thresholds empirically derived from solely the pre-flare MFRs, two distinct different regimes are shown in the variation of the MFR controlling parameters through flares. For the events with both parameters below their thresholds before flare, we found no systematic change of the parameters after the flares, in either the eruptive or confined events. In contrast, for the events with any of the two parameters exceeding their threshold before flare (most of them are eruptive), there is systematic decrease in the parameters to below their thresholds after flares. These results provide a strong constraint for the values of the instability thresholds and also stress the necessity of exploring other eruption mechanisms in addition to the ideal instabilities. **2014 February 4, 2017 September 6**

**Table 1.** List of events and parameters of their pre- and post-flare MFRs. (2011-2017)

## A Study of Pre-Flare Solar Coronal Magnetic Fields: Magnetic Flux Ropes

Aiying Duan, Chaowei Jiang, Wen He, Xueshang Feng, Peng Zou, Jun Cui

ApJ **884** 73 **2019**

<https://arxiv.org/pdf/1908.08643.pdf>

<https://doi.org/10.3847/1538-4357/ab3e33>

Magnetic flux ropes (MFRs) are thought to be the central structure of solar eruptions, and their ideal MHD instabilities can trigger the eruption. Here we performed a study of all the MFR configurations that lead to major solar flares, either eruptive or confined, from 2011 to 2017 near the solar disk center. The coronal magnetic field is reconstructed from observed magnetograms, and based on magnetic twist distribution, we identified the MFR, which is defined as a coherent group of magnetic field lines winding an axis with more than one turn. It is found that 90% of the events possess pre-flare MFRs, and their three-dimensional structures are much more complex in details than theoretical MFR models. We further constructed a diagram based on two parameters, the magnetic twist number which controls the kink instability (KI), and the decay index which controls the torus instability (TI). It clearly shows lower limits for TI and KI thresholds, which are  $n_{crit}=1.3$  and  $|Tw|_{crit}=2$ , respectively, as all the events above  $n_{crit}$  and nearly 90% of the events above  $|Tw|_{crit}$  erupted. Furthermore, by such criterion, over 70% of the events can be discriminated between eruptive and confined flares, and KI seems to play a nearly equally important role as TI in discriminating between the two types of flare. There are more than half of events with both parameters below the lower limits, and 29% are eruptive. These events might be triggered by magnetic reconnection rather than MHD instabilities. **2011-02-15, 2011-03-09, 2011-08-03, 2012-01-23, 2012-03-06, 2012-05-10, 2012-07-02, 2012-07-05, 2012-07-12, 2013-04-11, 2013-10-24, 2013-11-01, 2013-11-03, 2013-11-05, 2013-11-08, 2013-12-31, 2014-01-07, 2014-02-02, 2014-02-04, 2014-03-29, 2014-04-18, 2014-09-28, 2014-10-22, 2014-10-24, 2014-11-07, 2014-12-04, 2014-12-18, 2014-12-20, 2015-03-11/12, 2013-06-22, 2015-06-25, 2015-08-24, 2015-09-04, 2015-09-28, 2017-09-06**

<https://doi.org/10.3847/1538-4357/ab32e9>

We report the formation of a complicated coronal mass ejection (CME) on **2015 August 23** by using the high temporal and high spatial resolution multi-wavelength observations taken by the Solar Dynamic Observatory and the Solar and Heliospheric Observatory. The CME exhibited both jet-like and bubble-like components simultaneously, and therefore we call it a twin CME. Detailed imaging and kinematic analysis results indicate that the twin CME were evolved from the eruption of a mini-filament driven blowout jet at the east edge of an equatorial coronal hole, in which the activation of the mini-filament was tightly associated with the continuous flux cancellation and quasi-periodic jet-like activities in the filament channel. Due to the magnetic reconnection between the filament and the ambient open field lines, the

filament broke partially at the northern part and resulted in an intriguing blowout jet in the south direction. It is interesting that the ejecting jet was deflected by a group of remote open field lines, which resulted in the significant direction change of the jet from southward to eastward. Based on the close temporal and spatial relationships among the jet, filament eruption, and the twin CME, we conclude that the jet-like CME should be the coronal extension of the jet plasma, while the bubble-like one should be originated from the eruption of the mini-filament confined by the closed magnetic fields at the jet-base.

New Astronomy 2016

<http://arxiv.org/pdf/1605.02299v1.pdf>

The present study provides important details on homologous eruptions of a solar prominence that occurred in active region NOAA 10904 on **2006 August 22**. We report on the preeruptive phase of the homologous feature as well as the kinematics and the morphology of a forth from a series of prominence eruptions that is critical in defining the nature of the previous consecutive eruptions. The evolution of the overlying coronal field during homologous eruptions is discussed and a new observational criterion for homologous eruptions is provided. We find a distinctive sequence of three activation periods each of them containing preeruptive precursors such as a brightening and enlarging of the prominence body followed by small surge- like ejections from its southern end observed in the radio 17 GHz. We analyse a fourth eruption that clearly indicates a full reformation of the prominence after the third eruption. The fourth eruption although occurring 11 hrs later has an identical morphology, the same angle of propagation with respect to the radial direction, as well as similar kinematic evolution as the previous three eruptions. We find an important feature of the homologous eruptive prominence sequence that is the maximum height increase of each consecutive eruption. The present analysis establishes that all four eruptions observed in H $\{\alpha\}$  are of confined type with the third eruption undergoing a thermal disappearance during its eruptive phase. We suggest that the observation of the same direction of the magnetic flux rope (MFR) ejections can be consider as an additional observational criterion for MFR homology. This observational indication for homologous eruptions is important, especially in the case of events of typical or poorly distinguishable morphology of eruptive solar phenomena.

### **Filament Leg--Leg Reconnection as a Source of Prominent Supra-Arcade Downflows**

ApJL 937 L10 2022

<https://arxiv.org/pdf/2209.00306.pdf>

<https://iopscience.iop.org/article/10.3847/2041-8213/ac8eaf/pdf>

We report on interaction of the legs of the erupting filament of **2012 August 31** and associated prominent supra-arcade downflows (P-SADs) as observed by the Atmospheric Imaging Assembly onboard the Solar Dynamics Observatory. We employ a number of image processing techniques to enhance weak interacting features. As the filament erupts, both legs stretch outwards. The positive-polarity leg also untwists and splits into two parts. The first part runs into the conjugate (negative-polarity) leg, tearing it apart. The second part then converges into the remnant of the conjugate leg, after which both weaken and finally disappear. All these episodes of interaction of oppositely-oriented filament legs are followed by appearance of P-SADs, seen in the on-disk projection to be shaped as loop-tops, along with many weaker SADs. All SADs are preceded by hot supra-arcade downflowing loops. This observed evolution is consistent with the three-dimensional rr-rf (leg-leg) reconnection, where the erupting flux rope reconnects with itself. In our observations, as well as in some models, the reconnection in this geometry is found to be long-lasting. It plays a substantial role in the evolution of the flux rope of the erupting filament and leads to prominent supra-arcade downflows.

### **Observation of all pre- and post-reconnection structures involved in three-dimensional reconnection geometries in solar eruptions**

ApJ 887 71 2019

<https://arxiv.org/pdf/1910.08620.pdf>

[sci-hub.se/10.3847/1538-4357/ab4f86](https://sci-hub.se/10.3847/1538-4357/ab4f86)

We report on observations of the two newly-identified reconnection geometries involving erupting flux ropes. In 3D, a flux rope can reconnect either with a surrounding coronal arcade (recently named "ar-rf" reconnection) or with itself ("rr-rf" reconnection), and both kinds of reconnection create a new flux rope field line and a flare loop. For the first time, we identify all four constituents of both reconnections in a solar eruptive event, the filament eruption of **2011 June 07** observed by SDO/AIA. The ar-rf reconnection manifests itself as shift of one leg of the filament by more than 25" northward. At its previous location, a flare arcade is formed, while the new location of the filament leg previously

corresponded to a footpoint of a coronal loop in 171 Å. In addition, the evolution of the flare ribbon hooks is also consistent with the occurrence of ar-rf reconnection as predicted by MHD simulations. Specifically, the growing hook sweeps footpoints of preeruptive coronal arcades, and these locations become inside the hook. Furthermore, the rr-rf reconnection occurs during the peak phase above the flare arcade, in an apparently X-type geometry involving a pair of converging bright filament strands in the erupting filament. A new flare loop forms near the leg of one of the strands, while a bright blob, representing a remnant of the same strand, is seen ascending into the erupting filament. All together, these observations vindicate recent predictions of the 3D standard solar flare model.

## **Expanding and Contracting Coronal Loops as Evidence of Vortex Flows Induced by Solar Eruptions**

J. Dudík, F. P. Zuccarello, G. Aulanier, [B. Schmieder](#), [P. Démoulin](#)

ApJ **844** 54 2017

<https://arxiv.org/pdf/1706.04783.pdf>

Eruptive solar flares were predicted to generate large-scale vortex flows at both sides of the erupting magnetic flux rope. This process is analogous to a well-known hydrodynamic process creating vortex rings. The vortices lead to advection of closed coronal loops located at peripheries of the flaring active region. Outward flows are expected in the upper part and returning flows in the lower part of the vortex. Here, we examine two eruptive solar flares, an X1.1-class flare SOL2012-03-05T03:20 and a C3.5-class SOL2013-06-19T07:29. In both flares, we find that the coronal loops observed by the Atmospheric Imaging Assembly in its 171 Å, 193 Å, or 211 Å-passbands show coexistence of expanding and contracting motions, in accordance with the model prediction. In the X-class flare, multiple expanding/contracting loops coexist for more than 35 minutes, while in the C-class flare, an expanding loop in 193 Å appears to be close-by and co-temporal with an apparently imploding loop arcade seen in 171 Å. Later, the 193 Å-loop also switches to contraction. These observations are naturally explained by vortex flows present in a model of eruptive solar flares.

## **CME Deflection and East-West Asymmetry of Energetic Storm Particle Intensity during Solar Cycles 23 and 24**

A. Santa Fe Duenas<sup>1,2</sup>, R. W. Ebert<sup>1,2</sup>, Gang Li<sup>3</sup>, Zheyi Ding<sup>4</sup>, M. A. Dayeh<sup>1,2</sup>, M. I. Desai<sup>1,2</sup> and L. K. Jian<sup>5</sup>

ApJ **2024**

<https://arxiv.org/pdf/2404.01993.pdf>

We investigate the East-West asymmetry in energetic storm particle (ESP) heavy ion intensities at interplanetary shocks driven by coronal mass ejections (CMEs) during solar cycles (SCs) 23 and 24. We use observations from NASA's ACE and STEREO missions of helium (He), oxygen (O), and iron (Fe) intensities from ~0.13 to 3 MeV/nucleon. We examine the longitudinal distribution of ESP intensities and the correlation of ESP intensities with the near-Sun CME speed and the average transit CME speed for eastern and western events. We observed an East-West asymmetry reversal of ESP heavy ion intensities from SC 23 to 24. We have determined that this change in asymmetry is caused by a shift in the heliolongitude distribution of the CME speed ratio (the ratio of CME near-Sun speed to CME average transit speed) from west to east. **November 10 and 11, 2012**

## **The catalog of Hvar Observatory solar observations**

[Mateja Dumbovic](#), [Luci Karbonini](#), [Jasa Calogovic](#), [Filip Matkovic](#), [Karmen Martinic](#), [Akshay Kumar Remeshan](#), [Roman Brajsa](#), [Bojan Vrsnak](#)

Solar Phys. **2024**

<https://arxiv.org/pdf/2404.18576>

We compile the catalog of Hvar Observatory solar observations in the time period corresponding to regular digitally stored chromospheric and photospheric observations 2010-2019. We make basic characterisation of observed phenomena and compare them to catalogs which are based on full disc solar images. We compile a catalog of observed ARs consisting of 1100 entries, where each AR is classified according to McIntosh and Mt Wilson classifications. We find that HVAR observations are biased towards more frequently observing more complex ARs and observing them in longer time periods, likely related to the small FOV not encompassing the whole solar disc. In H $\alpha$  observations we catalog conspicuous filaments/prominences and flares. We characterise filaments according to their location, chirality (if possible) and eruptive signatures. Analysis of the eruptive filaments reveals a slight bias in HVAR catalog towards observation of partial eruptions, possibly related to the observers tendency to observe filament which already showed some activity. In the flare catalog we focus on their observed eruptive signatures (loops or ribbons) and their shape. In addition, we associate them to GOES soft X-ray flares to determine their corresponding class. We find that HVAR observations seem biased towards more frequently observing stronger flares and observing them in longer time periods. We demonstrate the feasibility of the catalog on a case study of the flare detected on **2 August 2011** in HVAR H $\alpha$  observations and related Sun-to-Earth phenomena. Through flare-CME-ICME association we demonstrate the agreement of remote and in situ properties. The data used for this study, as well as the catalog, are made publicly available.

## **The 2019 International Women's Day event: A two-step solar flare with multiple eruptive signatures and low Earth impact**

**Dumbovic**, M., **Veronig**, A. M., **Podladchikova**, T., **Thalmann**, J. K., **Chikunova**, G., **Dissauer**, K., **Magdalenic**, J., **Temmer**, M., Guo, J., **Samara**, E

A&A **2021**

<https://arxiv.org/pdf/2106.15417.pdf>

We present a detailed analysis of an eruptive event that occurred on early **2019 March 8** in active region AR 12734, to which we refer as the International Women's day event. The event under study is intriguing in several aspects: 1) low-coronal eruptive signatures come in "pairs" (a double-peak flare, two coronal dimmings, and two EUV waves); 2) although the event is characterized by a complete chain of eruptive signatures, the corresponding coronagraphic signatures are weak; 3) although the source region of the eruption is located close to the center of the solar disc and the eruption is thus presumably Earth-directed, heliospheric signatures are very weak with little Earth-impact. We analyze a number of multi-spacecraft and multi-instrument (both remote-sensing and in situ) observations, including Soft X-ray, (extreme-) ultraviolet (E)UV), radio and white-light emission, as well as plasma, magnetic field and particle measurements. We employ 3D NLFF modeling to investigate the coronal magnetic field configuration in and around the active region, the GCS model to make a 3D reconstruction of the CME geometry and the 3D MHD numerical model EUHFORIA to model the background state of the heliosphere. Our results indicate two subsequent eruptions of two systems of sheared and twisted magnetic fields, which merge already in the upper corona and start to evolve further out as a single entity. The large-scale magnetic field significantly influences both, the early and the interplanetary evolution of the structure. During the first eruption the stability of the overlying field was disrupted which enabled the second eruption. We find that during the propagation in the interplanetary space the large-scale magnetic field, i.e. , the location of heliospheric current sheet between the AR and the Earth likely influences propagation and the evolution of the erupted structure(s).

## **Validation of the CME Geomagnetic Forecast Alerts Under the COMESEP Alert System**

Mateja **Dumbović**, Nandita Srivastava, Yamini K. Rao, Bojan Vršnak, Andy Devos, Luciano Rodriguez

**Solar Physics** August **2017**, 292:96 **File**

<https://link.springer.com/content/pdf/10.1007%2Fs11207-017-1120-5.pdf>

Under the European Union 7th Framework Programme (EU FP7) project Coronal Mass Ejections and Solar Energetic Particles (COMESEP, <http://comesep.aeronomy.be>), an automated space weather alert system has been developed to forecast solar energetic particles (SEP) and coronal mass ejection (CME) risk levels at Earth. The COMESEP alert system uses the automated detection tool called Computer Aided CME Tracking (CACTus) to detect potentially threatening CMEs, a drag-based model (DBM) to predict their arrival, and a CME geoeffectiveness tool (CGFT) to predict their geomagnetic impact. Whenever CACTus detects a halo or partial halo CME and issues an alert, the DBM calculates its arrival time at Earth and the CGFT calculates its geomagnetic risk level. The geomagnetic risk level is calculated based on an estimation of the CME arrival probability and its likely geoeffectiveness, as well as an estimate of the geomagnetic storm duration. We present the evaluation of the CME risk level forecast with the COMESEP alert system based on a study of geoeffective CMEs observed during 2014. The validation of the forecast tool is made by comparing the forecasts with observations. In addition, we test the success rate of the automatic forecasts (without human intervention) against the forecasts with human intervention using advanced versions of the DBM and CGFT (independent tools available at the Hvar Observatory website, <http://oh.geof.unizg.hr>). The results indicate that the success rate of the forecast in its current form is unacceptably low for a realistic operation system. Human intervention improves the forecast, but the false-alarm rate remains unacceptably high. We discuss these results and their implications for possible improvement of the COMESEP alert system.

## **Anticorrelated temperature-density profiles in the quiet solar corona and coronal mass ejections: Approach based on the spine-type Hamiltonians**

Yu.V. **Dumin**

A&A **2020**

<https://arxiv.org/pdf/2002.08624.pdf>

Context: The mechanism of the solar corona heating remains one of key problems in astrophysics for a few decades; but none of the proposed mechanisms can give a definitive answer to this question. As a result, the novel scenarios are still suggested. Aims: Here, we perform a critical consideration of the recently-proposed mechanism for the formation of the anticorrelated temperature and density profiles due to specific features of relaxation in the strongly non-equilibrium plasmas described by the so-called spin-type Hamiltonians [L. Casetti and S. Gupta, 2014, Eur. Phys. J. B 87, 91; T.N. Teles et al., 2015, Phys. Rev. E 92, 020101(R)]. Methods: We employ the universal property of the above-mentioned systems to produce the long-lived anticorrelated temperature-density distributions and analyse their most important qualitative features that should be expected in the context of the coronal plasmas. Results: As follows from our consideration, the anticorrelated profiles predicted by the spine-type Hamiltonians can be hardly relevant to explanation of the temperature distribution in the quiet solar corona. However, they might be interesting for the interpretation of the large-scale inhomogeneity of the powerful coronal mass ejections, possessing the filament-type structure. **4 Jan 2002**

## **Tracking a *Ulysses* High-latitude ICME Event Back to Its Solar Origins**

C. **Dumitrache** · N.A. Popescu · A. Oncica

Solar Phys (2011) 272:137–157, **File**

High-latitude interplanetary mass ejections (ICMEs) observed beyond 1 AU are not studied very often. They are useful for improving our understanding of the 3D heliosphere. As there are only few such events registered by the Ulysses spacecraft, the task of detecting their solar counterparts is a challenge, especially during high solar activity periods, because there are dozens coronal mass ejections (CMEs) registered by SOHO that might be chosen as candidates. We analyzed a high-latitude ICME registered by the Ulysses spacecraft on 18 January 2002. Our investigation focused on the correlation between various plasma parameters that allow the identification to be made of the ICME and its components such as the forward shock, the magnetic cloud and the reverse shock.

Using a linear approach and a graphical method we have been able to track the ICME event back to the Sun and to compute the day of the occurrence of the solar CME. In order to decide among several CME candidates which one is the right solar counterpart of our event, we have performed a follow-up computation of these CMEs from the Sun to Ulysses, by using two different speed formulas. First, the computation was simply based on the initial CME velocity, while the other was based on the ICME velocity estimated from the CME initial speed (Lindsay et al. 1999).

Differences of hours have been obtained between the arrival time predicted in these two ways, but the second one gave the best results. Both methods indicated the same two CMEs as the solar counterparts. We have found the solar source of these CMEs as being a huge polar filament that erupted in several steps.

This ICME event displayed a double magnetic cloud configuration. A minimum variance analysis helped us to detect the smooth rotation of the clouds and their helicity. Both magnetic clouds show the same helicity as the filament that erupted and released them. A cylinder-shape model of both clouds gives the same helicity sign.

### **CMEs ‘en rafale’ observations and simulations**

Cristiana **Dumitrache**

Proceedings of the International Astronomical Union / Volume 4 / Symposium S257, pp 251 - 255 ,

Published online: 16 May 2009, **File**

A CME is triggered by the disappearance of a stable equilibrium as a result of the slow evolution of the photospheric magnetic field. This disappearance may be due to a loss of ideal-MHD equilibrium or stability as in the kink mode, or to a loss of resistive-MHD equilibrium as a result of magnetic reconnection. We have obtained CMEs in sequence by a time dependent magnetohydrodynamic computation performed on three solar radii. These successive CMEs resulted from a prominence eruption. Velocities of these CMEs decrease in time, from a CME to another. We present observational evidences for large-scale magnetic reconnections that caused the destabilization of a sigmoid filament. These reconnections covered half of the solar disk and produced CMEs in squall (sequential CMEs).

### **CMEs' speed, travel time and temperature: A Thermodynamic approach**

Héctor J. **Durand-Manterola**, Alberto Flandes, Ana Leonor Rivera, Alejandro Lara and Tatiana Niembro  
JGR 2017

<http://onlinelibrary.wiley.com/doi/10.1002/2017JA024369/epdf>

<http://sci-hub.cc/10.1002/2017JA024369>

Due to their important role in Space weather, Coronal Mass Ejections or CMEs have been thoroughly studied in order to forecast their speed and transit time from the Sun to the Earth. We present a Thermodynamic analytical model that describes the dynamics of CMEs. The thermodynamic approach has some advantages with respect to the hydrodynamic approach. First, it deals with the energy involved, which is a scalar quantity. Second, one may calculate the work done by the different forces separately and sum all contributions to determine the changes in speed, which simplifies the problem and allows us to obtain fully rigorous results. Our model considers the drag force, which dominates the dynamics of CMEs and the solar gravitational force, which has a much smaller effect, but it is, still, relevant enough to be considered.

We derive an explicit analytical expression for the speed of CMEs in terms of its most relevant parameters and obtain an analytical expression for the CME temperature. The model is tested with a CME observed at three different heliocentric distances with three different spacecraft (SOHO, ACE and Ulysses); also, with a set of 11 CMEs observed with the SOHO, Wind and ACE spacecraft and, finally, with two events observed with the STEREO spacecraft. In all cases, we have a consistent agreement between the theoretical and the observed speeds and transit times. Additionally, for the set of 11 events, we estimate their temperatures at their departure position from their temperatures measured near the orbit of the Earth.

**Table 2.** CMEs data parameters for the 11 selected CMEs. 2001-2007

### **A multiwavelength study of an M-class flare and the origin of an associated eruption from NOAA AR 11045**

**Dwivedi**, B. N.; Srivastava, Abhishek K.; Kumar, Mukul; Kumar, Pankaj

E-print, March 2012, New Astr.

In this paper, we study multiwavelength observations of an M6.4 flare in Active Region NOAA 11045 on **7 February 2010**. The space- and ground-based observations from STEREO, SoHO/MDI, EIT, and Nobeyama Radioheliograph were used for the study. This active region rapidly appeared at the north-eastern limb with an unusual emergence of a magnetic field. We find a unique observational signature of the magnetic field configuration at the flare site. Our observations show a change from dipolar to quadrupolar topology. This change in the magnetic field configuration

results in its complexity and a build-up of the flare energy. We did not find any signature of magnetic flux cancellation during this process. We interpret the change in the magnetic field configuration as a consequence of the flux emergence and photospheric flows that have opposite vortices around the pair of opposite polarity spots. The negative-polarity spot rotating counterclockwise breaks the positive-polarity spot into two parts. The STEREO-A 195 ° and STEREO-B 171 ° coronal images during the flare reveal that a twisted flux tube expands and erupts resulting in a coronal mass ejection (CME). The formation of co-spatial bipolar radio contours at the same location also reveals the ongoing reconnection process above the flare site and thus the acceleration of non-thermal particles. The reconnection may also be responsible for the detachment of a ring-shaped twisted flux tube that further causes a CME eruption with a maximum speed of 446 km/s in the outer corona.

### **Coronal radio-sounding detection of a CME during the 1997 Galileo solar conjunction**

A.I. **Efimov**, V.K. Rudash, L.N. Samoznaev, M.K. Bird, I.V. Chashei and D. Plettemeier

[Advances in Space Research](#), [Volume 42, Issue 1](#), 1 July 2008, Pages 110-116

Frequency fluctuations of the Galileo S-band radio signal were recorded nearly continuously during the spacecraft's solar conjunction from December 1996 to February 1997. A strong propagating disturbance, most probably associated with a coronal mass ejection (CME), was detected on **7 February** when the radio ray path proximate point was on the west solar limb at about 54 solar radii from the Sun. The CME passage through the line of sight is characterized by a significant increase in the fluctuation intensity of the recorded frequency and by an increase in the plasma speed from about  $234 \text{ km s}^{-1}$  up to about  $755 \text{ km s}^{-1}$ . These velocity estimates are obtained from a correlation analysis of frequency fluctuations recorded simultaneously at two widely-separated ground stations. The density turbulence power spectrum is found to steepen behind the CME front. The Galileo radio-sounding data are compared with SOHO/LASCO observations of the CME in the corona and with WIND spacecraft data near the Earth's orbit.

### **A Simple Technique for Identifying the Propagation Direction of CMEs in 3D Space**

Y. I. **Egorov** & [V. G. Fainshtein](#)

[Solar Physics](#) volume 296, Article number: 161 (2021)

<https://link.springer.com/content/pdf/10.1007/s11207-021-01904-3.pdf>

<https://doi.org/10.1007/s11207-021-01904-3>

By now several methods have been proposed enabling to determine the kinematic characteristics of coronal mass ejections (CMEs) in 3D space. Many of these methods are based on using the triangulation technique and stereoscopic observations of the CMEs with two and more spacecraft. As a rule, these methods involve relatively complicated procedures. Nevertheless, there is a need for a simple technique to find 3D characteristics of a CME motion fairly quickly. Such a technique, in particular, will enable to estimate on which side of the Sun (front side or back side for an observer on the Earth) the CME emerged, as well as to efficiently solve a problem relevant for solar-terrestrial physics: to determine the time of the CME arrival into Earth's orbit. Such a simple technique is proposed in this article. The technique comprises two stages. First, one identifies the CME motion direction in the solar equatorial plane by using the data from any pair of the COR2 and LASCO (Large Angle and Spectrometric Coronagraph) C3 coronagraphs on board the Solar Terrestrial Relations Observatory (STEREO) A, B and the Solar and Heliospheric Observatory (SOHO), respectively. Next, one measures the angle between the CME motion direction in 3D space and the equatorial plane. We illustrate the technique for five CMEs that emerged either on the front side or back side of the Sun. An important advantage of the proposed technique is the possibility to quickly filter the events, that emerged on the front or back side of the Sun, by using only the information of the CME central position angle from a CME catalog. For the investigated CMEs, we obtained the time dependencies of the motion direction in the equatorial plane (angle  $\varphi\varphi$ ), the angle between the CME motion direction in 3D space and the equatorial plane ( $\lambda\lambda$ ), the distance from Sun's center to the CME leading edge in 3D space (R3DR3D). For some investigated events, we compared our values for angle  $\varphi\varphi$  and distance R3DR3D with those obtained in other articles. **5 Apr 2008, 17 May 2008, 12 Dec 2008, 3 Nov 2011, 29 Mar 2014**

### **Studying Magnetic Field Variations Accompanying the 2011 June 7 Eruptive Event, by Using Nonlinear Force-Free Field Modeling**

Y. I. **Egorov**, [V. G. Fainshtein](#), [I. I. Myshyakov](#), [S. A. Anfinogentov](#)...

[Solar Physics](#) volume 295, Article number: 52 (2020)

<https://link.springer.com/content/pdf/10.1007/s11207-020-01613-3.pdf>

We study the features of the magnetic field variations within the **2011 June 7** eruptive event that includes a large filament eruption, a flare, and a CME formation. The magnetic field characteristics were obtained by using vector measurements of the magnetic field with the SDO/HMI and 3D magnetic field calculations based on nonlinear force-free field (NLFFF) modeling. Strong and relatively fast variations in the photospheric field characteristics after the flare onset are shown to be observed only within a small site ( $20'' \times 20'' \times 20''$ ) of the eruption region in the neighborhood of the polarity inversion line (PIL).

We found that the magnetic field strength, the electric current density, current helicity density and free magnetic energy density above this region are growing with height reaching their maximums at the level of  $\sim 15 \text{ Mm}$ . After 2011 July 7 00:00 UT, this height started gradually reducing.

The NLFFF extrapolation revealed the presence of a magnetic flux rope elongated approximately along the main PIL and an arcade of magnetic field lines over it. The flux-rope axis is located at height of  $\sim 15 \text{ Mm}$ . The flux-rope

footpoints approximately coincide with the eruptive filament footpoints. Thus, we concluded that the detected flux rope is associated with the magnetic structure of the observed filament. The detected strong variation of the magnetic field within the eruption region are most probably associated with the magnetic field reconfiguration after the filament eruption. The  $T_n$  parameter, which is the average magnetic field twist within the flux rope, was found to increase up to 2.5 rotations before the flare onset, and to dramatically decrease afterward. This may reflect the developing of kink instability that presumably triggered this eruption.

### **Ensemble forecasting of coronal mass ejections using the WSA-ENLIL with CONED Model**

D. **Emmons**<sup>1,2,\*</sup>, A. Acebal, A. Pulkkinen, <sup>3,4</sup>, A. Taktakishvili, P. MacNeice<sup>3</sup>, D. Odstrcil  
Space Weather, Volume 11, Issue 3, pages 95–106, March 2013

The combination of the Wang-Sheeley-Arge (WSA) coronal model, ENLIL heliospherical model version 2.7, and CONED Model version 1.3 (WSA-ENLIL with CONED Model) was employed to form ensemble forecasts for 15 halo coronal mass ejections (halo CMEs). The input parameter distributions were formed from 100 sets of CME cone parameters derived from the CONED Model. The CONED Model used image processing along with the bootstrap approach to automatically calculate cone parameter distributions from SOHO/LASCO imagery based on techniques described by Pulkkinen et al. (2010). The input parameter distributions were used as input to WSA-ENLIL to calculate the temporal evolution of the CMEs, which were analyzed to determine the propagation times to the L1 Lagrangian point and the maximum Kp indices due to the impact of the CMEs on the Earth's magnetosphere. The Newell et al. (2007) Kp index formula was employed to calculate the maximum Kp indices based on the predicted solar wind parameters near Earth assuming two magnetic field orientations: a completely southward magnetic field and a uniformly distributed clock-angle in the Newell et al. (2007) Kp index formula. The forecasts for 5 of the 15 events had accuracy such that the actual propagation time was within the ensemble average plus or minus one standard deviation. Using the completely southward magnetic field assumption, 10 of the 15 events contained the actual maximum Kp index within the range of the ensemble forecast, compared to 9 of the 15 events when using a uniformly distributed clock angle.

### **Global Energetics of Thirty-eight Large Solar Eruptive Events**

**Emslie**, A. G.; Dennis, B. R.; Shih, A. Y.; Chamberlin, P. C.; Mewaldt, R. A.; Moore, C. S.; Share, G. H.; Vourlidas, A.; Welsch, B. T.

Astrophysical Journal, Volume 759, Issue 1, article id. 71, 18 pp. (2012)

<http://arxiv.org/abs/1209.2654>

[http://www.astro.umd.edu/~share/publications/emslie\\_12.pdf](http://www.astro.umd.edu/~share/publications/emslie_12.pdf)

We have evaluated the energetics of 38 solar eruptive events observed by a variety of spacecraft instruments between 2002 February and 2006 December, as accurately as the observations allow. The measured energetic components include: (1) the radiated energy in the Geostationary Operational Environmental Satellite 1-8 Å band, (2) the total energy radiated from the soft X-ray (SXR) emitting plasma, (3) the peak energy in the SXR-emitting plasma, (4) the bolometric radiated energy over the full duration of the event, (5) the energy in flare-accelerated electrons above 20 keV and in flare-accelerated ions above 1 MeV, (6) the kinetic and potential energies of the coronal mass ejection (CME), (7) the energy in solar energetic particles (SEPs) observed in interplanetary space, and (8) the amount of free (non-potential) magnetic energy estimated to be available in the pertinent active region. Major conclusions include: (1) the energy radiated by the SXR-emitting plasma exceeds, by about half an order of magnitude, the peak energy content of the thermal plasma that produces this radiation; (2) the energy content in flare-accelerated electrons and ions is sufficient to supply the bolometric energy radiated across all wavelengths throughout the event; (3) the energy contents of flare-accelerated electrons and ions are comparable; (4) the energy in SEPs is typically a few percent of the CME kinetic energy (measured in the rest frame of the solar wind); and (5) the available magnetic energy is sufficient to power the CME, the flare-accelerated particles, and the hot thermal plasma. **2002 February 20, 2002 May 22, 2002 November 9, 2003 May 27, 2003 October 28, 2004 July 15, 2004 July 25, 2005 January 20,**  
**Table 1.** Event List with Component Energies ( $\times 10^{30}$  ergs)

### **Energy Partition in Large Solar Eruptive Events,**

Gordon **Emslie** and Brian Dennis

RHESSI Science Nugget, No. 185, Oct 2012

Where flare energy comes from, and where it goes to.

The paper also concludes that the energy radiated by the SXR-emitting plasma exceeds, by about half an order of magnitude, the peak energy content of the thermal plasma that produces this radiation, a situation that requires continuous re-energization of the hot plasma throughout the flare. Also, the energy contents in flare-accelerated electrons and ions are comparable, and together they are sufficient to supply the bolometric energy radiated across all wavelengths throughout the event. Finally, the paper finds that, in general, the available magnetic energy is sufficient to power the CME, the flare-accelerated particles, and the hot thermal plasma. This reaffirms the generally-held belief that the fundamental power source for SEEs lies in stressed active-region magnetic fields.

## Energy partition in two solar flare/CME events

**Emslie**, A. G., Kucharek, H.; Dennis, B. R.; Gopalswamy, N.; Holman, G. D.; Share, G. H.; Vourlidas, A.; Forbes, T. G.; Gallagher, P. T.; Mason, G. M.; and 5 coauthors

Journal of Geophysical Research, Volume 109, Issue A10, CiteID A10104, **2004**

Using coordinated observations from instruments on the Advanced Composition Explorer (ACE), the Solar and Heliospheric Observatory (SOHO), and the Ramaty High Energy Solar Spectroscopic Imager (RHESSI), we have evaluated the energetics of two well-observed flare/CME events on 21 April 2002 and **23 July 2002**. For each event, we have estimated the energy contents (and the likely uncertainties) of (1) the coronal mass ejection, (2) the thermal plasma at the Sun, (3) the hard X-ray producing accelerated electrons, (4) the gamma-ray producing ions, and (5) the solar energetic particles. The results are assimilated and discussed relative to the probable amount of nonpotential magnetic energy available in a large active region.

## Observations of a Flare-Generated Blast Wave in a Pseudo Coronal Mass Ejection Event

V. G. **Eselevich**, M. V. Eselevich, I. V. Zimovets,

*Solar Physics* June **2019**, 294:73

[sci-hub.se/10.1007/s11207-019-1467-x](https://doi.org/10.1007/s11207-019-1467-x)

We present an analysis of the event near the east limb, **SOL2014-03-06T09:23**, in which a pseudo coronal mass ejection (CME) was detected by the Large Angle and Spectrometric Coronagraph (LASCO) C2 instrument and indicated as “Poor Event; Only C2” in the Solar and Heliospheric Observatory (SOHO) LASCO CME Catalog. The analysis was performed based on two main methods: 1) investigation of the difference brightness profiles along specific directions in the solar corona using the EUV observations by the Atmospheric Imaging Assembly (AIA) instrument onboard the Solar Dynamics Observatory (SDO); 2) investigation of the spatially-resolved observations of the type II radio bursts made with the Nançay Radioheliograph. Based on the analysis performed we argue that the observed pseudo-CME could be a blast wave caused by impulsive flare energy release in the low corona. We also argue that, in the limited height range of  $\approx 0.2R_{\odot}$ – $0.5R_{\odot}$ , the front of this blast wave could steepen into a shock front.

## Evidence for shock generation in the solar corona in the absence of coronal mass ejections.

**Eselevich**, V.G., Eselevich, M.V., Zimovets, I.V., Sharykin, I.N.:

**2017**, Astron. Rep. 61, 805. DOI. ADS.

[sci-hub.se/10.1134/S1063772917080030](https://doi.org/10.1134/S1063772917080030)

The solar event **SOL2012-10-23T03:13**, which was associated with a X1.8 flare without an accompanying coronal mass ejection (CME) and with a Type II radio burst, is analyzed. A method for constructing the spatial and temporal profiles of the difference brightness detected in the AIA/SDO EUV and EUV channels is used together with the analysis of the Type II radio burst. The formation and propagation of a region of compression preceded by a collisional shock detected at distances  $R < 1.3 R_{\odot}$  from the center of the Sun is observed in this event ( $R_{\odot}$  is the solar radius). Comparison with a similar event studied earlier, SOL2011-02-28T07:34 [1], suggests that the region of compression and shock could be due to a transient (impulsive) action exerted on the surrounding plasma by an eruptive, high-temperature magnetic rope. The initial instability and eruption of this rope could be initiated by emerging magnetic flux, and its heating from magnetic reconnection. The cessation of the eruption of the rope could result from its interaction with surrounding magnetic structures (coronal loops).

## Initial formation of an “impulsive” coronal mass ejection

V. G. **Eselevich**, M. V. Eselevich, I. V. Zimovets, G. V. Rudenko

Astronomy Reports November **2016**, Volume 60, Issue 11, pp 1016–1027 **File**

Astronomicheskii Zhurnal, **2016**, Vol. 93, No. 11, pp. 990–1002.

An “impulsive” coronal mass ejection (CME) observed on **August 24, 2014** is analyzed using ultraviolet images obtained in the SDO/AIA 193, 304, 1600, and 1700 Å channels and H $\alpha$  (6562.8 Å) data obtained with the EI Teide and Big Bear telescopes. The formation of this impulsive CME was related to a magnetic tube (rope) moving with a velocity of  $\approx 35$  km/s and containing plasma that was cooler than the photospheric material. Moving in the corona, the magnetic tube collides with a quasi-stationary coronal magnetic rope, with its two bases rooted in the photosphere. This interaction results in the formation of the CME, with the surface of the coronal magnetic rope becoming the CME frontal structure. According to SDO/HMI data, no enhancements or changes in magnetic flux were detected in the vicinity of the CME bases during its formation. This may support the hypothesis that the magnetic tube starts its motion from layers in the vicinity of the temperature minimum.

## Evidence of a blast shock wave formation in a “CME–streamer” interaction

V.G. **Eselevich**, M.V. Eselevich, V.M. Sadykov, I.V. Zimovets

Advances in Space Research Volume 56, Issue 12, 15 December **2015**, Pages 2793–2803

<http://www.sciencedirect.com/science/article/pii/S0273117715002434>

Analysis of the solar event on **16 February 2011** (SOL2011-02-16T14:19) allows to classify it as an “impulsive” coronal mass ejection (CME) event. It is argued that the observed deviation of a streamer ray from its pre-event state and generation of a metric type II radio burst in this event was a result of a “CME–streamer” interaction in the lower corona ( $r \lesssim 1.5R_{\odot}$ ). Most probably, it was a consequence of an impulsive action of a compressed magnetic field to the

streamer. This compression of the coronal magnetic field was due to a moving and expanding magnetic flux rope, which was a core of the CME. The estimated radial speed of the type II burst sources was significantly ( $\approx 2\text{--}8$  times) larger than the radial speed of the erupting flux rope, and it decreased rapidly with time. This indicates that during the “CME–streamer” interaction a blast shock wave could be excited and propagated along the streamer.

### **Differences in the development of the initial phase of the formation of two types of coronal mass ejections**

V. G. [Eselevich](#), M. V. Eselevich

Cosmic Research, January **2015**, Volume 53, Issue 1, pp 21-30

Kosmicheskie Issledovaniya, **2015**, Vol. 53, No. 1, pp. 24–34.

Based on the results of an analysis of AIA/SDO and EUVI/STEREO data it was confirmed that the initial phase of the “gradual” coronal mass ejection (CME) begins as a motion from the rest of the outer shell of a coronal magnetic rope, which then becomes the basis of the frontal structure of a CME. It is shown by an example of an analysis of an event on **January 5, 2013** that a different type of CME, “impulsive,” can occur as a result of the ejection of a “cavity” from the lower solar corona (the 193 Å channel), which then becomes the basis for future CME. An analysis of the three-dimensional structure of the cavity, its dynamics and kinematics, as well as a comparison of the results of an analysis with numerical calculations allow us to interpret observations as a manifestation of the rapid rise of the magnetic tube (rope) filled with cold plasma. The appearance of the rope in the lower corona probably is a result of its rapid floating (with supersonic velocity) from the solar convective zone. Theoretical estimates show that the cause of the ejection of the magnetic tube from the convective zone can be the development of a Parker’s instability (“slow” wave).

### **Physical differences between the initial phase of the formation of two types of coronal mass ejections**

V. G. [Eselevich](#), M. V. Eselevich

Astronomy Reports, April **2014**, Volume 58, Issue 4, pp 260-271

Astronomicheskii Zhurnal, **2014**, Vol. 91, No. 4, pp. 320–331.

Physical differences in the formation of “gradual” and “impulsive” coronal mass ejections (CMEs) at heights of  $h < 0.2 R_{\odot}$  just before and during the initial phase of their motion are studied using AIA/SDO ultraviolet data ( $h$  is the altitude above the solar surface and  $R_{\odot}$  is the solar radius). The basic structure of a gradual CME is a magnetic rope located in the corona. During an hour or more preceding the initial phase, the magnetic rope demonstrates an increase in brightness and transverse size, first of the low, inner elements of the rope and then of elements in its outer envelope most distant from the Sun. The rope remains motionless during this time. The initial phase of a gradual CME begins from the motion of the magnetic rope’s outer envelope, which further becomes the basis for the CME frontal structure. At this stage, the inner low elements of the rope remain almost motionless. The initial phase of an impulsive CME begins with the appearance near the photosphere of a cavity moving away from the Sun; the dynamics of this cavity probably correspond to a magnetic tube filled with cool plasma rising from beneath the photosphere. This magnetic tube collides with and drags arch structures, which initially block the tube’s motion. These arch structures contribute to the CME formation, although the magnetic tube itself forms the basis of the CME.

### **Blast-wave and piston shocks connected with the formation and propagation of a coronal mass ejection**

V. G. [Eselevich](#), M. V. Eselevich, I. V. Zimovets

Astronomy Reports, February **2013**, Volume 57, Issue 2, pp 142-151

Astronomicheskii Zhurnal, **2013**, Vol. 90, No. 2, pp. 166–176. [Файл](#)

The solar coronal mass ejection observed on **November 3, 2010** is analyzed using AIA/SDO data (images in the 193 and 211 Å channels) and white-corona images obtained with the SOHO LASCO C2 and C3 coronagraphs. We have succeeded in revealing both piston and blast-wave shocks attributed to the formation and propagation of a coronal mass ejection. Both of these types of shocks could be responsible for type II radio bursts propagating in front of each shock.

### **DISTURBED ZONE AND PISTON SHOCK AHEAD OF CORONAL MASS EJECTION**

V. [Eselevich](#) and M. Eselevich

**2012** ApJ 761 68

The **2010 June 13** coronal mass ejection (CME) propagating toward the position angle P.A.  $245^{\circ}$  (measured counterclockwise from the Sun's north pole) was studied from the SDO/AIA and SOHO/LASCO C2, C3 data. We show that ahead of the CME frontal structure, as a result of its interaction with the undisturbed solar wind, a disturbed region (with an increased and disturbed plasma density), whose size increases as the CME travels away from the Sun, emerges gradually. Discontinuity formation at the disturbed zone front is observed in the narrow P.A.  $245^{\circ}\text{--}250^{\circ}$  range. Its characteristics satisfy the properties of a piston collision shock. In the other directions relative to the CME motion axis (P.A.  $> 250^{\circ}$  and P.A.  $< 245^{\circ}$ ), there exists only the disturbed zone, whose density gradually decreases with distance. The discontinuity that was always observed at all distances where measurements were made is absent. The analysis of this CME and several other limb CMEs with different velocities from the MK4, LASCO C2, C3, and STEREO/COR2 data confirmed the previously established laws of piston shock formation ahead of a CME, which are as follows: (1) Shock formation ahead of a CME in a vicinity along its propagation axis may occur at various distances  $R = R_u$  from

the Sun's center. Its formation is determined by fulfilling a local inequality  $u(R) > V_A(R)$ , where  $u(R)$  is a CME velocity relative to the surrounding solar wind and  $V_A(R)$  is a local Alfvén velocity that is approximately equal to the velocity of fast magnetic sound in the solar corona. (2) At  $R < 6 R_\odot$ , the shock front width  $\delta F$  is on the order of the proton mean free path  $\lambda_p$ , and the mechanism for energy dissipation at the front is, apparently, collisional. (3) At  $R = 10-15 R_\odot$ , one observes the formation of a new discontinuity  $\delta F \sim \lambda_p$  wide at the head of the collision front. Within limits of error,  $\delta F$  does not depend on  $R$  and is determined to be  $\delta F \approx 0.1-0.2 R_\odot$  by the LASCO C3 spatial resolution and  $\delta F \approx 0.03 R_\odot$  for COR2. This discontinuity is identified with a collisionless shock.

### Some properties of the development of the perturbed zone and shock preceding a coronal mass ejection

M. V. [Eselevich](#) & V. G. Eselevich

Astronomy Reports, Volume 55, Number 11, 1038-1050, 2011, File

*Astronomicheskii Zhurnal*, 2011, Vol. 88, No. 11, pp. 1124–1136.

SOHO/LASCO C2 and C3 data have been used to carry out a detailed study of the perturbed zone and shock that form as a coronal mass ejection (CME) moves away from the Sun, as a result of its interaction with the ambient solar wind. The event of **January 4, 2002** is used as an example. The perturbed zone is most extensive along the direction of propagation of the CME, decreases away from this direction, and reaches its minimum values perpendicular to this direction. The mass of the perturbed zone is  $\geq 0.1$  of the total mass of the CME. The condition for the formation of a shock preceding the CME (in the direction of propagation of the CME) is  $V - V_{SW} > V_A$ , where  $V$ ,  $V_{SW}$ , and  $V_A$  are the CME, solar wind, and Alfvén velocities, respectively. Perpendicular to the CME axis, at distances of  $\approx 4-6 R_\odot$  from the center of the Sun, the condition for the formation of shock is  $V/2 > V_A$ .

### Relations estimated at shock discontinuities excited by coronal mass ejections

M. V. [Eselevich](#) and V. G. Eselevich

Astronomy Reports, Volume 55, Number 4, 359-373, 2011

*Astronomicheskii Zhurnal*, 2011, Vol. 88, No. 4, pp. 393–408

An analysis of SOHO/LASCO C3 data shows that there are discontinuities in the radial profiles of the plasma density within limited regions in front of each of ten coronal mass ejections, which represent shocks. The shock velocities in various events reach  $V \approx 800-2500$  km/s. A comparison of the dependence of the Alfvén Mach number  $M_A$  on the shock strength  $\rho_2/\rho_1$  detected at distances  $R > 10 R_\odot$  from the center of the Sun with calculations carried out using ideal magnetic hydrodynamics shows that the effective ratio of specific heats  $\gamma$  describing processes inside the shock front varies from 2 to  $5/3$  ( $\rho_1$  and  $\rho_2$  are the densities in front of and behind the shock, and  $R_\odot$  is the solar radius). This corresponds to an effective number of degrees of freedom between two and three. A similar dependence  $M_A(\rho_2/\rho_1)$  was found for near-Earth bow shocks and interplanetary collisionless shocks. These features support the hypothesis that the studied discontinuities preceding coronal mass ejections are collisionless shocks.

### Detecting the widths of shock fronts preceding coronal mass ejections

M. V. [Eselevich](#)

Astronomy Reports, Volume 54, Number 2, 173-183, 2010, File

*Astronomicheskii Zhurnal*, 2010, Vol. 87, No. 2, pp. 197–208.

The perturbed zones and shocks preceding coronal mass ejections (CMEs) are studied using the data of the Mark 4, LASCO C2, and LASCO C3 coronagraphs. Detection of the perturbed zone indicating the presence or absence of the shock is most reliable in a frame moving with the frontal structure of the CME. The ability to correctly measure the width  $\delta F$  of the shock front using the Mark 4 and LASCO C2 data is established. The front width  $\delta F$  observed along the streamer belt at distances  $R < 5 R_\odot$  from the center of the Sun is of the order of the mean free path of protons. This means that the energy dissipation in the shock front is collisional at such distances. At distances  $R \geq (10 - 15) R_\odot$ , a new discontinuity with a front  $\delta^* F$  is formed. In the errors,  $\delta^* F \approx (0.1 - 0.2) R_\odot$  is independent of the distance  $R$  and is determined by the LASCO C3 spatial resolution. Initially, the discontinuity on the scale  $\delta^* F$  is weak and coexists with the front with width  $\delta F$ . The relative amplitude of this discontinuity increases and the brightness profile behind it flattens as long as the distance  $R$  increases. This transformation of the brightness profile from a front of width  $\delta F$  to a discontinuity of width  $\delta^* F \ll \delta F$  is explained as a transition from a collisional to a collisionless shock.

### **LEARNING FROM THE OUTER HELIOSPHERE: INTERPLANETARY CORONAL MASS EJECTION SHEATH FLOWS AND THE EJECTA ORIENTATION IN THE LOWER CORONA**

R. M. **Evans**<sup>1</sup>, M. Opher<sup>1,2</sup>, and T. I. Gombosi<sup>3</sup>

*Astrophysical Journal*, 728:41 (7pp), 2011 February

The magnetic field structure of the ejecta of a coronal mass ejection (CME) is not known well near the Sun. Here we demonstrate, with a numerical simulation, a relationship between the subsonic plasma flows in the CME-sheath and the ejecta magnetic field direction. We draw an analogy to the outer heliosphere, where Opher et al. used *Voyager 2* measurements of the solar wind in the heliosheath to constrain the strength and direction of the local interstellar magnetic field. We simulate three ejections with the same initial free energy, but different ejecta magnetic field orientations in relation to the global coronal field. Each ejection is launched into the same background solar wind using the Space Weather Modeling Framework. The different ejecta magnetic field orientations cause the CME-pause (the location of pressure balance between solar wind and ejecta material) to evolve differently in the lower corona. As a result, the CME-sheath flow deflections around the CME-pauses are different. To characterize this non-radial deflection, we use  $\theta_F = \tan^{-1} v_N/v_T$ , where  $v_N$  and  $v_T$  are the normal and tangential plasma flow as measured in a spacecraft-centered coordinate system. Near the CME-pause, we found that  $\theta_F$  is very sensitive to the ejecta magnetic field, varying from  $45^\circ$  to  $98^\circ$  between the cases when the CME-driven shock is located at  $4.5R_\odot$ . The deflection angle for each case is found to evolve due to rotation of the ejecta magnetic field. We find that this rotation should slow or stop by  $10R_\odot$  (also suggested by observational studies). These results indicate that an observational study of CME-sheath flow deflection angles from several events (to account for the interaction with the solar wind), combined with numerical simulations (to estimate the ejecta magnetic field rotation between eruption and  $10R_\odot$ ) can be used to constrain the ejecta magnetic field in the lower corona.

### **Alfvén Profile in the Lower Corona: Implications for Shock Formation.**

(2009). *Solar Physics*, 254(2), 387-445

<http://sci-hub.tw/10.1007/s11207-008-9299-0>

Mounted on the sides of two widely separated spacecraft, the two Heliospheric Imager (HI) instruments onboard NASA's STEREO mission view, for the first time, the space between the Sun and Earth. These instruments are wide-angle visible-light imagers that incorporate sufficient baffling to eliminate scattered light to the extent that the passage of solar coronal mass ejections (CMEs) through the heliosphere can be detected. Each HI instrument comprises two cameras, HI-1 and HI-2, which have  $20^\circ$  and  $70^\circ$  fields of view and are off-pointed from the Sun direction by  $14.0^\circ$  and  $53.7^\circ$ , respectively, with their optical axes aligned in the ecliptic plane. This arrangement provides coverage over solar elongation angles from  $4.0^\circ$  to  $88.7^\circ$  at the viewpoints of the two spacecraft, thereby allowing the observation of Earth-directed CMEs along the Sun – Earth line to the vicinity of the Earth and beyond. Given the two separated platforms, this also presents the first opportunity to view the structure and evolution of CMEs in three dimensions. The STEREO spacecraft were launched from Cape Canaveral Air Force Base in late October 2006, and the HI instruments have been performing scientific observations since early 2007. The design, development, manufacture, and calibration of these unique instruments are reviewed in this paper. Mission operations, including the initial commissioning phase and the science operations phase, are described. Data processing and analysis procedures are briefly discussed, and groundtest results and in-orbit observations are used to demonstrate that the performance of the instruments meets the original scientific requirements.

### **Velocity Oscillations in CME and Related Shock: A Comparative Analysis.**

**Fainshtein**, V.G., Egorov, Y.I.

*Sol Phys* 299, 9 (2024).

<https://doi.org/10.1007/s11207-024-02250-w>

A number of studies have concluded that the velocity of coronal mass ejections (CME) does not change monotonically with time, but exhibits oscillations. They analyzed moving CMEs with oscillation-averaged velocities varying within a wide range. Investigations in the past several years have identified the CME boundary positions relying on data in

various CME catalogs providing the positions of the most remote and generally fastest part of the CME boundary. Unlike the previous investigations, we examined the velocity oscillations of both the CME (i.e., its body) and the CME-related shock for relatively fast CMEs. The characteristics of the two structures have been found to differ noticeably. In all cases considered, it was found that the amplitude of velocity oscillations was higher for a shock than for a CME body. In 7 out of 16 cases, the period of shock velocity oscillations is longer than the period of CME velocity oscillations; in 6 cases it is shorter.

### **Onset of a CME-Related Shock Within the Large-Angle Spectrometric Coronagraph (LASCO) Field of View**

V.G.[Fainshtein](#), [Ya.I.Egorov](#)

[Solar Physics](#) September 2019, 294:126

<https://link.springer.com/content/pdf/10.1007%2Fs11207-019-1519-2.pdf>

<https://doi.org/10.1007/s11207-019-1519-2>

We investigated the onset of a CME-related shock within the Large-Angle Spectrometric Coronagraph (LASCO) field of view (FOV). To detect the first moment of the shock onset, we found a CME on **17 July 2012** that formed at a relatively high altitude and moved with slow acceleration. We examined the possible mechanisms of shock generation. It was shown that bow-shock and piston-shock mechanisms can participate in shock generation, either at different stages of CME movement, or simultaneously. This event has been found to be accompanied by generation of solar energetic particles (SEP). We concluded that, at their initial stage, the source of SEP fluxes may be a solar flare, while the later dramatic increase in the flux of fast protons may be due to their generation in a CME-driven shock.

### **Coronal magnetic field value radial distributions obtained by using the information on fast halo coronal mass ejections**

V.G.[Fainshtein](#), [Ya.I.Egorov](#)

[Solar Phys.](#) 2017

<https://arxiv.org/pdf/1712.09046.pdf>

Based on the method of finding coronal magnetic field value radial profiles  $B(R)$  described in (Gopalswamy and Yashiro, 2011), and applied for the directions close to the sky plane, we determined magnetic field value radial distributions along the directions close to the Sun-Earth axis. For this purpose, by using the method in (Xue, Wang, and Dou, 2005), from the SOHO/LASCO data, we found 3D characteristics for fast halo coronal mass ejections (HCMEs) and for the HCME-related shocks. Through these data, we managed to obtain the  $B(R)$  distributions as far as 43 solar radii from the Sun center, which is approximately by a factor of 2 farther, than those in (Gopalswamy and Yashiro, 2011). We drew a conclusion that, to improve the accuracy of the Gopalswamy-Yashiro method to find the coronal magnetic field, one should develop a technique to detect the CME sites that move in the slow and in the fast solar wind. We propose a technique to select the CMEs, whose central (paraxial) part moves, indeed, in the slow wind. **2003-11-18, 2011-03-08**

### **Origin of a CME-related shock within the LASCO C3 field-of-view**

V.G.[Fainshtein](#), [Ya.I.Egorov](#)

[Solar Phys.](#) 2017

<https://arxiv.org/pdf/1712.09051.pdf>

We study the origin of a CME-related shock within the LASCO C3 field-of-view (FOV). A shock originates, when a CME body velocity on its axis surpasses the total velocity  $V_A + V_{SW}$ , where  $V_A$  is the Alfvén velocity,  $V_{SW}$  is the slow solar wind velocity. The formed shock appears collisionless, because its front width is manifold less, than the free path of coronal plasma charged particles. The Alfvén velocity dependence on the distance was found by using characteristic values of the magnetic induction radial component and of the proton concentration in the Earth orbit, and by using the known regularities of the variations in these solar wind characteristics with distance. A peculiarity of the analyzed CME is its formation at a relatively large height, and the CME body slow acceleration with distance. We arrived at a conclusion that the formed shock is a bow one relative to the CME body moving at a super Alfvén velocity. At the same time, the shock formation involves a steeping of the front edge of the coronal plasma disturbed region ahead of the CME body, which is characteristic of a piston shock. **2012 July 17**

### **Kinematics of CMEs and associated shock waves as deduced from LASCO data: comparative analysis**

V.G. [Fainshtein](#), [Ya.I. Egorov](#), [Yu.S. Zagainova](#)

2017

<https://arxiv.org/pdf/1712.09218.pdf>

From data by LASCO C2 and C3 coronagraphs, depending on time (distance), we have determined positions and velocities of the front for fast limb CMEs' body with their sources near the limb, and for the body of halo-type CME with the sources near the solar disk center. These characteristics of CME body are compared to similar kinematic characteristics obtained for CME body-associated shock waves (shocks). For the body of halo-type CME with the sources near the solar disk center and associated shocks, we determined and compared their kinematic characteristics in

3D space. It has been shown that for all the considered CME groups, the shock velocity is higher than the CME body velocity, both velocities decrease as the mass ejection moves. As this takes place, the distance between CME body and shock grows. On average, distance from CME body to shock, and velocity difference of these structures is greater for a halo CME, and even greater for a model CME in 3D. **2003-11-18, 2004-11-07, 2005-09-05, 2005-09-13**

**Table 1:** left column: CMEs with their sources within 30° related to the limb; right column: halo CMEs) with their sources within 30° as related to the solar disk center

### **On the occurrence and the motion of fast impulsive coronal mass ejections associated with powerful flares and unassociated with eruptive filaments**

V. G. **Fainshtein**, Yu. S. Zagainova

Cosmic Research, January **2015**, Volume 53, Issue 1, pp 31-46

Kosmicheskie Issledovaniya, **2015**, Vol. 53, No. 1, pp. 35–50.

The formation and initial stage of the motion of several rapid, impulsive coronal mass ejections of the “halo” type (HCME) associated with flares of M and X class, but unassociated with the eruption of solar filaments, was studied using GOES-12/SXI, SOHO/EIT, and SDO/AIA data. The HCMEs considered can be divided into three groups according to the features of their formation: (i) some HCMEs arise due to an imbalance of single emission looped structures observed in the 195 Å channel of an EIT instrument for several hours before the first recording of mass ejection in the field of view of an SXI X-ray telescope, and after the eruption, these loops become structural elements of HCMEs; (ii) HCMEs can be formed as a result of an imbalance of several loops in the process of combining these loops into a single structure; and (iii) HCME formation begins with the upward motion of the group of coronal loops observed using the AIA data first in the “hot” 131 Å channel, a few minutes later in the “cold” 211 Å channel, later in the 193 Å channel, and, finally, in the 171 Å channel. The action of moving looped structures on the overlying regions of the corona leads to the formation and the motion of the frontal structure of HCMEs with increased brightness. In this case, these eruptive loops do not become structural elements of HCMEs. All investigated HCMEs began their translational motion before the occurrence of the associated flares. According to the results of studying the kinematics of the considered HCMEs we concluded that there are two types of coronal mass ejections differing according to the time profile of the velocity, which is determined by the area and the magnetic configuration of the active region where the mass ejection was formed. It is shown that HCMEs occurring at different times in the same active region have the same type of velocity profile.

### **Initiation of CMEs associated with filament eruption, and the nature of CME related shocks**

V.G. **Fainshtein**, , Ya.I. Egorov

Advances in Space Research, Volume 55, Issue 3, 1 February **2015**, Pages 798–807

<http://www.sciencedirect.com/science/article/pii/S027311771400310X>

Using data from SDO, PROBA2 and other spacecraft, Fainshtein and Egorov (2013) have discovered processes accompanying initiation of six limb CMEs and have studied features of their motion. The said CMEs occurred after eruption of prominence or hot emission loop and were associated with X-ray flares. The follow-up study of the CMEs, associated with the prominence eruption, showed that the formation of such mass ejections and the initial stage of their motion may be characterised by special features. In this work, we give examples of CMEs with such features. We have revealed a positive correlation between the height of the CME-related eruptive prominence and the height of the frontal structure of CMEs measured before they began to move. By analysing two of the CMEs, using SDO data, we found out that the kinematics of CME body and its related shock differs considerably. We have established that the time dependence of shock position and velocity obtained from SDO data is in agreement with theoretical dependencies of variation in these motion parameters with time in the context of self-similar motion of an explosion shock. We have concluded that the shock are not piston-like with the CME body acting as a piston. **13 October 2010, 8 March 2011, 7 June 2011, 29 June 2011**

### **Investigation of CME properties using the data of SDO and PROBA2 spacecraft**

V.G. **Fainshtein**, Y.I. Egorov

Cosmic Res., 51 (**2013**), pp. 1–12

Formation and motion (at the initial stage) of six limb CMEs detected in the period June 2010 to June 2011 are investigated using the high-resolution data of the PROBA2 and SDO spacecraft combined with the data of SOHO/LASCO coronagraphs. It is demonstrated that several loop-like structures of enhanced brightness originate in the region of CME formation, and they move one after another with, as a rule, different velocities. These loop-like structures in the final analysis form the frontal structure of CME. Time dependences of the velocity and acceleration of the ejection’s front are obtained for all CMEs under consideration. A conclusion is drawn about possible existence of two classes of CMEs depending on their velocity time profiles. Ejections, whose velocity after reaching its maximum sharply drops by a value of more than 100 km/s and then goes over into a regime of slow change, belong to the first class. Another class of CMEs is formed by ejections whose velocity changes slowly immediately after reaching the maximum. It is demonstrated that the CME’s angular dimension increases at the initial stage of ejection motion up to a factor of 3 with a time scale of doubling the angular size value within the limits 3.5–11 min since the moment of the first measurement of this parameter of an ejection. For three CMEs it is shown that at the initial stage of their motion for a certain time interval they are stronger expanded than grow in the longitude direction.

## **Determining the Full Halo Coronal Mass Ejection Characteristics**

V.G. [Fainshtein](#)

Sun and Geosphere, **2010**; 5(1): 23 – 27, [File](#)

Observing halo coronal mass ejections (HCMEs) in the coronagraph field of view allows one to only determine the apparent parameters in the plane of the sky. Recently, several methods have been proposed allowing one to find some true geometrical and kinematical parameters of HCMEs. In most cases, a simple cone model was used to describe the CME shape. Observations show that various modifications of the cone model ("ice cream models") are most appropriate for describing the shapes of individual CMEs. This paper uses the method of determining full HCME parameters proposed by the author earlier, for determining the parameters of 45 full HCMEs, with various modifications of their shapes. I show that the determined CME characteristics depend significantly on the chosen CME shape. I conclude that the absence of criteria for a preliminary evaluation of the CME shape is a major source of error in determining the true parameters of a full HCME with any of the known methods. I show that, regardless of the chosen CME form, the trajectory of practically all the HCMEs in question deviate from the radial direction towards the Sun-Earth axis at the initial stage of their movement, and their angular size, on average, significantly exceeds that of all the observable CMEs.

## **Relationship between CME Parameters and Large-Scale Structure of Solar Magnetic Fields**

V.G. [Fainshtein](#)<sup>1</sup>, E.V. Ivanov<sup>2</sup>

Sun and Geosphere, **2010**; 5(1): 28 – 33, [File](#)

In this work, we explore how the parameters of coronal mass ejections (CME) associated with eruptive prominences (EP) depend on their position relative to the coronal streamer belt (CSB) and coronal streamer chains (CSCs). We show that the CMEs whose axes are close to CSB propagate at lower mean speed than the CMEs observed in the vicinity of CSCs. The CMEs concentrated at CSCs have larger mean kinetic energy than those associated with CSB. The mean mass is maximum for the events associated with CSB and minimum for events observed near the base of open magnetic field configurations (OMF) - counterparts of coronal holes. The mean angular size is virtually the same for the CMEs of both types. The CME deviation from the radial trajectory has been studied. It is shown that CMEs may deviate noticeably from the radial propagation both on their way from the origin site (prominence eruption site) up to about 2.5 solar radii ( $R_o$ ) and farther, from  $\sim 2.5$  up to  $20 R_o$ . In the epoch of solar minimum and at the rise of the cycle, the deviation in the first part of the trajectory (up to  $2.5 R_o$ ) is mainly towards the equator. In the other phases, no preferable direction has been revealed. As the EP latitude increases up to  $\pm 45^\circ$ , the CME deviation, on the average, increases, too. It is shown that about 50% of all CMEs change the sense of deviation when passing from the near-solar part of the trajectory to its far part so that, as the CME moves away from the Sun, its propagation becomes more radial. The results obtained show that large-scale solar magnetic fields have a significant effect on the characteristics and propagation of coronal mass ejections.

## **Determining the full halo coronal mass ejection characteristics**

V.G. [Fainshtein](#)

Proceedings of the International Astronomical Union / Volume 4 / Symposium S257, pp 279 – 281,

Published online: 16 May **2009**, [File](#)

In this paper we determined the parameters of 45 full halo coronal mass ejections (HCMEs) for various modifications of their cone forms ("ice cream cone models"). We show that the CME determined characteristics depend significantly on the CME chosen form. We show that, regardless of the CME chosen form, the trajectory of practically all the considered HCMEs deviate from the radial direction to the Sun-to-Earth axis at the initial stage of their movement.

## **The expansion of a coronal mass ejection within LASCO field of view: some regularities**

V.G. [Fainshtein](#)

Proceedings of the International Astronomical Union / Volume 4 / Symposium S257, pp 257 – 263,

Published online: 16 May **2009**, [File](#)

Forty five limb CMEs related with eruptive prominences and/or near-to-limb post-eruptive arcades have been tested. It is shown that CMEs can be divided into two groups. The first group includes coronal mass ejections whose " $2\alpha$ " latitude angular sizes apparent in the plane of the sky remain unchanged within measurement accuracy of several degrees. The second one is formed by CMEs that expand "non-radially", namely, their angular sizes increase by the relative value (10-30)% up to the position of the ejection front  $RF = R_{\text{em}}$  and run to the maximal value  $2\alpha_m$  at this distance. It has been found that CMEs of the second type are, on the average, wider, faster and have an outer shell brighter and with higher plasma density for long distances. It is shown that on average  $R_{\text{em}}$  increases as  $2\alpha_m$  rises.

## **A tool for empirical forecasting of major flares, coronal mass ejections, and solar particle events from a proxy of active-region free magnetic energy**

**Falconer**, David; Barghouty, Abdunnasser F.; Khazanov, Igor; Moore, Ron  
Space Weather, Vol. 9, No. 4, S04003, 2011, [File](#)

This paper describes a new forecasting tool developed for and currently being tested by NASA's Space Radiation Analysis Group (SRAG) at Johnson Space Center, which is responsible for the monitoring and forecasting of radiation exposure levels of astronauts. The new software tool is designed for the empirical forecasting of M- and X-class flares, coronal mass ejections, and solar energetic particle events. For each type of event, the algorithm is based on the empirical relationship between the event rate and a proxy of the active region's free magnetic energy. Each empirical relationship is determined from a data set of ~40,000 active-region magnetograms from ~1300 active regions observed by SOHO/Michelson Doppler Imager (MDI) that have known histories of flare, coronal mass ejection, and solar energetic particle event production. The new tool automatically extracts each strong-field magnetic area from an MDI full-disk magnetogram, identifies each as a NOAA active region, and measures the proxy of the active region's free magnetic energy from the extracted magnetogram. For each active region, the empirical relationship is then used to convert the free-magnetic-energy proxy into an expected event rate. The expected event rate in turn can be readily converted into the probability that the active region will produce such an event in a given forward time window. Descriptions of the data sets, algorithm, and software in addition to sample applications and a validation test are presented. Further development and transition of the new tool in anticipation of SDO/HMI are briefly discussed.

## **THE "MAIN SEQUENCE" OF EXPLOSIVE SOLAR ACTIVE REGIONS: DISCOVERY AND INTERPRETATION**

**David A. Falconer**<sup>1,2,3</sup>, [Ronald L. Moore](#)<sup>1</sup>, [G. Allen Gary](#)<sup>3</sup> and [Mitzi Adams](#)<sup>1</sup>  
ApJ 700 L166-L169, 2009

We examine the location and distribution of the production of coronal mass ejections (CMEs) and major flares by sunspot active regions in the phase space of two whole-active-region magnetic quantities measured from 1897 SOHO/MDI magnetograms. These magnetograms track the evolution of 44 active regions across the central disk of radius 0.5 R<sub>Sun</sub>. The two quantities are LWLSG, a gauge of the total free energy in an active region's magnetic field, and LΦ, a measure of the active region's total magnetic flux. From these data and each active region's history of production of CMEs, X flares, and M flares, we find (1) that CME/flare-productive active regions are concentrated in a straight-line "main sequence" in (log LWLSG, log LΦ) space, (2) that main-sequence active regions have nearly their maximum attainable free magnetic energy, and (3) evidence that this arrangement plausibly results from equilibrium between input of free energy to an explosive active region's magnetic field in the chromosphere and corona by contortion of the field via convection in and below the photosphere and loss of free energy via CMEs, flares, and coronal heating, an equilibrium between energy gain and loss that is analogous to that of the main sequence of hydrogen-burning stars in (mass, luminosity) space.

## **MAGNETOGRAM MEASURES OF TOTAL NONPOTENTIALITY FOR PREDICTION OF SOLAR CORONAL MASS EJECTIONS FROM ACTIVE REGIONS OF ANY DEGREE OF MAGNETIC COMPLEXITY**

D. A. **Falconer**,<sup>1</sup> R. L. Moore, and G. A. Gary  
Astrophysical Journal, 689:1433–1442, 2008

For investigating the magnetic causes of coronal mass ejections (CMEs) and for forecasting the CME productivity of active regions, in previous work we have gauged the total nonpotentiality of a whole active region by either of two measures, LSSM and LSGM, two measures of the magnetic field along the main neutral line in a vector magnetogram of the active region. This previous work was therefore restricted to nominally bipolar active regions, active regions that have a clearly identifiable main neutral line. In the present paper, we show that our work can be extended to include multipolar active regions of any degree of magnetic complexity by replacing LSSM and LSGM with their generalized counterparts, WLSS and WLSG, which are corresponding integral measures covering all neutral lines in an active region instead of only the main neutral line. In addition, we show that for active regions within 30 heliocentric degrees of disk center, WLSG can be adequately measured from line-of-sight magnetograms instead of vector magnetograms. This approximate measure of active-region total nonpotentiality, LWLSG, with the extensive set of 96 minute cadence full-disk line-of-sight magnetograms from SOHO MDI, can be used to study the evolution of active-region total nonpotentiality leading to the production of CMEs.

## **MAGNETIC CAUSES OF SOLAR CORONAL MASS EJECTIONS: DOMINANCE OF THE FREE MAGNETIC ENERGY OVER THE MAGNETIC TWIST ALONE**

D. A. **Falconer**, R. L. Moore, and G. A. Gary  
The Astrophysical Journal, 644:1258–1272, 2006, [File](#)

We examine the magnetic causes of coronal mass ejections (CMEs) by examining, along with the correlations of active-region magnetic measures with each other, the correlations of these measures with active-region CME productivity observed in time windows of a few days, either centered on or extending forward from the day of the magnetic measurement.

From the deprojected magnetograms, we find evidence that (1) magnetic twist and magnetic size are separate but comparably strong causes of active-region CME productivity, and (2) the total free magnetic energy in an active region's magnetic field is a stronger determinant of the active region's CME productivity than is the field's overall twist (or helicity) alone.

## **A data-driven MHD simulation of the 2011-02-15 coronal mass ejection from Active Region NOAA 11158**

[Yuhong Fan](#), [Maria D. Kazachenko](#), [Andrey N. Afanasyev](#), [George H. Fisher](#)

ApJ **975** 206 2024

<https://arxiv.org/pdf/2409.17507>

<https://iopscience.iop.org/article/10.3847/1538-4357/ad7f53/pdf>

We present a boundary data-driven magneto-hydrodynamic (MHD) simulation of the **2011-02-15** coronal mass ejection (CME) event of Active Region (AR) NOAA 11158. The simulation is driven at the lower boundary with an electric field derived from the normal magnetic field and the vertical electric current measured from the Solar Dynamics Observatory (SDO) Helioseismic Magnetic Imager (HMI) vector magnetograms. The simulation shows the build up of a pre-eruption coronal magnetic field that is close to the nonlinear force-free field (NLFFF) extrapolation, and it subsequently develops multiple eruptions. The sheared/twisted field lines of the pre-eruption magnetic field show qualitative agreement with the brightening loops in the SDO Atmospheric Imaging Assembly (AIA) hot passband images. We find that the eruption is initiated by the tether-cutting reconnection in a highly sheared field above the central polarity inversion line (PIL) and a magnetic flux rope with dipped field lines forms during the eruption. The modeled erupting magnetic field evolves to develop a complex structure containing two distinct flux ropes and produces an outgoing double-shell feature consistent with the Solar TERrestrial RELations Observatory B / Extreme UltraViolet Imager (STEREO-B/EUVI) observation of the CME. The foot points of the erupting field lines are found to correspond well with the dimming regions seen in the SDO/AIA observation of the event. These agreements suggest that the derived electric field is a promising way to drive MHD simulations to establish the realistic pre-eruption coronal field based on the observed vertical electric current and model its subsequent dynamic eruption.

## **An improved MHD simulation of the 2006 December 13 coronal mass ejection of active region NOAA 10930**

[Yuhong Fan](#)

ApJ **941** 61 2022

<https://arxiv.org/pdf/2211.03736.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/aca0ec/pdf>

We present a magnetohydrodynamic (MHD) simulation of the coronal mass ejection (CME) on **13 December 2006** in the emerging delta-sunspot active region 10930, improving upon a previous simulation by Fan (2016) as follows. (1) Incorporate an ambient solar wind instead of using a static potential magnetic field extrapolation as the initial state. (2) In addition to imposing the emergence of a twisted flux rope, also impose at the lower boundary a random electric field that represents the effect of turbulent convection, which drives field-line braiding and produces resistive and viscous heating in the corona. With the inclusion of this heating, which depends on the magnetic field topology, we are able to model the synthetic soft X-ray images that would be observed by the X-Ray Telescope (XRT) of the Hinode satellite, produced by the simulated coronal magnetic field. We find that the simulated pre-eruption magnetic field with the build up of a twisted magnetic flux rope, produces synthetic soft X-ray emission that shows qualitatively similar morphology as that observed by the Hinode/XRT for both the ambient coronal loops of the active region and the central inverse-S shaped "sigmoid" that sharpens just before the onset of the eruption. The synthetic post-flare loop brightening also shows similar morphology as that seen in the Hinode/XRT image during the impulsive phase of the eruption. It is found that the kinematics of the erupting flux rope is significantly affected by the open magnetic fields and fast solar wind streams adjacent to the active region.

## **Simulations of prominence eruption preceded with large amplitude longitudinal oscillations and draining**

[Yuhong Fan](#)

ApJ **898** 34 2020

<https://arxiv.org/pdf/2006.11619.pdf>

<https://doi.org/10.3847/1538-4357/ab9d7f>

We present magnetohydrodynamic (MHD) simulations of the evolution from quasi-equilibrium to eruption of a prominence-forming twisted coronal flux rope under a coronal streamer. We have compared the cases with and without the formation of prominence condensations, and the case where prominence condensations form but we artificially initiate the draining of the prominence. We find that the prominence weight has a significant effect on the stability of the flux rope, and can significantly increase the loss-of-equilibrium height. The flux rope can be made to erupt earlier

by initiating draining of the prominence mass. We have also performed a simulation where large amplitude longitudinal oscillations of the prominence are excited during the quasi-static phase. We find that the gravity force along the magnetic field lines is the major restoring force for the oscillations, in accordance with the "pendulum model", although the oscillation periods are higher (by about 10% to 40%) than estimated from the model because of the dynamic deformation of the field line dips during the oscillations. The oscillation period is also found to be slightly smaller for the lower part of the prominence in the deeper dips compared to the upper part in the shallower dips. The oscillations are quickly damped out after about 2-3 periods and are followed by prominence draining and the eventual eruption of the prominence. However we do not find a significant enhancement of the prominence draining and earlier onset of eruption with the excitation of the prominence oscillations compared to the case without.

## **MHD simulation of prominence-cavity system**

Yuhong [Fan](#), [Tie Liu](#)

Frontiers in Astronomy and Space Sciences                      2019

<https://arxiv.org/pdf/1905.08226.pdf>

<https://www.frontiersin.org/articles/10.3389/fspas.2019.00027/full>

[sci-hub.se/10.3389/fspas.2019.00027](http://sci-hub.se/10.3389/fspas.2019.00027)

We present magnetohydrodynamic simulation of the evolution from quasi-equilibrium to onset of eruption of a twisted, prominence-forming coronal magnetic flux rope underlying a corona streamer. The flux rope is built up by an imposed flux emergence at the lower boundary. During the quasi-static phase of the evolution, we find the formation of a prominence-cavity system with qualitative features resembling observations, as shown by the synthetic SDO/AIA EUV images with the flux rope observed above the limb viewed nearly along its axis. The cavity contains substructures including "U"-shaped or horn-like features extending from the prominence enclosing a central "cavity" on top of the prominence. The prominence condensations form in the dips of the highly twisted field lines due to runaway radiative cooling and the cavity is formed by the density depleted portions of the prominence-carrying field lines extending up from the dips. The prominence "horns" are threaded by twisted field lines containing shallow dips, where the prominence condensations have evaporated to coronal temperatures. The central "cavity" enclosed by the horns is found to correspond to a central hot and dense core containing twisted field lines that do not have dips. The flux rope eventually erupts as its central part rises quasi-statically to a critical height consistent with the onset of the torus instability. The erupting flux rope accelerates to a fast speed of nearly 900 km/s and the associated prominence eruption shows significant rotational motion and a kinked morphology.

## **The eruption of a prominence carrying coronal flux rope: forward synthesis of the magnetic field strength measurement by the COronal Solar Magnetism Observatory Large Coronagraph**

Yuhong [Fan](#), [Sarah Gibson](#), [Steve Tomczyk](#)

ApJ            866 57            2018

<https://arxiv.org/pdf/1808.06142.pdf>

[sci-hub.tw/10.3847/1538-4357/aadd0e](http://sci-hub.tw/10.3847/1538-4357/aadd0e)

From a magnetohydrodynamic (MHD) simulation of the eruption of a prominence hosting coronal flux rope, we carry out forward synthesis of the circular polarization signal (Stokes V signal) of the FeXIII emission line at 1074.7 nm produced by the MHD model as measured by the proposed COronal Solar Magnetism Observatory (COSMO) Large Coronagraph (LC) and infer the line-of-sight magnetic field  $B_{LOS}$  above the limb. With an aperture of 150 cm, integration time of 12 min, and a resolution of 12 arcsec, the LC can measure a significant  $B_{LOS}$  with sufficient signal to noise level, from the simulated flux rope viewed nearly along its axis with a peak axial field strength of about 10 G. The measured  $B_{LOS}$  is found to relate well with the axial field strength of the flux rope for the height range of the prominence, and can discern the increase with height of the magnetic field strength in that height range that is a definitive signature of the concave upturning dipped field supporting the prominence. The measurement can also detect an outward moving  $B_{LOS}$  due to the slow rise of the flux rope as it develops the kink instability, during the phase when its rise speed is still below about 41 km/s and up to a height of about 1.3 solar radii. These results suggest that the COSMO LC has great potential in providing quantitative information about the magnetic field structure of CME precursors (e.g. the prominence cavities) and their early evolution for the onset of eruption.

## **MHD simulation of prominence eruption**

[Yuhong Fan](#)

ApJ            862 54            2018

<https://arxiv.org/pdf/1806.06305.pdf>

<http://sci-hub.tw/http://iopscience.iop.org/article/10.3847/1538-4357/aaccee/meta>

We carry out magnetohydrodynamic (MHD) simulations of the quasi-static evolution and eruption of a twisted coronal flux rope under a coronal streamer built up by an imposed flux emergence at the lower boundary. The MHD model incorporates a simple empirical coronal heating, optically thin radiative cooling, and field aligned thermal conduction, and thus allows the formation of prominence condensations. We find that during the quasi-static evolution, prominence/filament condensations of an elongated, sigmoid morphology form in the dips of the significantly twisted field lines of the emerged flux rope due to run-away radiative cooling. A prominence cavity also forms surrounding the prominence, which is best observed above the limb with the line-of-sight nearly along the length of the flux rope, as

shown by synthetic SDO/AIA EUV images. The magnetic field supporting the prominence is significantly non-force-free despite the low plasma-beta. By comparing with a simulation that suppresses prominence formation, we find that the prominence weight is dynamically important and can suppress the onset of the kink instability and hold the flux rope in equilibrium for a significantly long time, until draining of the prominence plasma develops and lightens the prominence weight. The flux rope eventually develops the kink instability and erupts, producing a prominence eruption. The synthetic AIA 304 angstrom images show that the prominence is lifted up into an erupting loop, exhibiting helical features along the loop and substantial draining along the loop legs, as often seen in observations.

## **Turbulence and Heating in the Flank and Wake Regions of a Coronal Mass Ejection**

Siteng [Fan](#), [Jiansen He](#), [Limei Yan](#), [Steven Tomczyk](#), [Hui Tian](#)...

[Solar Physics](#) January 2018, 293:6

As a coronal mass ejection (CME) passes, the flank and wake regions are typically strongly disturbed. Various instruments, including the Large Angle and Spectroscopic Coronagraph (LASCO), the Atmospheric Imaging Assembly (AIA), and the Coronal Multi-channel Polarimeter (CoMP), observed a CME close to the east limb on **26 October 2013**. A hot ( $\approx 10$  MK) rising blob was detected on the east limb, with an initial ejection flow speed of  $\approx 330$  km s<sup>-1</sup>. The magnetic structures on both sides and in the wake of the CME were strongly distorted, showing initiation of turbulent motions with Doppler-shift oscillations enhanced from  $\approx \pm 3$  km s<sup>-1</sup> to  $\approx \pm 15$  km s<sup>-1</sup> and effective thermal velocities from  $\approx 30$  km s<sup>-1</sup> to  $\approx 60$  km s<sup>-1</sup>, according to the CoMP observations at the Fe xiii line. The CoMP Doppler-shift maps suggest that the turbulence behaved differently at various heights; it showed clear wave-like torsional oscillations at lower altitudes, which are interpreted as the antiphase oscillation of an alternating red/blue Doppler shift across the strands at the flank. The turbulence seems to appear differently in the channels of different temperatures. Its turnover time was  $\approx 1000$  seconds for the Fe 171 Å channel, while it was  $\approx 500$  seconds for the Fe 193 Å channel. Mainly horizontal swaying rotations were observed in the Fe 171 Å channel, while more vertical vortices were seen in the Fe 193 Å channel. The differential-emission-measure profiles in the flank and wake regions have two components that evolve differently: the cool component decreased over time, evidently indicating a drop-out of cool materials due to ejection, while the hot component increased dramatically, probably because of the heating process, which is suspected to be a result of magnetic reconnection and turbulence dissipation. These results suggest a new turbulence-heating scenario of the solar corona and solar wind.

## **MHD simulations of the eruption of coronal flux ropes under coronal streamers**

Yuhong [Fan](#)

ApJ **844** 26 **2017**

<https://arxiv.org/pdf/1706.06076.pdf>

<http://sci-hub.cc/10.3847/1538-4357/aa7a56>

Using three-dimensional magnetohydrodynamic (MHD) simulations, we investigate the eruption of coronal flux ropes underlying coronal streamers and the development of a prominence eruption. We initialize a quasi-steady solution of a coronal helmet streamer, into which we impose at the lower boundary the slow emergence of a part of a twisted magnetic torus. As a result a quasi-equilibrium flux rope is built up under the streamer. With varying sizes of the streamer and the different length and total twist of the emerged flux rope, we found different scenarios for the evolution from quasi-equilibrium to eruption. In the cases with a broad streamer, the flux rope remains well confined until there is sufficient twist such that it first develops the kink instability and evolves through a sequence of kinked, confined states with increasing height until it eventually develops a "hernia-like" ejective eruption. For the significantly twisted flux ropes, prominence condensations form in the dips of the twisted field lines due to run-away radiative cooling. Once formed, the prominence carrying field becomes significantly non-force-free due to the prominence weight despite being low plasma  $\beta$ . As the flux rope erupts, we obtain the eruption of the prominence, which shows substantial draining along the legs of the erupting flux rope. The prominence may not show a kinked morphology even though the flux rope becomes kinked. On the other hand, in the case with a narrow streamer, the flux rope with less than 1 wind of twist can erupt via the onset of the torus instability.

## **Modeling the initiation of the 2006 December 13 coronal mass ejection in AR 10930: the structure and dynamics of the erupting flux rope**

Yuhong [Fan](#)

ApJ **824** 93 **2016**

<http://arxiv.org/pdf/1604.05687v1.pdf>

We carry out a three-dimensional magneto-hydrodynamic (MHD) simulation to model the initiation of the coronal mass ejection (CME) on **13 December 2006** in the emerging  $\delta$ -sunspot active region NOAA 10930. The setup of the simulation is similar to a previous simulation by Fan (2011), but with a significantly widened simulation domain to accommodate the wide CME. The simulation shows that the CME can result from the emergence of a east-west oriented twisted flux rope whose positive, following emerging pole corresponds to the observed positive rotating sunspot emerging against the southern edge of the dominant pre-existing negative sunspot. The erupting flux rope in the simulation accelerates to a terminal speed that exceeds 1500 km/s and undergoes a counter-clockwise rotation of nearly

180 degrees such that its front and flanks all exhibit southward directed magnetic fields, explaining the observed southward magnetic field in the magnetic cloud impacting the Earth. With continued driving of flux emergence, the source region coronal magnetic field also shows the reformation of a coronal flux rope underlying the flare current sheet of the erupting flux rope, ready for a second eruption. This may explain the build up for another X-class eruptive flare that occurred the following day from the same region.

## **MHD Equilibria and Triggers for Prominence Eruption**

Yuhong [Fan](#)

Chapter 12 of Solar Prominences, Astrophysics and Space Science Library, Volume 415. ISBN 978-3-319-10415-7. Springer International Publishing Switzerland, **2015**, p. 297

<http://arxiv.org/pdf/1512.08044v1.pdf>

Magneto-hydrodynamic (MHD) simulations of the emergence of twisted magnetic flux tubes from the solar interior into the corona are discussed to illustrate how twisted and sheared coronal magnetic structures (with free magnetic energy), capable of driving filament eruptions, can form in the corona in emerging active regions. Several basic mechanisms that can disrupt the quasi-equilibrium coronal structures and trigger the release of the stored free magnetic energy are discussed. These include both ideal processes such as the onset of the helical kink instability and the torus instability of a twisted coronal flux rope structure and the non-ideal process of the onset of fast magnetic reconnections in current sheets. Representative MHD simulations of the non-linear evolution involving these mechanisms are presented.

## **THERMAL SIGNATURES OF TETHER-CUTTING RECONNECTIONS IN PRE-ERUPTION CORONAL FLUX ROPES: HOT CENTRAL VOIDS IN CORONAL CAVITIES**

Y. [Fan](#)

**2012 ApJ 758 60**

Using a three-dimensional MHD simulation, we model the quasi-static evolution and the onset of eruption of a coronal flux rope. The simulation begins with a twisted flux rope emerging at the lower boundary and pushing into a pre-existing coronal potential arcade field. At a chosen time the emergence is stopped with the lower boundary taken to be rigid. Then the coronal flux rope settles into a quasi-static rise phase during which an underlying, central sigmoid-shaped current layer forms along the so-called hyperbolic flux tube (HFT), a generalization of the X-line configuration. Reconnections in the dissipating current layer effectively add twisted flux to the flux rope and thus allow it to rise quasi-statically, even though the magnetic energy is decreasing as the system relaxes. We examine the thermal features produced by the current layer formation and the associated "tether-cutting" reconnections as a result of heating and field aligned thermal conduction. It is found that a central hot, low-density channel containing reconnected, twisted flux threading under the flux rope axis forms on top of the central current layer. When viewed in the line of sight roughly aligned with the hot channel (which is roughly along the neutral line), the central current layer appears as a high-density vertical column with upward extensions as a "U"-shaped dense shell enclosing a central hot, low-density void. Such thermal features have been observed within coronal prominence cavities. Our MHD simulation suggests that they are the signatures of the development of the HFT topology and the associated tether-cutting reconnections, and that the central void grows and rises with the reconnections, until the flux rope reaches the critical height for the onset of the torus instability and dynamic eruption ensues.

## **ON THE ERUPTION OF CORONAL FLUX ROPES**

Y. [Fan](#)

**2010 ApJ 719 728; File**

We present three-dimensional MHD simulations of the evolution of the magnetic field in the corona where the emergence of a twisted magnetic flux tube is driven at the lower boundary into a pre-existing coronal potential arcade field. Through a sequence of simulations in which we vary the amount of twisted flux transported into the corona before the emergence is stopped, we investigate the conditions that lead to a dynamic eruption of the resulting coronal flux rope. It is found that the critical condition for the onset of eruption is for the center of the flux rope to reach a critical height at which the corresponding potential field declines with height at a sufficiently steep rate, consistent with the onset of the torus instability of the flux rope. In some cases, immediately after the emergence is stopped, the coronal flux rope first settles into a quasi-static rise with an underlying sigmoid-shaped current layer developing. Preferential heating of field lines going through this current layer may give rise to the observed quiescent X-ray sigmoid loops before eruption. Reconnections in the current layer during the initial quasi-static stage is found to add detached flux to the coronal flux rope, allowing it to rise quasi-statically to the critical height and dynamic eruption of the flux rope then ensues. By identifying field lines whose tops are in the most intense part of the current layer during the eruption, we deduce the evolution and morphology of the post-flare X-ray loops and the flare ribbons at their footpoints.

## **THE EMERGENCE OF A TWISTED FLUX TUBE INTO THE SOLAR ATMOSPHERE: SUNSPOT ROTATIONS AND THE FORMATION OF A CORONAL FLUX ROPE**

Y. [Fan](#)

2009 ApJ 697 1529-1542

We present a three-dimensional simulation of the dynamic emergence of a twisted magnetic flux tube from the top layer of the solar convection zone into the solar atmosphere and corona. It is found that after a brief initial stage of flux emergence during which the two polarities of the bipolar region become separated and the tubes intersecting the photosphere become vertical, significant rotational motion sets in within each polarity. The rotational motions of the two polarities are found to twist up the inner field lines of the emerged fields such that they change their orientation into an inverse configuration (i.e., pointing from the negative polarity to the positive polarity over the neutral line). As a result, a flux rope with sigmoid-shaped, dipped core fields forms in the corona, and the center of the flux rope rises in the corona with increasing velocity as the twisting of the flux rope footpoints continues. The rotational motion in the two polarities is a result of propagation of nonlinear torsional Alfvén waves along the flux tube, which transports significant twist from the tube's interior portion toward its expanded coronal portion. This is a basic process whereby twisted flux ropes are developed in the corona with increasing twist and magnetic energy, leading up to solar eruptions.

### **ONSET OF CORONAL MASS EJECTIONS DUE TO LOSS OF CONFINEMENT OF CORONAL FLUX ROPES**

Y. **Fan** and S. E. Gibson

The Astrophysical Journal, 668:1232Y1245, 2007

Using MHD numerical simulations in a three-dimensional spherical geometry, we model the loss of confinement and eruption of a flux rope emerging quasi-statically into a preexisting coronal arcade field. Our numerical experiments investigated two distinct mechanisms that led to the eruption of the flux rope.

### **Dynamics of Threads Wrapping a Filament's Leg Prior to the Eruption on 2021 October 28**

Yue **Fang**<sup>1</sup>, Jun Zhang<sup>1</sup>, Yi Bi<sup>2</sup>, and Zhiping Song<sup>1</sup>

2023 ApJ 955 87

<https://iopscience.iop.org/article/10.3847/1538-4357/acf19e/pdf>

Although the magnetic field structures of solar filaments have been studied for several decades, the detailed evolution of the structure around a filament prior to its eruption is rarely observed. On **2021 October 28** in AR 12887, a major solar flare (X1.0 class) occurred at 15:35 UT. Based on the Solar Dynamics Observatory high-spatial-resolution observations, we find this flare is associated with the eruption of two filaments, namely F1 and F2. The two filaments are initially independent. The western leg (WLEG) of F1 approaches the northern leg of F2, due to the continuous movement and rotation of the magnetic field in which the WLEG roots in. We find first that there are some threads wrapping the WLEG. Brightening and bidirectionally plasmoid flows that originate from a brightening are detected in these threads, then the threads disappear, and the two filaments connect. NLFFF extrapolation reveals that there is a toroidal magnetic structure enveloping the WLEG and corresponding spatially to the threads. It is expected that a filament is enveloped by toroidal magnetic fields. According to the observations and extrapolation, we suggest that these threads represent the toroidal magnetic fields wrapping the WLEG. This paper provides new details about the dynamics of the toroidal magnetic fields. Magnetic reconnection takes place in the toroidal fields and thus destroys the fields, then F1 and F2 connect, and subsequently, the two filaments erupt and the flare occurs.

### **Coronal rain in magnetic arcades: Rebound shocks, Limit cycles, and Shear flows**

X. **Fang**, C. Xia, **R. Keppens**, **T. Van Doorselaere**

2015

<http://arxiv.org/pdf/1507.00882v1.pdf>

We extend our earlier multidimensional, magnetohydrodynamic simulations of coronal rain occurring in magnetic arcades with higher resolution, grid-adaptive computations covering a much longer (>6 hour) timespan. We quantify how in-situ forming blob-like condensations grow along and across field lines and show that rain showers can occur in limit cycles, here demonstrated for the first time in 2.5D setups. We discuss dynamical, multi-dimensional aspects of the rebound shocks generated by the siphon inflows and quantify the thermodynamics of a prominence-corona-transition-region like structure surrounding the blobs. We point out the correlation between condensation rates and the cross-sectional size of loop systems where catastrophic cooling takes place. We also study the variations of the typical number density, kinetic energy and temperature while blobs descend, impact and sink into the transition region. In addition, we explain the mechanisms leading to concurrent upflows while the blobs descend. As a result, there are plenty of shear flows generated with relative velocity difference around 80 km s<sup>-1</sup> in our simulations. These shear flows are siphon flows set up by multiple blob dynamics and they in turn affect the deformation of the falling blobs. In particular, we show how shear flows can break apart blobs into smaller fragments, within minutes.

### **Rotating Solar Jets in Simulations of Flux Emergence with Thermal Conduction**

Fang **Fang**, Yuhong Fan, Scott W. McIntosh

ApJL, 2014 789 L19

<http://arxiv.org/pdf/1406.2220v1.pdf>

We study the formation of coronal jets through numerical simulation of the emergence of a twisted magnetic flux rope into a pre-existing open magnetic field. Reconnection inside the emerging flux rope in addition to that between the

emerging and pre-existing fields give rise to the violent eruption studied. The simulated event closely resembles the coronal jets ubiquitously observed by Hinode/XRT and demonstrates that heated plasma is driven into the extended atmosphere above. Thermal conduction implemented in the model allows us to qualitatively compare simulated and observed emission from such events. We find that untwisting field lines after the reconnection drive spinning outflows of plasma in the jet column. The Poynting flux in the simulated jet is dominated by the untwisting motions of the magnetic fields loaded with high-density plasma. The simulated jet is comprised of spires of untwisting field that are loaded with a mixture of cold and hot plasma and exhibit rotational motion of order 20 km/s and match contemporary observations.

### **A new multi-wavelength solar telescope: Optical and Near-infrared Solar Eruption Tracer (ONSET)**

Research in Astronomy and Astrophysics, Volume 13, Issue 12, article id. 1509-1517 (2013).

<https://arxiv.org/pdf/1307.4533.pdf>

A new multi-wavelength solar telescope, the Optical and Near-infrared Solar Eruption Tracer (ONSET) of Nanjing University, has been constructed. It was fabricated at the Nanjing Institute of Astronomical Optics & Technology, and the operation is jointly administered with Yunnan Astronomical Observatory. ONSET is able to observe the Sun in three wavelength windows: He I 10830 Å, H $\alpha$  and white-light at 3600 Å and 4250 Å, which are selected in order to simultaneously record the dynamics of the corona, chromosphere and photosphere respectively. Full-disk or partial-disk solar images with a field of 10' at three wavelengths can be obtained nearly simultaneously. It is designed to trace solar eruptions with high spatial and temporal resolutions. This telescope was installed at a new solar observing site near Fuxian Lake in Yunnan Province, southwest China. The site is located at E102N24, with an altitude of 1722 m. The seeing is stable and has high quality. We give a brief description of the scientific objectives and the basic structure of ONSET. Some preliminary results are also presented. **21 April 2011, 2012 March 9, 2013 March 13, 2013 April 30**

### **BUILDUP OF MAGNETIC SHEAR AND FREE ENERGY DURING FLUX EMERGENCE AND CANCELLATION**

Fang [Fang](#)<sup>1</sup>, Ward Manchester IV<sup>1</sup>, William P. Abbett<sup>2</sup>, and Bart van der Holst

**2012** ApJ 754 15

We examine a simulation of flux emergence and cancellation, which shows a complex sequence of processes that accumulate free magnetic energy in the solar corona essential for the eruptive events such as coronal mass ejections, filament eruptions, and flares. The flow velocity at the surface and in the corona shows a consistent shearing pattern along the polarity inversion line (PIL), which together with the rotation of the magnetic polarities, builds up the magnetic shear. Tether-cutting reconnection above the PIL then produces longer sheared magnetic field lines that extend higher into the corona, where a sigmoidal structure forms. Most significantly, reconnection and upward-energy-flux transfer are found to occur even as magnetic flux is submerging and appears to cancel at the photosphere. A comparison of the simulated coronal field with the corresponding coronal potential field graphically shows the development of non-potential fields during the emergence of the magnetic flux and formation of sunspots.

### **Torsional Alfvén Wave Cascade and Shocks Evolving in Solar Jets**

S. Vasheghani [Farahani](#)<sup>1</sup>, S. M. Hejazi<sup>1</sup>, and M. R. Boroomand<sup>2</sup>

**2021** ApJ 906 70

<https://doi.org/10.3847/1538-4357/abca8c>

The aim of this study is to model the nature of nonlinear torsional magnetohydrodynamic waves propagating in solar jets as they are elevated to the outer solar atmosphere. The contribution of sequential processes to the transfer of energy is taken under consideration: the nonlinear cascade and shock formation. Thus a straight magnetic cylinder embedded in a plasma with an initial magnetic field and parallel flow to the cylinder axis is implemented. To resemble a jet where the oscillation wavelength highly exceeds the radius, the second-order thin flux tube approximation proves adequate. A Cohen–Kulsrud type equation is presented, and its solution highly depends on the parameter presented in this study, which itself is constituted of various environmental and equilibrium conditions that affect the perturbations of the variables as well as the nonlinear forces connected to Alfvén wave propagation. The shock formation time of torsional waves is inversely proportional to the density contrast of the jet, while the efficiency of energy transfer to shorter scales is directly proportional to the density contrast. While the parallel flow with a shear at the boundary expedites shock formation, its efficiency regarding energy transfer is dramatically enhanced by the plasma- $\beta$ , significantly contributing to coronal heating. The observational and seismological aspect of the present study is that faster jets are less probable for observations at higher altitudes, as they experience energy transfer mostly at the base of the corona, while slow speed jets may be observed at higher altitudes contributing to solar wind acceleration.

### **Coronal Jet Collimation by Nonlinear Induced Flows**

S. Vasheghani [Farahani](#) and S. M. Hejazi

**2017** ApJ 844 148

<http://sci-hub.cc/10.3847/1538-4357/aa7da5>

We consider a straight, initially non-rotating, untwisted magnetic cylinder embedded in a plasma with a straight magnetic field, where a shear between the internal and external flows exists. By implementing magnetohydrodynamic theory and taking into account the second-order thin flux tube approximation, the balance between the internal nonlinear forces is visualized. The nonlinear differential equation containing the ponderomotive, magnetic tension, and centrifugal forces in the presence of the shear flow is obtained. The solution presents the scale of influence of the propagating torsional Alfvén wave on compressive perturbations. Explicit expressions for the compressive perturbations caused by the forces connected to the torsional Alfvén wave show that, in the presence of a shear flow, the magnetic tension and centrifugal forces do not cancel each other's effects as they did in its absence. This shear flow plays in favor of the magnetic tension force, resulting in a more efficient collimation. Regarding the ponderomotive force, the shear flow has no effect. The phase relations highlight the interplay of the shear flow and the plasma- $\beta$ . As the shear flow and plasma- $\beta$  increase, compressive perturbation amplitudes emerge. We conclude that the jet collimation due to the torsional Alfvén wave highly depends on the location of the jet. The shear flow tightens the collimation as the jet elevates up to the solar corona.

### **Torsional wave propagation in solar tornadoes**

S. Vasheghani [Farahani](#)<sup>1</sup>, E. Ghanbari<sup>2</sup>, G. Ghaffari<sup>1</sup> and H. Safari

A&A 599, A19 (2017) 10.1051/0004-6361/201629563

**Aims.** We investigate the propagation of torsional waves in coronal structures together with their collimation effects in the context of magnetohydrodynamic (MHD) theory. The interplay of the equilibrium twist and rotation of the structure, e.g. jet or tornado, together with the density contrast of its internal and external media is studied to shed light on the nature of torsional waves.

**Methods.** We consider a rotating magnetic cylinder embedded in a plasma with a straight magnetic field. This resembles a solar tornado. In order to express the dispersion relations and phase speeds of the axisymmetric magnetohydrodynamic waves, the second-order thin flux tube approximation is implemented for the internal medium and the ideal MHD equations are implemented for the external medium.

**Results.** The explicit expressions for the phase speed of the torsional wave show the modification of the torsional wave speed due to the equilibrium twist, rotation, and density contrast of the tornado. The speeds could be either sub-Alfvénic or ultra-Alfvénic depending on whether the equilibrium twist or rotation is dominant. The equilibrium twist increases the phase speed while the equilibrium rotation decreases it. The good agreement between the explicit versions for the phase speed and that obtained numerically proves adequate for the robustness of the model and method. The density ratio of the internal and external media also play a significant role in the speed and dispersion.

The aim of this research topic is to present multi-faceted research, from distinctive perspectives involving the forefront of Heliophysics—the science about the Sun, the Earth, and what's in-between, on the magnetic structures and other key ingredients of CMEs at different evolution stages. Multiple analysis tools, including theoretical, numerical, and observational ones, are employed, making use of a variety of ground-based and space-borne remote-sensing and in-situ measurements.

### **Observations of magnetic flux ropes opened or disconnected from the Sun by magnetic reconnection in interplanetary space**

HengQiang [Feng](#), Yan Zhao, Jiemin Wang, Qiang Liu, and Guoqing Zhao

Front. Phys., 12 May 2021 |

<https://doi.org/10.3389/fphy.2021.679780>

<https://www.frontiersin.org/articles/10.3389/fphy.2021.679780/full>

During solar eruptions, many closed magnetic flux ropes are ejected into interplanetary space, which contribute to the heliospheric magnetic field and have important space weather effect because of their coherent magnetic field. Therefore, understanding the evolution of these closed flux ropes in the interplanetary space is important. In this paper, we examined all the magnetic and plasma data measured in 1997 by the Wind spacecraft and identified 621 reconnection exhausts. Of the 621 reconnection events, 31 were observed at the boundaries of magnetic flux ropes and were thought to cause the opening or disconnection magnetic field lines of the adjacent ropes. Of the 31 magnetic reconnection events, 29 were interchange reconnections and the closed field lines of these related flux ropes were opened by them. Only 2 of the 31 magnetic reconnection events disconnected the opened field lines of the original flux ropes. These observations indicate that interchange reconnection and disconnection may be two important mechanisms changing the magnetic topology of the magnetic flux ropes during their propagation during the interplanetary space.

The **Advanced Space-based Solar Observatory (ASO-S)** is a mission aiming at exploring solar flares, coronal mass ejections (CMEs), solar magnetic field and their relationships. To fulfill its major scientific objectives, ASO-S has three elaborately-designed payloads onboard: the Full-disk vector MagnetoGraph (FMG), the Lyman-alpha Solar Telescope (LST), and the Hard X-ray Imager (HXI) dedicated to observe vector magnetic fields, CMEs, and flares, respectively. Beside the scientific objectives, we have an operational objective to observe solar eruptions and magnetic field for making related space weather forecasts. More specifically, we have set a priority for the downlink of CME data observed by LST, and will distribute those data to different space weather prediction centers in China within 2 h once the Science Operation and Data Center (SODC) of ASO-S receive the data. After data downlink and archiving, different automatic detection, tracking, and cataloging procedures are planned to run for the most critical solar eruptive features. On the other hand, based on the distributed and downloaded data, different space weather prediction centers are to activate their forecast systems for the ASO-S observed solar eruption events. Our particular interests are currently focused on nowcast of different eruption events, prediction of CME arrivals, forecast of solar flares and the onset of solar eruptions. We are also working on further forecast potentials using the ASO-S data to make contributions to other possible important issues of space weather.

## **On the error analyses of polarization measurements of the white-light coronagraph aboard ASO-S**

Li [Feng](#), [Hui Li](#), [Bernd Inhester](#), [Bo Chen](#), [Beili Ying](#), [Lei Lu](#), [Weiqun Gan](#)

Research in Astron. Astrophys. **2018**

<https://arxiv.org/pdf/1810.13003.pdf>

The Advanced Space-based Solar Observatory (ASO-S) mission aims to explore two most spectacular eruptions in the Sun: solar flares and coronal mass ejections (CMEs), and their magnetism. For the studies of CMEs, the payload Lyman-alpha Solar Telescope (LST) has been proposed. It includes a traditional white-light coronagraph and a Lyman-alpha coronagraph which opens a new window to CME observations. Polarization measurements taken by white-light coronagraphs are crucial to derive fundamental physical parameters of CMEs. To make such measurements, there are two options of Stokes polarimeter which have been used by existing white-light coronagraphs for space missions. One uses a single or triple linear polarizers, the other involves both a half-wave plate and a linear polarizer. We find that the former option subjects to less uncertainty in the derived Stokes vector propagated from detector noise. The latter option involves two plates which are prone to internal reflections and may have a reduced transmission factor. Therefore, the former option is adopted as our Stokes polarimeter scheme for LST. Based on the parameters of the intended linear polarizer(s) colorPol provided by CODIXX and the half-wave plate 2-APW-L2-012C by Altechna, it is further shown that the imperfect maximum transmittance of the polarizer significantly increases the variance amplification of Stokes vector by at least about 50% when compared with the ideal case. The relative errors of Stokes vector caused by the imperfection of colorPol polarizer and the uncertainty due to the polarizer assembling in the telescope are estimated to be about 5%. Among the considered parameters, we find that the dominant error comes from the uncertainty in the maximum transmittance of the polarizer.

## **Why does the apparent mass of a coronal mass ejection increase?**

Li [Feng](#), Yuming Wang, [Fang Shen](#), [Chenglong Shen](#), [Bernd Inhester](#), [Lei Lu](#), [Weiqun Gan](#)

ApJ **812** 70 **2015**

<http://arxiv.org/pdf/1509.02246v1.pdf>

Mass is one of the most fundamental parameters characterizing the dynamics of a coronal mass ejection (CME). It has been found that CME apparent mass measured from the brightness enhancement in coronagraph images shows an increasing trend during its evolution in the corona. However, the physics behind it is not clear. Does the apparent mass gain come from the mass outflow from the dimming regions in the low corona, or from the pileup of the solar wind plasma around the CME when it propagates outwards from the Sun? We analyzed the mass evolution of six CME events. Their mass can increase by a factor of 1.6 to 3.2 from 4 to 15 Rs in the field of view (FOV) of the coronagraph on board the Solar Terrestrial Relations Observatory (STEREO). Over the distance about 7 to 15 Rs, where the coronagraph occulting effect can be negligible, the mass can increase by a factor of 1.3 to 1.7. We adopted the 'snow-plough' model to calculate the mass contribution of the piled-up solar wind in the height range from about 7 to 15 Rs. For 2/3 of the events, the solar wind pileup is not sufficient to explain the measured mass increase. In the height range from about 7 to 15 Rs, the ratio of the modeled to the measured mass increase is roughly larger than 0.55. Although the ratios are believed to be overestimated, the result gives evidence that the solar wind pileup probably makes a non-negligible contribution to the mass increase. It is not clear yet whether the solar wind pileup is a major contributor to the final mass derived from coronagraph observations. However, our study suggests that the solar wind pileup plays increasingly important role in the mass increase as a CME moves further away from the Sun.

## Radial Flow Pattern of a Slow CME

Li **Feng**, Bernd Inhester, Weiqun Gan

ApJ **805** 113 **2015**

<http://arxiv.org/pdf/1503.08502v1.pdf>

Height-time plots of the leading edge of coronal mass ejections (CME) have often been used to study CME kinematics. We propose a new method to analyze the CME kinematics in more detail by determining the radial mass transport process throughout the entire CME. Thus our method is able to estimate not only the speed of the CME front but also the radial flow speed inside the CME. We have applied the method to a slow CME with an average leading edge speed about  $480 \text{ km s}^{-1}$ . In the Lagrangian frame, the speed of the individual CME mass elements stay almost constant within 2 and 15 RS, the range over which we analyzed the CME. Hence we have no evidence of net radial forces acting on parts of the CME in this range nor of a pile-up of mass ahead of the CME. We find evidence that the leading edge trajectory obtained by tie-pointing may gradually lag behind the Lagrangian front-side trajectories derived from our analysis. Our results also allow a much more precise estimate of the CME energy. Compared with conventional estimates using the CME total mass and leading-edge motion, we find that the latter may overestimate the kinetic energy and the gravitational potential energy. **November 10 2010**

## MAGNETIC ENERGY PARTITION BETWEEN THE CORONAL MASS EJECTION AND FLARE FROM AR 11283

L. **Feng**<sup>1,2</sup>, T. Wiegmann<sup>2</sup>, Y. Su<sup>3</sup>, B. Inhester<sup>2</sup>, Y. P. Li<sup>1</sup>, X. D. Sun<sup>4</sup>, and W. Q. Gan

**2013** ApJ **765** 37

On **2011 September 6**, an X-class flare and a halo coronal mass ejection (CME) were observed from Earth erupting from the same active region AR 11283. The magnetic energy partition between them has been investigated. SDO/HMI vector magnetograms were used to obtain the coronal magnetic field using the nonlinear force-free field (NLFFF) extrapolation method. The free magnetic energies before and after the flare were calculated to estimate the released energy available to power the flare and the CME. For the flare energetics, thermal and nonthermal energies were derived using the RHESSI and GOES data. To obtain the radiative output, SDO/EVE data in the 0.1-37 nm waveband were utilized. We have reconstructed the three-dimensional (3D) periphery of the CME from the coronagraph images observed by STEREO-A, B, and SOHO. The mass calculations were then based on a more precise Thomson-scattering geometry. The subsequent estimate of the kinetic and potential energies of the CME took advantage of the more accurate mass, and the height and speed in a 3D frame. The released free magnetic energy resulting from the NLFFF model is about  $6.4 \times 10^{31}$  erg, which has a possible upper limit of  $1.8 \times 10^{32}$  erg. The thermal and nonthermal energies are lower than the radiative output of  $2.2 \times 10^{31}$  erg from SDO/EVE for this event. The total radiation covering the whole solar spectrum is probably a few times larger. The sum of the kinetic and potential energy of the CME could go up to  $6.5 \times 10^{31}$  erg. Therefore, the free energy is able to power the flare and the CME in AR 11283. Within the uncertainty, the flare and the CME may consume a similar amount of free energy.

## Comparisons of CME Morphological Characteristics Derived from Five 3D Reconstruction Methods

L. **Feng**<sup>1, 2</sup>, B. Inhester<sup>2</sup> and M. Mierla

Solar Phys., January **2013**, Volume 282, Issue 1, pp 221-238; **File**

We compare different methods to reconstruct three-dimensional (3D) coronal mass ejection (CME) morphology. The explored methods include geometric localisation, mask fitting, forward modelling, polarisation ratio, and local correlation tracking plus triangulation. These five methods are applied to the same CME event that occurred on **7 August 2010**. Their corresponding results are presented and compared, especially in their propagation direction and spatial extent in 3D. We find that the mask fitting and geometric localisation methods produce consistent results. Reconstructions including three-view observations are more precise than reconstructions done with only two views. Compared to the forward modelling method, in which an a priori shape of the CME geometry is assumed, the mask fitting has more flexibility. The polarisation ratio method makes use of the Thomson scattering geometry. We find that spatially the 3D CME derived from the mask fitting lies mostly in the overlap region obtained with the polarisation method using data from STEREO. In addition, the mask fitting can help resolve the front/back ambiguity inherent in the polarisation ratio method. However, the local correlation tracking plus triangulation did not show consistent results with the other four methods. This method performed poorly, primarily because the two STEREO spacecraft had a large angular separation. Under these circumstances, it is difficult to identify points taken from independent images that correspond to the same physical feature. Excluding the local correlation tracking method, the latitude of the CME's centre of gravity derived from the other methods deviates within  $1^\circ$ , and the longitude differs within  $19^\circ$ .

## RADIO SIGNATURES OF CORONAL-MASS-EJECTION-STREAMER INTERACTION AND SOURCE DIAGNOSTICS OF TYPE II RADIO BURST

S. W. **Feng**, Y. Chen, X. L. Kong, G. Li, H. Q. Song, X. S. Feng, and Ying Liu

**2012** ApJ **753** 21, **File**

It has been suggested that type II radio bursts are due to energetic electrons accelerated at coronal shocks. Radio observations, however, have poor or no spatial resolutions to pinpoint the exact acceleration locations of these electrons.

In this paper, we discuss a promising approach to infer the electron acceleration location by combining radio and white light observations. The key assumption is to relate specific morphological features (e.g., spectral bumps) of the dynamic spectra of type II radio bursts to imaging features (e.g., coronal mass ejection (CME) going into a streamer) along the CME (and its driven shock) propagation. In this study, we examine the CME-streamer interaction for the solar eruption dated on **2003 November 1**. The presence of spectral bump in the relevant type II radio burst is identified, which is interpreted as a natural result of the shock-radio-emitting region entering the dense streamer structure. The study is useful for further determinations of the location of type II radio burst and the associated electron acceleration by CME-driven shock.

## **MORPHOLOGICAL EVOLUTION OF A THREE-DIMENSIONAL CORONAL MASS EJECTION CLOUD RECONSTRUCTED FROM THREE VIEWPOINTS**

L. Feng<sup>1,2</sup>, B. Inhester<sup>2</sup>, Y. Wei<sup>2</sup>, W. Q. Gan<sup>1</sup>, T. L. Zhang<sup>3</sup>, and M. Y. Wang

**2012 ApJ 751 18**

The propagation properties of coronal mass ejections (CMEs) are crucial to predict its geomagnetic effect. A newly developed three-dimensional (3D) mask fitting reconstruction method using coronagraph images from three viewpoints has been described and applied to the CME ejected on **2010 August 7**. The CME's 3D localization, real shape, and morphological evolution are presented. Due to its interaction with the ambient solar wind, the morphology of this CME changed significantly in the early phase of evolution. Two hours after its initiation, it was expanding almost self-similarly. The CME's 3D localization is quite helpful to link remote sensing observations to in situ measurements. The investigated CME was propagating to Venus with its flank just touching STEREO B. Its corresponding interplanetary CME in the interplanetary space shows a possible signature of a magnetic cloud with a preceding shock in Venus Express (VEX) observations, while from STEREO B only a shock is observed. We have calculated three principal axes for the reconstructed 3D CME cloud. The orientation of the major axis is, in general, consistent with the orientation of a filament (polarity inversion line) observed by SDO/AIA and SDO/HMI. The flux rope axis derived by the Minimal Variance Analysis from VEX indicates a radial-directed axis orientation. It might be that locally only the leg of the flux rope passed through VEX. The height and speed profiles from the Sun to Venus are obtained. We find that the CME speed possibly had been adjusted to the speed of the ambient solar wind flow after leaving the COR2 field of view and before arriving at Venus. A southward deflection of the CME from the source region is found from the trajectory of the CME geometric center. We attribute it to the influence of the coronal hole where the fast solar wind emanated from.

## **Streamer Wave Events Observed in Solar Cycle 23**

S. W. Feng, Y. Chen, B. Li, H. Q. Song, X. L. Kong, L. D. Xia and X. S. Feng

*Solar Phys* (2011) 272:119–136, **File**

In this paper we conduct a data survey searching for well-defined streamer wave events observed by the Large Angle and Spectrometric Coronagraph (LASCO) on-board the Solar and Heliospheric Observatory (SOHO) throughout Solar Cycle 23. As a result, eight candidate events are found and presented here. We compare different events and find that in most of them the driving CMEs' ejecta are characterized by a high speed and a wide angular span, and the CME-streamer interactions occur generally along the flank of the streamer structure at an altitude no higher than the bottom of the field of view of LASCO C2. In addition, all front-side CMEs have accompanying flares. These common observational features shed light on the excitation conditions of streamer wave events.

We also conduct a further analysis on one specific streamer wave event on 5 June 2003. The heliocentric distances of four wave troughs/crests at various exposure times are determined; they are then used to deduce the wave properties like period, wavelength, and phase speeds. It is found that both the period and wavelength increase gradually with the wave propagation along the streamer plasma sheet, and the phase speed of the preceding wave is generally faster than that of the trailing ones. The associated coronal seismological study yields the radial profiles of the Alfvén speed and magnetic field strength in the region surrounding the streamer plasma sheet. Both quantities show a general declining trend with time. This is interpreted as an observational manifestation of the recovery process of the CME-disturbed corona. It is also found that the Alfvénic critical point is at about  $10 R_{\odot}$ , where the flow speed, which equals the Alfvén speed, is  $\sim 200 \text{ km s}^{-1}$ .

## **Evolution of a Halo Coronal Mass Ejection of **March 09, 2012** Associated with EUV Waves**

**Fernandes**, F. C. R.; Sampaio, L. S.; Cunha-Silva, R. D.

Ground-based Solar Observations in the Space Instrumentation Era

ASP Conference Series, Vol. 504, p. 67, **2016**

<http://aspbooks.org/publications/504/067.pdf>

In this work we analyse the evolution of a halo coronal mass ejection (CME) observed on **March 09, 2012**, exhibiting a velocity of  $950 \text{ ms}^{-1}$ . The EUV images recorded by the Extreme Ultraviolet Imager (EUVI), aboard STEREO show evidence of a shockwave produced by the expansion of the CME. The event was also associated with an M.6 class X-ray solar flare, starting at 03:22 UT, peaking at 03:53 UT and ending at 04:18 UT. Type II radio emission was also recorded in the metric wavelength (100–250 MHz) by e-Callisto spectrographs. The following spectrum-temporal

parameters of type II burst were estimated: starting frequency of  $(220 \pm 5)$  MHz, ending frequency of  $(170 \pm 5)$  MHz, frequency bandwidth of 34.3 MHz and starting and ending time of about 03:41:51 UT and 03:46:49 UT, respectively.

## **Development of Torus and Kink Instabilities in Eruptive Prominences**

Boris **Filippov**

2024 ApJ 977 259

<https://iopscience.iop.org/article/10.3847/1538-4357/ad95fe/pdf>

Several filament eruptions with pronounced writhing of the axis of the structure are analyzed. Initially, smooth arches of eruptive filaments are transformed into large-scale helical structures with at least one complete turn due to the development of kink instability. However, the initiation of the eruptions seems to be caused not by the kink instability but by catastrophic loss of equilibrium or torus instability. Calculations of the decay index of the coronal potential magnetic field indicate that the studied filaments began to rise rapidly at heights where the decay index was close to unity, the threshold for the catastrophic loss of equilibrium of straight flux ropes. Although it is often assumed that the kink instability precedes the subsequent torus instability leading to a full eruption, these examples testify to the possibility of the reverse order of the eruption development. **2012 May 22. 2014 June 19, 2021 May 9**

## **Influence of the Geometrical Shape of a Prominence and Structure of the Coronal Magnetic Field on the Probability of Eruption, Flare Development, and Coronal Mass Ejection.**

**Filippov**, B.P.

*Geomagn. Aeron.* **64**, 11–18 (2024).

<https://doi.org/10.1134/S0016793223600777>

The equilibrium conditions of a magnetic flux rope containing a prominence depend on the properties of the surrounding magnetic field of the corona and geometry of the flux rope itself. The eruption of a prominence is usually associated with a loss of stability in the external field upon reaching a height above which the field decay index exceeds the critical value for eruptive instability development. For flux ropes with an axis in the form of a straight line or a circle, the critical value of the field decay index is 1–1.5. By extrapolating the magnetic field in the corona from field measurements in the photosphere, it would be possible to predict the probability of eruption of a particular prominence. However, taking into account the fact that the ends of the magnetic flux rope are rooted in the photosphere and remain fixed because they are frozen in the photospheric plasma, significantly affects the critical value of the index and complicates the forecasting problem. If the magnetic flux rope retains the shape of a torus segment in its evolution, then the critical value of the field decay index for its vertex depends on what part of the torus it constitutes, being minimal for approximately half the torus and having a value significantly less than unity. How the eruption of a flux rope will develop after loss of equilibrium also depends on what part of the complete torus it constitutes at the time of onset of eruption. Shorter flux ropes are accelerated very energetically, but briefly, generating stronger electric induction fields that trigger flare processes. However, the terminal velocity that a short flux rope can achieve during acceleration is less than that of longer ropes that accelerate less intensely but for a longer time. The induction effects of the latter are less pronounced, so that they are capable of producing only weak flarelike manifestations. Thus, the eruption of a short prominence, which has gained a relatively low velocity, can be stopped at a certain height in the corona without generating a coronal mass ejection, but such a “failed eruption” contributes to the development of flare phenomena. Conversely, eruptions of long prominences more often lead to coronal mass ejections and weak flare manifestations.

## **High-altitude Spider-type Prominence above the Magnetic Null Point**

Boris **Filippov**<sup>1</sup>

2023 ApJ 958 184

<https://iopscience.iop.org/article/10.3847/1538-4357/ad02f9/pdf>

Rather unique observations of a high-altitude spider-type prominence in 2023 February are presented. The prominence or corresponding filament on the disk was not visible all the time but could appear and disappear in the course of a particular day. However, it persisted during the whole half of a solar rotation, being observable from day to day starting from the east limb of the Sun to the west limb. We show that the prominence was located in sagged coronal field lines just above a coronal magnetic null point. The presence of the null point and magnetic dips above it is confirmed by calculations of the potential magnetic field. The mass of the prominence apparently was appearing due to the condensation of hot coronal plasma after several eruptions that occurred in an active-region complex where the prominence was located. The prominence material flowed down along widely spread large coronal loops as coronal rain and was sometimes swept away by subsequent eruptions. **2023 February 7-21, 15**

## **Rising of a magnetic null point in the wake of an erupting flux rope**

**Filippov**

Monthly Notices of the Royal Astronomical Society, Volume 512, Issue 1, May 2022, Pages 1357–1364,

<https://doi.org/10.1093/mnras/stac575>

Arcades of flare loops rise, slowing down in the wake of eruptive prominences. They lag significantly from the top of prominences and do not reach too great heights in the corona. It is widely accepted that their evolution is governed by the limited reconnection rate in the current sheet developed below the eruptive prominence. We suggest that the shape

of eruptive prominences may be the determining factor in the ascension of the arcade. Arcade deceleration and their limited heights are analysed in the frame of a simple rectangular circuit model representing prominence eruption. A null point that appears below the rising electric current does not follow it to a great height but is detained by the influence of the field created by currents flowing along the vertical segments, 'legs', of the rectangular contour. As a result, the flare loops are able to reach only limited heights even with fast reconnection in a small current sheet.

## Dependence of the eruptive filaments dynamics on their length

**B. Filippov**

MNRAS, Volume 509, Issue 4, February 2022, Pages 5713–5720,

<https://doi.org/10.1093/mnras/stab3403>

We analyse numerically a model of eruption of a thin flux rope with the endpoints frozen in the photosphere. The flux rope is assumed to maintain a shape of partial current-carrying torus staying initially in equilibrium in the external dipolar magnetic field. There is an unstable equilibrium point, which can be reached by slow evolution of the system, and then a catastrophic loss of equilibrium and flux-rope eruption follow. Parameters of eruption, such as acceleration, velocity, electric field generated at the null point, depend in particular on the initial length of the flux rope or in other words on the endpoints separation. Analysis of the sample of 30 eruptive events observed on the Sun in the period from 2012 to 2016 showed that the eruptions of shorter filaments are more often associated with flaring phenomena and not followed by coronal mass ejections (CMEs). Eruptions of most lengthy filaments are followed as a rule by CMEs but are much rarely associated with flares.

## Critical decay index for eruptions of 'short' filaments

**Boris Filippov**

MNRAS Volume 503, Issue 3, May 2021, Pages 3926–3930,

<https://doi.org/10.1093/mnras/stab756>

<https://arxiv.org/ftp/arxiv/papers/2103/2103.07231.pdf>

<https://academic.oup.com/mnras/article-pdf/503/3/3926/36900760/stab756.pdf>

Model of a partial current-carrying torus loop anchored to the photosphere is analyzed. Conditions of the catastrophic loss of equilibrium are considered and corresponding value of the critical decay index of external magnetic field is found. Taking into account line-tying conditions leads to non-monotonous dependence of the critical decay index on the height of the apex and length of the flux rope (its endpoints separation). For relatively short flux ropes, the critical decay index is significantly lower than unity, which is in contrast to widespread models with the typical critical decay index above unity. The steep decrease of the critical index with height at low heights is due to the sharp increase of the curvature of the flux-rope axis that transforms from a nearly straight line to a crescent.

## Mass of prominences experiencing failed eruptions

**B. Filippov**

PASAustralia 2021

<https://arxiv.org/pdf/2103.03634.pdf>

A number of solar filaments/prominences demonstrate failed eruptions, when a filament at first suddenly starts to ascend and then decelerates and stops at some greater height in the corona. The mechanism of the termination of eruptions is not clear yet. One of the confining forces able to stop the eruption is the gravity force. Using a simple model of a partial current-carrying torus loop anchored to the photosphere and photospheric magnetic field measurements as the boundary condition for the potential magnetic field extrapolation into the corona, we estimated masses of 15 eruptive filaments. The values of the filament mass show rather wide distribution in the range of  $4 \times 10^{15}$  -  $270 \times 10^{16}$ g. Masses of the most of filaments, laying in the middle of the range, are in accordance with estimations made earlier on the basis of spectroscopic and white-light observations. **2014 March 20**  
Table 1 and 2 Failed filament eruptions (2012-2016)

## Failed prominence eruptions near 24 cycle maximum

**B. Filippov**

MNRAS Volume 494, Issue 2, Pages 2166–2177, 2020

<https://arxiv.org/pdf/2003.12988.pdf>

<https://doi.org/10.1093/mnras/staa896>

We analyze 16 failed filament eruptions observed near 24 solar cycle maximum from May 2013 to July 2014. No significant rotation of filament spines is observed during the ascent in all studied failed eruptions, which does not support kink-instability mechanism of triggering the eruptions. We calculate potential magnetic field distributions in the corona above the initial locations of the filaments to study their height dependence. In seven events, the vertical profiles of the decay index  $n$  are monotonic. The other nine events occur in the regions with the switchback or saddle-like  $n$ -profiles. The direction of the horizontal field near the saddle bottom is turned through more than  $100^\circ$  relative its direction at the initial filament position, which reveals the quadrupolar magnetic configuration with null points in these regions. The eruptive filaments stop above the null points where the total Lorenz force is directed upward. The most reasonable force that can terminate filament ascending and balance the Lorenz force seems the gravity. **2014 March 22, 2014 March 28**

**Table 1.** Failed filament eruptions in the quadrupolar magnetic configuration

**Table 2.** Failed filament eruptions in the dipolar magnetic configuration

## **Solar Total Eclipse of 21 August 2017: Study of the Inner Corona Dynamical Events Leading to a CME**

Boris [Filippov](#), [Serge Koutchmy](#), [Nicolas Lefaudeux](#)

Solar Phys. 295:24 2020

<https://arxiv.org/pdf/2001.10203.pdf>

[sci-hub.si/10.1007/s11207-020-1586-4](https://sci-hub.si/10.1007/s11207-020-1586-4)

Total solar eclipse (TSE) coronal large and small scale events were reported in the historical literature but a definite synoptic coverage was missing for studying a relationship with the more general magnetic context of the solar-disk. We here analyze temporal changes in the solar corona before, during, and after the total solar eclipse on 21 August 2017 from a set of ground-based and of space-borne observations. High-quality ground-based white-light (W-L) observations and a deep image processing allow us to reveal these changes for the first time with a fraction of a one-minute time resolution. Displacements of a number of fine coronal features were measured for the first time at these small radial distances, using a diffraction limited instrument at a single site. The comparison with space-based observations, including observations from the *Solar Terrestrial Relations Observatory* (STEREO) mission, showed that the features belong to a slow coronal mass ejection (CME) propagating through the corona with the nearly constant speed of 250 km/s. Our TSE images provide the same typical velocity as measured at a distance of one solar radius from the surface. The event was initiated by coronal dynamics manifested by a prominence eruption that started just before the eclipse observations and an ascent of a U-shaped structure visible in the AIA 171 Å channel, which we assume as the lower part of a coronal cavity. The prominence material was observed draining down towards the chromosphere along the prominence arch. While the prominence disappears in the STEREO-A field-of-view at the height of about 6' above the limb, the corresponding flux rope seems to continue towards the outer corona and produces the slow CME with turbulent motion. The overall mass of the moving features is evaluated based on absolute photometrical data extracted from our best W-L eclipse image.

## **Mass ejections from the solar atmosphere**

**Review**

B P [Filippov](#)1

[Physics-Uspekhi](#), Volume 62, 847-864 2019

Uspekhi Fizicheskikh Nauk 189 (9) 905 - 924 (2019)

<https://doi.org/10.3367/UFNr.2018.10.038467>

<https://sci-hub.ru/10.3367/UFNe.2018.10.038467>

Coronal mass ejections are the largest-scale eruptive phenomenon in the solar system. Their drastic effect on space weather is a reason for the significant interest in observing, simulating, and forecasting these events. We describe the main features of mass ejections from the solar atmosphere, their physical parameters and frequency, and its dependence on the solar cycle phase. We consider potential sources of ejections in the solar atmosphere and magnetic field configurations wherein the energy needed for sudden explosive acceleration of large masses of matter can be stored. The main instabilities of coronal structures that lead to the triggering and development of eruptive processes are analyzed. We show that coronal mass ejections are related to other manifestations of solar activity, while the eruptive processes observed using various techniques in various layer of the solar atmosphere and interplanetary space are the same phenomenon. We discuss indicators of the Sun's pre-eruptive regions approaching a catastrophe and the options to use them to forecast eruptions and space weather disturbances.

## **Difference of source regions between fast and slow coronal mass ejections**

B. [Filippov](#)

PASAustralia 2019

<https://arxiv.org/pdf/1904.04060.pdf>

Coronal mass ejections (CMEs) are tightly related to filament eruptions and usually are their continuation in the upper solar corona. It is common practice to divide all observed CMEs into fast and slow ones. Fast CMEs usually follow eruptive events in active regions near big sunspot groups and associated with major solar flares. Slow CMEs are more related to eruptions of quiescent prominences located far from active regions. We analyze ten eruptive events with particular attention to the events on **2013 September 29** and on **2016 January 26**, one of which was associated with a fast CME, while another was followed by a slow CME. We estimated the initial store of free magnetic energy in the two regions and show the resemblance of pre-eruptive situations. The difference of late behaviour of the two eruptive prominences is a consequence of the different structure of magnetic field above the filaments. We estimated this structure on the basis of potential magnetic field calculations. Analysis of other eight events confirmed that all fast CMEs originate in regions with rapidly changing with height value and direction of coronal magnetic field.

## **Two Scenarios for the Eruption of Magnetic Flux Ropes in the Solar Atmosphere**

[Filippov](#), B.P., [Den, O.E.](#)

[Astronomy Reports](#) 62(5), c. 359-365 2018

<https://link.springer.com/content/pdf/10.1134%2FS1063772918050037.pdf>

Eruptions of material from lower to upper layers of the solar atmosphere can be divided into two classes. The first class of eruptions maintain their (usually loop-like) shapes as they increase in size (eruptive prominences), or display a sudden expansion of fairly shapeless clumps of plasma in all directions (flare sprays). The second class refers to narrow, collimated flows of plasma on various scales (spicules, surges, jets). It is obvious that the magnetic configurations in

which these phenomena develop differ: for the first class they form closed structures that confine the plasma, and in the second class open structures directing flows of plasma in a particular direction, as a rule, upward. At the same time, the mechanisms initiating eruptions of both classes could be similar, or even practically identical. This mechanism could be instability of twisted magnetic tubes (flux ropes), leading to different consequences under different conditions. It is shown that the results of eruptive instability are determined by the ratio of the scales of the magnetic flux rope and the confining coronal field, and also by the configuration of the ambient magnetic field in the corona. Observations of both types of eruptions are analyzed, the conditions for their development are examined, and phenomenological models are proposed. **April 13, 2010, January 27, 2012, April 10–11, 2013**

## Two-step solar filament eruptions

Boris **Filippov**

MNRAS **2017**

<https://arxiv.org/pdf/1712.08173.pdf>

Coronal mass ejections (CMEs) are closely related to eruptive filaments and usually are the continuation of the same eruptive process into the upper corona. There are failed filament eruptions when a filament decelerates and stops at some greater height in the corona. Sometimes the filament after several hours starts to rise again and develops into the successful eruption with a CME formation. We propose a simple model for the interpretation of such two-step eruptions in terms of equilibrium of a flux rope in a two-scale ambient magnetic field. The eruption is caused by a slow decrease of the holding magnetic field. The presence of two critical heights for the initiation of the flux-rope vertical instability allows the flux rope to stay after the first jump some time in a metastable equilibrium near the second critical height. If the decrease of the ambient field continues, the next eruption step follows. **2011 October 18**

## Formation of a rotating jet during the filament eruption on 10-11 April 2013

B. **Filippov**, A. K. Srivastava, B. N. Dwivedi, S. Masson, G. Aulanier, N. C. Joshi, W. Uddin

MNRAS **2015**

<http://arxiv.org/pdf/1505.01615v1.pdf>

We analyze multi-wavelength and multi-viewpoint observations of a helically twisted plasma jet formed during a confined filament eruption on **10-11 April 2013**. Given a rather large scale event with its high spatial and temporal resolution observations, it allows us to clearly understand some new physical details about the formation and triggering mechanism of twisting jet. We identify a pre-existing flux rope associated with a sinistral filament, which was observed several days before the event. The confined eruption of the filament within a null point topology, also known as an Eiffel tower (or inverted-Y) magnetic field configuration results in the formation of a twisted jet after the magnetic reconnection near a null point. The sign of helicity in the jet is found to be the same as that of the sign of helicity in the filament. Untwisting motion of the reconnected magnetic field lines gives rise to the accelerating plasma along the jet axis. The event clearly shows the twist injection from the pre-eruptive magnetic field to the jet.

## Solar Magnetic Flux Ropes

**Review**

Boris **Filippov**, Olesya Martsenyuk, Abhishek K. Srivastava, and Wahab Uddin

Journal of Astrophysics & Astronomy, **2015**

<http://arxiv.org/ftp/arxiv/papers/1501/1501.02562.pdf>

The most probable initial magnetic configuration of a CME is a flux rope consisting of twisted field lines which fill the whole volume of a dark coronal cavity. The flux ropes can be in stable equilibrium in the coronal magnetic field for weeks and even months, but suddenly they lose their stability and erupt with high speed. Their transition to the unstable phase depends on the parameters of the flux rope (i.e., total electric current, twist, mass loading etc.), as well as on the properties of the ambient coronal magnetic field. One of the major governing factors is the vertical gradient of the coronal magnetic field which is estimated as decay index ( $n$ ). Cold dense prominence material can be collected in the lower parts of the helical flux tubes. Filaments are therefore good tracers of the flux ropes in the corona, which become visible long before the beginning of the eruption. The perspectives of the filament eruptions and following CMEs can be estimated by the comparison of observed filament heights with calculated decay index distributions. The present paper reviews the formation of magnetic flux ropes, their stable and unstable phases, eruption conditions, and also discusses their physical implications in the solar corona. **18.08.1995, June 17, 1998, 23.12.1998, 08.10.1999, 19.12.2000, 26.05.2001, 30.05.2001, 24.07.2001, August 1, 2001, 18.08.2001, 31.08.2001, 21.09.2001, 02.11.2002, 04.08.2004, 28.02.2005, 25 September 2011, 10-12 November 2001, 3-4 Aug 2012**

## Effects of coronal mass ejections on distant coronal streamers

B. P. **Filippov**, P. Kayshap, A. K. Srivastava, O. V. Martsenyuk

Astronomy Reports, August **2014**, Volume 58, Issue 8, pp 578-586

Astronomicheskii Zhurnal, **2014**, Vol. 91, No. 8, pp. 668–676.

<http://arxiv.org/pdf/1408.4324v1.pdf>

The effects of a large coronal mass ejection (CME) on a solar coronal streamer located roughly  $90^\circ$  from the main direction of the CME propagation observed on **January 2, 2012** by the SOHO/LASCO coronagraph are analyzed. Radial coronal streamers undergo some bending when CMEs pass through the corona, even at large angular distances from the streamers. The phenomenon resembles a bending wave traveling along the streamer. Some researchers interpret these phenomena as the effects of traveling shocks generated by rapid CMEs, while others suggest they are waves excited inside the streamers by external impacts. The analysis presented here did not find convincing arguments

in favor of either of these interpretations. It is concluded that the streamer behavior results from the effect of the magnetic field of a moving magnetic flux rope associated with the coronal ejection. The motion of the large-scale magnetic flux rope away from the Sun changes the surrounding magnetic field lines in the corona, and these changes resemble the half-period of a wave running along the streamer.

## **Filament eruption with apparent reshuffle of endpoints**

Boris [Filippov](#)

MNRAS, 2014

<http://arxiv.org/pdf/1405.5784v1.pdf>

Filament eruption on **30 April - 1 May 2010**, which shows the reconnection of one filament leg with a region far away from its initial position, is analyzed. Observations from three viewpoints are used for as precise as possible measurements of endpoint coordinates. The northern leg of the erupting prominence loop 'jumps' laterally to the latitude lower than the latitude of the originally southern endpoint. Thus, the endpoints reshuffled their positions in the limb view. Although this behaviour could be interpreted as the asymmetric zipping-like eruption, it does not look very likely. It seems more likely to be reconnection of the flux-rope field lines in its northern leg with ambient coronal magnetic field lines rooted in a quiet region far from the filament. From calculations of coronal potential magnetic field, we found that the filament before the eruption was stable for vertical displacements, but was liable to violation of the horizontal equilibrium. This is unusual initiation of an eruption with combination of initial horizontal and vertical flux-rope displacements showing a new unexpected possibility for the start of an eruptive event.

## **Filament eruption on 2010 October 21 from three viewpoints**

Boris [Filippov](#)

E-print, June 2013, [File](#); ApJ

A filament eruption on **2010 October 21** observed from three different viewpoints by the Solar Terrestrial Relations Observatory (STEREO) and the Solar Dynamic Observatory (SDO) is analyzed with invoking also data from the Solar and Heliospheric Observatory (SOHO) and the Kanzelhöhe Solar Observatory. The position of the filament just before the eruption at the central meridian not far from the center of the solar disk was favorable for photospheric magnetic field measurements in the area below the filament. Because of this, we were able to calculate with high precision the distribution of the coronal potential magnetic field near the filament. We found that the filament began to erupt when it approached the height in the corona where the magnetic field decay index was greater than one. We determined also that during the initial stage of the eruption the filament moved along the magnetic neutral surface

## **Formation of a White-Light Jet Within a Quadrupolar Magnetic Configuration**

Boris [Filippov](#) · Serge Koutchmy · Ehsan Tavabi

Solar Phys (2013) 286:143–156

We analyze multi-wavelength and multi-viewpoint observations of a large-scale event viewed on **7 April 2011**, originating from an active-region complex. The activity leads to a white-light jet being formed in the outer corona. The topology and evolution of the coronal structures were imaged in high resolution using the Atmospheric Imaging Assembly (AIA) onboard the Solar Dynamics Observatory (SDO). In addition, large field-of-view images of the corona were obtained using the Sun Watcher using Active Pixel System detector and Image Processing (SWAP) telescope onboard the PROject for Onboard Autonomy (PROBA2) microsatellite, providing evidence for the connectivity of the coronal structures with outer coronal features that were imaged with the Large Angle Spectrometric Coronagraph (LASCO) C2 on the Solar and Heliospheric Observatory (SOHO). The data sets reveal an Eiffel-tower type jet configuration extending into a narrow jet in the outer corona. The event starts from the growth of a dark area in the central part of the structure. The darkening was also observed in projection on the disk by the Solar TERrestrial RELations Observatory-Ahead (STEREO-A) spacecraft from a different point of view. We assume that the dark volume in the corona descends from a coronal cavity of a flux rope that moved up higher in the corona but still failed to erupt. The quadrupolar magnetic configuration corresponds to a saddle-like shape of the dark volume and provides a possibility for the plasma to escape along the open field lines into the outer corona, forming the white-light jet.

## **Electric Current Equilibrium in the Corona**

Boris [Filippov](#)

Solar Physics, April 2013, Volume 283, Issue 2, pp 401-411

A hyperbolic flux-tube configuration containing a null point below the flux rope is considered as a pre-eruptive state of coronal mass ejections that start simultaneously with flares. We demonstrate that this configuration is unstable and cannot exist for a long time in the solar corona. The inference follows from general equilibrium conditions and from analyzing simple models of the flux-rope equilibrium. A direct consequence of the stable flux-rope equilibrium in the corona are separatrices in the horizontal-field distribution in the chromosphere. They can be recognized as specific "herring-bone structures" in a chromospheric fibril pattern.

## Deflection of coronal rays by remote CMEs: shock wave or magnetic pressure?

Boris [Filippov](#)<sup>1</sup> and A.K. Srivastava<sup>2</sup>

E-print, June 2009, [File](#), Solar Phys.

We analyze five events of the interaction of coronal mass ejections (CMEs) with the remote coronal rays located up to 90° away from the CME as observed by the SOHO/LASCO C2 coronagraph. Using sequences of SOHO/LASCO C2 images, we estimate the kink propagation in the coronal rays during their interaction with the corresponding CMEs ranging from 180 to 920 km s<sup>-1</sup> within the interval of radial distances from 3 R<sub>☉</sub> to 6 R<sub>☉</sub>. We conclude that all studied events do not correspond to the expected pattern of shock wave propagation in the corona. Coronal ray deflection can be interpreted as the influence of the magnetic field of a moving flux rope related to a CME. The motion of a large-scale flux rope away from the Sun creates changes in the structure of surrounding field lines, which are similar to the kink propagation along coronal rays. The retardation of the potential should be taken into account since the flux rope moves at high speed comparable with the Alfvén speed.

## (Stellar) Coronal mass ejections and type II radio emission variability during a magnetic cycle on the solar-type star ε Eridani

[Dúalta Ó Fionnagáin](#), [Robert D. Kavanagh](#), [Aline A. Vidotto](#), [Sandra V. Jeffers](#), [Pascal Petit](#), [Stephen Marsden](#), [Julien Morin](#), [Aaron A Golden](#)

ApJ 2021

<https://arxiv.org/pdf/2111.02284.pdf>

We simulate possible stellar coronal mass ejection (CME) scenarios over the magnetic cycle of ε Eridani (18 Eridani; HD 22049). We use three separate epochs from 2008, 2011, and 2013, and estimate the radio emission frequencies associated with these events. These stellar eruptions have proven to be elusive, although a promising approach to detect and characterise these phenomena are low-frequency radio observations of potential type II bursts as CME induced shocks propagate through the stellar corona. **Stellar type II radio bursts** are expected to emit below 450 MHz, similarly to their solar counterparts. We show that the length of time these events remain above the ionospheric cutoff is not necessarily dependent on the stellar magnetic cycle, but more on the eruption location relative to the stellar magnetic field. We find that these type II bursts would remain within the frequency range of LOFAR for a maximum of 20-30 minutes post-eruption for the polar CMEs, (50 minutes for 2nd harmonics). We find evidence of slower equatorial CMEs, which result in slightly longer observable windows for the 2008 and 2013 simulations. Stellar magnetic geometry and strength has a significant effect on the detectability of these events. We place the CMEs in the context of the stellar mass-loss rate (27-48 × solar mass-loss rate), showing that they can amount to 3-50% of the stellar wind mass-loss rate for ε Eridani. Continuous monitoring of likely stellar CME candidates with low-frequency radio telescopes will be required to detect these transient events.

## Global Forces in Eruptive Solar Flares: The Lorentz Force Acting on the Solar Atmosphere and the Solar Interior

G. H. [Fisher](#), D. J. Bercik, B. T. Welsch and H. S. Hudson

Solar Physics, Volume 277, Number 1, 59-76, 2012

We compute the change in the Lorentz force integrated over the outer solar atmosphere implied by observed changes in vector magnetograms that occur during large, eruptive solar flares. This force perturbation should be balanced by an equal and opposite force perturbation acting on the solar photosphere and solar interior. The resulting expression for the estimated force change in the solar interior generalizes the earlier expression presented by Hudson, Fisher, and Welsch (Astron. Soc. Pac. CS-383, 221, 2008), providing horizontal as well as vertical force components, and provides a more accurate result for the vertical component of the perturbed force. We show that magnetic eruptions should result in the magnetic field at the photosphere becoming more horizontal, and hence should result in a downward (toward the solar interior) force change acting on the photosphere and solar interior, as recently argued from an analysis of magnetogram data by Wang and Liu (Astrophys. J. Lett. 716, L195, 2010). We suggest the existence of an observational relationship between the force change computed from changes in the vector magnetograms, the outward momentum carried by the ejecta from the flare, and the properties of the helioseismic disturbance driven by the downward force change. We use the impulse driven by the Lorentz-force change in the outer solar atmosphere to derive an upper limit to the mass of erupting plasma that can escape from the Sun. Finally, we compare the expected Lorentz-force change at the photosphere with simple estimates from flare-driven gasdynamic disturbances and from an estimate of the perturbed pressure from radiative backwarming of the photosphere in flaring conditions.

## Analysis of the helical kink stability of differently twisted magnetic flux ropes

[Marta Florido-Llinas](#), [Teresa Nieves-Chinchilla](#), [Mark G. Linton](#)

Solar Phys. 295, Article number: 118 2020

<https://arxiv.org/pdf/2007.06345.pdf>

<https://link.springer.com/content/pdf/10.1007/s11207-020-01687-z.pdf>

Magnetic flux ropes (MFRs) are usually considered to be the magnetic structure that dominates the transport of helicity from the Sun into the heliosphere. They entrain a confined plasma within a helically organized magnetic structure and are able to cause geomagnetic activity. The formation, evolution and twist distribution of MFRs are issues subject to strong debate. Although different twist profiles have been suggested so far, none of them has been thoroughly explored yet. The aim of this paper is to present a theoretical study of the conditions under which MFRs with different twist profiles are kink stable and thereby shed some light on the aforementioned discussions. The magnetic field is modeled according to the circular-cylindrical analytical flux rope model in Nieves-Chinchilla et al. (2016) as well as the Lundquist and Gold-Hoyle models, and the kink stability is analyzed with a numerical method that has been developed based on Linton, Longcope, and Fisher (1996). The results are discussed in relation to MFR rotations, magnetic forces, the reversed chirality scenario and the expansion throughout the heliosphere, among others, providing a theoretical background to improve the current understanding of the internal magnetic configuration of CMEs. The data obtained by new missions like Parker Solar Probe or Solar Orbiter will give the opportunity to explore these results and ideas by observing MFRs closer than ever to the Sun.

## **Polarimetric Reconstruction of Coronal Mass Ejections from LASCO-C2 Observations**

O. **Floyd**, P. Lamy

[Solar Physics](#) November 2019, 294:168

<https://link.springer.com/content/pdf/10.1007%2Fs11207-019-1553-0.pdf>

The three-dimensional morphology and direction of propagation of coronal mass ejections (CMEs) are essential information for identifying their source on the solar disk, for understanding the processes of their ejection and propagation in the corona, and for forecasting their possible impact with the Earth or any other objects in the solar system. The polarization of the Thomson scattering by an electron is known to provide information on its position with respect to the plane of the sky. This polarimetric technique is applied to reconstruct 15 CMEs on the basis of white-light polarized images obtained with the Large Angle Spectrometric Coronagraph (LASCO) C2, which have been extensively corrected for instrumental effects. It does provide valuable results in spite of the time delays between the three observations required to build the polarization maps. Most of these CMEs exhibit complex structures making a classification in terms of simple shapes such as arcade of loops or flux rope difficult or even questionable. Three of these CMEs benefited from multiple observations allowing us to follow their three-dimensional development as they propagated outward. All CMEs are tracked back to the solar surface and in several instances, active regions are identified as the probable sources. Finally, the projected speeds and masses derived from white-light unpolarized observations have been corrected for the projection angle to produce unbiased values. **4 November 1998, 4 January 2002, 9 July 2002, 18 July 2002, 1 August 2002, 2 August 2002, 3 August 2002, 7 August 2002, 3 June 2005, 17 January 2010, 8 March 2011, 25 October 2011, 8 December 2011, 12 January 2012, 17 September 2013, 11 May 2014**

## **The Interaction Between Coronal Mass Ejections and Streamers: A Statistical View over 15 Years (1996 – 2010)**

O. **Floyd**, P. Lamy, A. Llebaria

[Solar Physics](#), April 2014, Volume 289, Issue 4, pp 1313-1339; **File**

We report on the statistical analysis of the interaction between coronal mass ejections (CMEs) and streamers based on 15 years (from 1996 to 2010 inclusive) of observation of the solar corona with the LASCO-C2 coronagraph. We used synoptic maps and improved the method of analysis of past investigations by implementing an automatic detection of both CMEs and streamers. We identified five categories of interaction based on photometric and geometric variations between the pre- and post-CME streamers: “brightening”, “dimming”, “emergence”, “disappearance”, and “deviation”. A sixth category, “no change”, included all cases where none of the above variations is observed. A “global set” of 21 242 CMEs was considered as well as a subset of the 10 % brightest CMEs (denoted “top-ten”) and three typical periods of solar activity: minimum, intermediate, and maximum. We found that about half of the global population of CMEs are not associated with streamers, whereas 93 % of the 10 % brightest CMEs are associated. When there is a CME-streamer association, approximately 95 % of the streamers experience a change, either geometric or radiometric. The “no change” category therefore amounts to approximately 5 %, but this percentage varies from 1 – 2 % during minimum to 7 – 8 % during intermediate periods of activity; values of 3 – 5 % are recorded during maximum. Emergences and disappearances of streamers are not dominant processes; they constitute 16 – 17 % of the global set and 23 % (emergence) and 28 % (disappearance) of the “top-ten” set. Streamer deviations are observed for 57 % and 70 % of, respectively, the global set and “top-ten” CMEs. The cases of dimming and brightening are roughly equally present and each case constitutes approximately 30 – 35 % of either set, global or “top-ten”.

## **ARTEMIS II: A Second-Generation Catalog of LASCO Coronal Mass Ejections Including Mass and Kinetic Energy**

O. **Floyd**, P. Lamy, Y. Boursier, A. Llebaria

E-print, May 2013; [Solar Physics](#), November 2013, Volume 288, Issue 1, pp 269-289; **File**

The ARTEMIS-I catalog of coronal mass ejections (CMEs) was initially developed on a first generation of low-resolution synoptic maps constructed from the SOHO/LASCO-C2 images of the K-corona and resulted in an online database listing all events detected since January 1996 (Boursier et al., [Solar Phys.](#) 257, 125, 2009). A new generation

of synoptic maps with higher temporal (a factor of 1.5) and angular (a factor of 2.5) resolutions allowed us to reconsider the question of CME detection and resulted in the production of a new catalog: ARTEMIS-II. The parameters estimated for each detected CME are still the date and time of appearance, the position angle, the angular width, and (when detected at several solar distances) the global and median velocities. The new synoptic maps correct for the limited number of velocity determinations reported in the ARTEMIS-I catalog. We now determine the propagation velocity of 79 % of detected CMEs instead of 30 % in the previous version. A final major improvement is the estimation of the mass and kinetic energy of all CMEs for which we could determine the velocity, that is  $\approx 13\,000$  CMEs until December 2010. Individual comparisons of velocity determination of 23 CMEs for which a full three-dimensional kinematical solution has been published indicate that ARTEMIS-II performs extremely well except at the highest velocities, an intrinsic limitation of our method. Finally, individual comparisons of mass determination of seven CMEs for which a robust solution has been obtained from stereographic observations demonstrate the quality of the ARTEMIS-II results.

## **X-ray Flare Associated with a Quiescent Filament Eruption and Coronal Mass Ejection**

**Foord**, Adi; Holman, Gordon D.

American Astronomical Society, AAS Meeting #225, #137.08, **2015**

To date, solar active regions are where most flares are found to occur. We present an analysis of multi-waveband observations of the large eruption of a 'quiescent' (outside of an active region) solar filament contemporaneous with X-ray emission. The eruption covers a 2-day time span, from **2013 September 29 to 2013 September 30**. The event was observed using the Reuven Ramaty High Energy Solar Spectroscopic Imager (RHESSI), the Solar Dynamics Observatory (SDO), and the Fermi Gamma-ray Space Telescope. Though not classified as a flare, the GOES class of the event was C1 and the X-ray light curves include a small impulsive-phase peak followed by a gradual-phase rise. The eruption produced a coronal mass ejection (CME) with a velocity of 1179 km/s. SDO Atmospheric Imaging Assembly (AIA) movies during the time span show that the filament lies outside any active region on the sun, and spans a length on the order of 600 arcseconds. Spatially resolved RHESSI emission during the gradual phase is found to come from an area along the post-eruption arcade, close to the westward expanding ribbon but confined to a length of only 150 arcseconds. No RHESSI emission is found along the eastward expanding ribbon. We infer the strength and geometry of the magnetic field during the eruption with the SDO Helioseismic and Magnetic Imager (HMI) and find a small ( $\sim 100$  arcseconds long) dipolar element within the filament channel that appears to be spatially correlated with the RHESSI emission. The dipolar element is observed to have magnetic field strengths as high as 1000 Gauss. The evolution of both the X-ray emission and AIA data support the notion that the flare was a consequence of magnetic reconnection between the dipole's magnetic field and the magnetic field supporting the filament. We conclude that solar eruptive events, which consist of both a flare and a CME, can occur outside active regions in association with a quiescent filament eruption if new, sufficiently strong magnetic flux emerges in the immediate area and reconnects with the filament's magnetic field.

<https://link.springer.com/content/pdf/10.1007/s11214-006-9019-8.pdf>

This chapter provides an overview of current efforts in the theory and modeling of CMEs. Five key areas are discussed: (1) CME initiation; (2) CME evolution and propagation; (3) the structure of interplanetary CMEs derived from flux rope modeling; (4) CME shock formation in the inner corona; and (5) particle acceleration and transport at CME driven shocks. In the section on CME initiation three contemporary models are highlighted. Two of these focus on how energy stored in the coronal magnetic field can be released violently to drive CMEs. The third model assumes that CMEs can be directly driven by currents from below the photosphere. CMEs evolve considerably as they expand from the magnetically dominated lower corona into the advectively dominated solar wind. The section on evolution and propagation presents two approaches to the problem. One is primarily analytical and focuses on the key physical processes involved. The other is primarily numerical and illustrates the complexity of possible interactions between the CME and the ambient medium. The section on flux rope fitting reviews the accuracy and reliability of various methods. The section on shock formation considers the effect of the rapid decrease in the magnetic field and plasma density with height. Finally, in the section on particle acceleration and transport, some recent developments in the theory of diffusive particle acceleration at CME shocks are discussed. These include efforts to combine self-consistently the process of particle acceleration in the vicinity of the shock with the subsequent escape and transport of particles to distant regions.

## **A review on the genesis of coronal mass ejections**

**Review**

T. G. **FORBES**

Journal of Geophysical Research, Volume 105, Issue A10, p. 23153-23166, **2000**

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2000JA000005>

This paper provides a short review of some of the basic concepts related to the origin of coronal mass ejections (CMEs). The various ideas which have been put forward to explain the initiation of CMEs are categorized in terms of whether they are force-free or non-force-free and ideal or nonideal. A few representative models of each category are examined to illustrate the principles involved. At the present time there is no model which is sufficiently developed to aid forecasters in their efforts to predict CMEs, but given the current pace of research, this situation could improve dramatically in the near future.

### **Coronal Cavity Survey: Morphological Clues to Eruptive Magnetic Topologies**

B. C. [Forland](#), S. E. Gibson, J. B. Dove, L. A. Rachmeler, Y. Fan

*Solar Phys* (2013) 288:603–615

We present a survey on coronal prominence cavities conducted using 19 months of data from the Atmospheric Imaging Assembly (AIA) instrument aboard the Solar Dynamics Observatory (SDO) satellite. Coronal cavities are elliptical regions of rarefied density lying above and around prominences. They can be long-lived (weeks to months) but are often observed to eventually erupt as part of a coronal mass ejection (CME). We determine morphological properties of the cavities both by qualitatively assessing their shape, and quantitatively fitting them with ellipses. We demonstrate consistency between these two approaches, and find that fitted ellipses are taller than they are wide for almost all cavities studied, in agreement with an earlier analysis of white-light cavities. We examine correlations between cavity shape, aspect ratio, and propensity for eruption. We find that cavities with a teardrop-shaped morphology are more likely to erupt, and we discuss the implications of this morphology for magnetic topologies associated with CME models. We provide the full details of the survey for broad scientific use as supplemental material.

### **KELVIN-HELMHOLTZ INSTABILITY OF THE CME RECONNECTION OUTFLOW LAYER IN THE LOW CORONA**

Claire [Foullon](#)<sup>1</sup>, Erwin Verwichte<sup>1</sup>, Katariina Nykyri<sup>2</sup>, Markus J. Aschwanden<sup>3</sup>, and Iain G. Hannah

E-print, Sept 2013; 2013 *ApJ* 767 170

New capabilities for studying the Sun allow us to image for the first time the magnetic Kelvin-Helmholtz (KH) instability developing at the surface of a fast coronal mass ejection (CME) less than 150 Mm above the solar surface. We conduct a detailed observational investigation of this phenomenon, observed off the east solar limb on **2010 November 3**, in the EUV with SDO/AIA. In conjunction with STEREO-B/EUVI, we derive the CME source surface position. We ascertain the timing and early evolution of the CME outflow leading to the instability onset. We perform image and spectral analysis, exploring the CME plasma structuring and its parabolic flow pattern. As we evaluate and validate the consistency of the observations with theoretical considerations and predictions, we take the view that the ejection layer corresponds to a reconnection outflow layer surrounding the erupting flux rope, accounting for the timing, high temperature (~11.6 MK), and high flow shear (~680 km s<sup>-1</sup>) on the unstable CME northern flank and for the observed asymmetry between the CME flanks. From the irregular evolution of the CME flow pattern, we infer a shear gradient consistent with expected spatial flow variations across the KH-unstable flank. The KH phenomenon observed is tied to the first stage of a linked flare-CME event.

### **MAGNETIC KELVIN-HELMHOLTZ INSTABILITY AT THE SUN**

*Astrophysical Journal Letters*, 729:L8 (4pp), 2011 March

Flows and instabilities play a major role in the dynamics of magnetized plasmas including the solar corona, magnetospheric and heliospheric boundaries, cometary tails, and astrophysical jets. The nonlinear effects, multiscale and microphysical interactions inherent to the flow-driven instabilities, are believed to play a role, e.g., in plasma entry across a discontinuity, generation of turbulence, and enhanced drag. However, in order to clarify the efficiency of macroscopic instabilities in these processes, we lack proper knowledge of their overall morphological features. Here we show the first observations of the temporally and spatially resolved evolution of the magnetic Kelvin-Helmholtz instability in the solar corona. Unprecedented high-resolution imaging observations of vortices developing at the surface of a fast coronal mass ejection are taken by the new *Solar Dynamics Observatory*, validating theories of the nonlinear dynamics involved. The new findings are a cornerstone for developing a unifying theory on flow-driven instabilities in rarefied magnetized plasmas, which is important for understanding the fundamental processes at work in key regions of the Sun-Earth system.

*New capabilities for studying the Sun allow us to detect and image KH waves for the first time, in a fast coronal mass ejection (CME) event where the instability develops at the flank of the CME ejection. 2010 November 3.*

2024 *ApJ* 964 15

<https://iopscience.iop.org/article/10.3847/1538-4357/ad26fb/pdf>

On **2021 September 28**, a C1.6 class flare occurred in active region NOAA 12871, located approximately at 27°S and 51°W on the solar disk with respect to Earth's point of view. This event was followed by a partial halo coronal mass ejection (CME) that caused the deflection of preexisting coronal streamer structures, as observed in visible-light coronagraphic images. An associated type II radio burst was also detected by both space- and ground-based instruments, indicating the presence of a coronal shock propagating into interplanetary space. By using H  $\alpha$  and Ly $\alpha$  (121.6 nm) observations from the Metis coronagraph on board the Solar Orbiter mission, we demonstrate for the first time the capability of UV imaging to provide, via a Doppler dimming technique, an upper limit estimate of the evolution of the 2D proton kinetic temperature in the CME-driven shock sheath as it passes through the field of view of the instrument. Our results suggest that over the 22 minutes of observations, the shock propagated with a speed decreasing from about  $740 \pm 110$  km s<sup>-1</sup> to  $400 \pm 60$  km s<sup>-1</sup>. At the same time, the postshock proton temperatures peaked at latitudes around the shock nose and decreased with time from about  $6.8 \pm 1.01$  MK to  $3.1 \pm 0.47$  MK. The application of the Rankine–Hugoniot jump conditions demonstrates that these temperatures are higher by a factor of about 2–5 than those expected from simple adiabatic compression, implying that significant shock heating is still going on at these distances.

## Estimate of Plasma Temperatures Across a CME-Driven Shock from a Comparison Between EUV and Radio Data

Federica [Frassati](#), [Salvatore Mancuso](#) & [Alessandro Bemporad](#)

[Solar Physics](#) volume 295, Article number: 124 (2020)

<https://link.springer.com/content/pdf/10.1007/s11207-020-01686-0.pdf>

In this work, we analyze the evolution of an EUV wave front associated with a solar eruption that occurred on **30 October 2014**, with the aim of investigating, through differential emission measure (DEM) analysis, the physical properties of the plasma compressed and heated by the accompanying shock wave. The EUV wave was observed by the Atmospheric Imaging Assembly (AIA) onboard the Solar Dynamics Observatory (SDO) and was accompanied by the detection of a metric Type II burst observed by ground-based radio spectrographs. The EUV signature of the shock wave was also detected in two of the AIA channels centered at 193 Å and 211 Å as an EUV intensity enhancement propagating ahead of the associated CME. The density compression ratio  $X$  of the shock as inferred from the analysis of the EUV data is  $X \approx 1.23$ , in agreement with independent estimates obtained from the analysis of the Type II band-splitting of the radio data and inferred by adopting the upstream–downstream interpretation. By applying the Rankine–Hugoniot jump conditions under the hypothesis of a perpendicular shock, we also estimate the temperature ratio as  $T_D/T_U \approx 1.55$  and the post-shock temperature as  $T_D \approx 2.75$  MK. The modest compression ratio and temperature jump derived from the EUV analysis at the shock passage are typical of weak coronal shocks. **CESRA #2735 Dec 2020** <http://www.astro.gla.ac.uk/users/eduard/cesra/?p=2735>

## Comprehensive Analysis of the Formation of a Shock Wave Associated with a Coronal Mass Ejection

Federica [Frassati](#)<sup>1,2</sup>, Roberto Susino<sup>1</sup>, Salvatore Mancuso<sup>1</sup>, and Alessandro Bemporad

**2019** ApJ 871 212

<http://sci-hub.tw/10.3847/1538-4357/aaf9af>

On **2014 November 1**, a solar prominence eruption associated with a C2.7 class flare and a type II radio burst resulted in a fast partial halo coronal mass ejection (CME). Images acquired in the extreme ultraviolet (EUV) by the Solar Dynamics Observatory/Atmospheric Imaging Assembly (AIA) and PROBA2/SWAP and in white light (WL) by Solar and Heliospheric Observatory/Large Angle and Spectrometric Coronagraph show the expansion of a bright compression front ahead of the CME. In this work, we present a detailed investigation of the CME-driven shock associated with this event following the early evolution of the compression front observed near the Sun up to the extended corona. Our aim is to shed light on the long-debated issue concerning the location and timing of shock formation in the corona. Through differential emission measure analysis, we derived, for the first time, the compression ratio across the expanding EUV front observed by AIA at different temperature ranges: higher compression ratios corresponded to higher plasma temperature ranges, as expected. Moreover, comparison between up- and downstream temperatures and those expected via adiabatic compression shows that no additional heating mechanisms occurred in the early front expansion phase, implying that the shock formed beyond the AIA field of view. Finally, the analysis of the associated type II radio burst, in combination with the inferred coronal density distribution, allowed us to identify a well-defined region located northward of the CME source region as the site for shock formation and to outline its kinematics in accordance with the evolution of the expanding front as obtained from the EUV and WL data.

## Study of the early phase of a Coronal Mass Ejection driven shock in EUV images

Federica [Frassati](#), Roberto Susino, Salvatore Mancuso & Alessandro Bemporad

Astrophysics and Space Science October **2017**, 362:194

<https://link.springer.com/content/pdf/10.1007%2Fs10509-017-3173-1.pdf>

The **November 1st, 2014** prominence eruption (associated with a C2.7 class flare) resulted in a fast, partial-halo Coronal Mass Ejection (CME). During its early propagation, the CME produced a type II radio burst (seen by the Bruny Island Radio Spectrometer) starting around 04:57 UT when the front entered into the LASCO/C2 field of view (FOV) and the top of the CME front was at the heliocentric distance of about  $2.5 R_{\odot}$ . In order to identify the source of the type II radio burst, we studied the kinematic of the eruption with EUV images acquired by SDO/AIA. Profiles of the observed EUV front speed have been compared with the Alfvén speed profiles derived by combining the plasma electron densities obtained from Emission Measure analysis and model magnetic fields extrapolated on the plane of the

sky. Our results show that the northern half of the front became super-Alfvénic at approximately the same time when the type-II radio burst started. A comparison between the starting frequency of the type II emission and the frequencies corresponding to the coronal densities of the locations where the EUV front became super-Alfvénic suggests that the radio sources should be located in the northern flank of the front.

## **CORONAL MASS EJECTION RECONSTRUCTION FROM THREE VIEWPOINTS VIA SIMULATION MORPHING. I. THEORY AND EXAMPLES**

Richard A. [Frazin](#)

2012 ApJ 761 24

The problem of reconstructing the three-dimensional (3D) density distribution of a coronal mass ejection (CME) from three simultaneous coronagraph observations is timely in that the COR1 and COR2 coronagraphs on the dual-spacecraft STEREO mission complement the LASCO coronagraphs on the SOHO satellite and the Mk4 on Mauna Loa. While the separation angle between the STEREO spacecraft and the Earth depends on the time since the launch in 2006, the reconstruction problem is always severely underinformed. So far, all 3D reconstruction efforts have made use of relatively simple parameterized models in order to determine the 3D structure of the CME. Such approaches do not utilize the power of 3D MHD simulation to inform the reconstruction. This paper considers the situation in which a specific CME event observed in coronagraphs from three viewpoints is later simulated by solving MHD equations. The reconstruction is then subjected to an invertible morphological operator chosen so that morphed MHD simulation is most consistent with the three-viewpoint coronagraph data. The morphological operations are explained mathematically and synthetic examples are given. The practical application to reconstructing CMEs from STEREO and SOHO data is discussed.

## **Intercomparison of the LASCO-C2, SECCHI-COR1, SECCHI-COR2, and Mk4 Coronagraphs**

Richard A. [Frazin](#), Alberto M. Vásquez, William T. Thompson, Russell J. Hewett, Philippe Lamy, Antoine Llebaria, Angelos Vourlidis and Joan Burkepile

Solar Physics, Volume 280, Number 1 (2012), 273-293, **2012**, DOI: 10.1007/s11207-012-0028-3

In order to assess the reliability and consistency of white-light coronagraph measurements, we report on quantitative comparisons between polarized brightness [pB] and total brightness [B] images taken by the following white-light coronagraphs: LASCO-C2 on SOHO, SECCHI-COR1 and -COR2 on STEREO, and the ground-based MLSO-Mk4. The data for this comparison were taken on **16 April 2007**, when both STEREO spacecraft were within  $3.1^\circ$  of Earth's heliographic longitude, affording essentially the same view of the Sun for all of the instruments. Due to the difficulties of estimating stray-light backgrounds in COR1 and COR2, only Mk4 and C2 produce reliable coronal-hole values (but not at overlapping heights), and these cannot be validated without rocket flights or ground-based eclipse measurements. Generally, the agreement between all of the instruments' pB values is within the uncertainties in bright streamer structures, implying that measurements of bright CMEs also should be trustworthy. Dominant sources of uncertainty and stray light are discussed, as is the design of future coronagraphs from the perspective of the experiences with these instruments.

## **TOWARD RECONSTRUCTION OF CORONAL MASS EJECTION DENSITY FROM ONLY THREE POINTS OF VIEW**

R. A. [Frazin](#)<sup>1</sup>, M. Jacob<sup>2</sup>, W. B. Manchester IV<sup>1</sup>, H. Morgan<sup>3,4</sup>, and M. B. Wakin<sup>5</sup>

Astrophysical Journal, 695:636–641, **2009** April

<http://www.iop.org/EJ/toc/-alert=43190/0004-637X/695/1>

Understanding the structure of coronal mass ejections (CMEs) is one of the primary challenges in solar astrophysics. White-light coronagraphs make images of line-of-sight projections of the CME electron density ( $N_e$ ). The combination of the coronagraphs on the STEREO and *SOHO* spacecraft provides three simultaneous viewpoints that vary in angle with time, according to the spacecraft orbits. Three viewpoints are not enough to permit tomographic reconstruction via classical methods, but we argue here that recent advances in image processing methods that take into account prior information about the CME geometry may allow one to determine the CME density structure with only three viewpoints. The prior information considered here is that the CME is separated from a known (or simple) background by a closed surface, which may be described by a level set. We propose an alternating iterative procedure in which the surface is evolved via geometric partial differential equations in one step and the interior (and exterior)  $N_e$  values are determined in the next step.

## **Predicting relationships between solar jet variables**

Leonard A [Freeman](#)

2019

<https://arxiv.org/ftp/arxiv/papers/1904/1904.08289.pdf>

Studies of spicules and similar solar jets have revealed a strong correlation between some of the kinematic variables, particularly between the initial velocity  $V$ , and the subsequent deceleration,  $a$ . It has been proposed that this is caused by, and offers proof for a shock wave mechanism acting on the spicules. However it is shown here that these correlations arise simply from the statistics of the sample of spicules being studied, for example in the range of spicule heights. The relationship between two kinematic variables has been expressed as a linear equation but there is no general agreement on the actual linear equation, which shows wide variations. The reason for these variations is analysed and it is shown how the different linear equations can be derived from the co-ordinates of a single point: the mean spicule height and deceleration of the group of spicules being studied. Another method sometimes used is to determine the correlation coefficient of two of the kinematic variables from their scatter plots. It is shown how this too can be calculated from the sample statistics. The problems of the linear equations for the  $(a, V)$  correlation disappear if a square law relationship is used instead, which also provides a simple physical interpretation of the results. The implications of these results and the possibility that spicule behaviour is partly due to magnetic fields are discussed.

## **The high helium abundance and charge states of the interplanetary CME and its material source on the Sun**

[Hui Fu](#), [R.A. Harrison](#), [J.A. Davies](#), [LiDong Xia](#), [XiaoShuai Zhu](#), [Bo Li](#), [ZhengHua Huang](#), [D. Barnes](#)

ApJL 2020

<https://arxiv.org/pdf/2008.08816.pdf>

Identifying the source of the material within coronal mass ejections (CMEs) and understanding CME onset mechanisms are fundamental issues in solar and space physics. Parameters relating to plasma composition, such as charge states and He abundance ( $\lambda_{\text{He}}$ ), may be different for plasmas originating from differing processes or regions on the Sun. Thus, it is crucial to examine the relationship between in-situ measurements of CME composition and activity on the Sun. We study the CME that erupted on **2014 September 10**, in association with an X1.6 flare, by analyzing AIA imaging and IRIS spectroscopic observations and its in-situ signatures detected by Wind and ACE. We find that during the slow expansion and intensity increase of the sigmoid, plasma temperatures of 9 MK, and higher, first appear at the footpoints of the sigmoid, associated with chromospheric brightening. Then the high-temperature region extends along the sigmoid. IRIS observations confirm that this extension is caused by transportation of hot plasma upflow. Our results show that chromospheric material can be heated to 9 MK, and above, by chromospheric evaporation at the sigmoid footpoints before flare onset. The heated chromospheric material can transport into the sigmoidal structure and supply mass to the CME. The aforementioned CME mass supply scenario provides a reasonable explanation for the detection of high charge states and elevated  $\lambda_{\text{He}}$  in the associated ICME. The observations also demonstrate that the quasi-steady evolution in the precursor phase is dominated by magnetic reconnection between the rising flux rope and the overlying magnetic field structure.

## **Physical processes involved in the EUV "Surge" Event of 09 May 2012**

Marcelo López [Fuentes](#), [Cristina H. Mandrini](#), [Mariano Poisson](#), [Pascal Démoulin](#), [Germán](#)

[Cristiani](#), [Fernando M. López](#), [Maria Luisa Luoni](#)

Solar Phys. 293:166 2018

<https://link.springer.com/content/pdf/10.1007%2Fs11207-018-1384-4.pdf>

We study an EUV confined ejection observed on **09 May 2012** in active region (AR) NOAA 11476. For the analysis we use observations in multiple wavelengths (EUV, X-rays,  $H\alpha$ , and magnetograms) from a variety of ground-based and space instruments. The magnetic configuration showed the presence of two rotating bipoles, with decreasing magnetic flux, within the following polarity of the AR. This evolution was present along some tens of hours before the studied event and continued even later. A minifilament with a length of  $\approx 30$  arcsec lay along the photospheric inversion line of the largest bipole. The minifilament was observed to erupt accompanied by an M4.7 flare (SOL20120509T12:23:00). Consequently, dense material, as well as twist, was injected along closed loops in the form of a very broad ejection whose morphology resembles that of typical  $H\alpha$  surges. We conclude that the flare and eruption can be explained as due to two reconnection processes, one occurring below the erupting minifilament and another one above it. This second process injects the minifilament plasma within the reconnected closed loops linking the main AR polarities. Analyzing the magnetic topology using a force-free model of the coronal field, we identify the location of quasi-separatrix layers (QSLs), where reconnection is prone to occur, and present a detailed interpretation of the chromospheric and coronal eruption observations. In particular, this event, contrary to what has been proposed in several models explaining surges and/or jets, is not originated by magnetic flux emergence but by magnetic flux cancellation accompanied by the rotation of the bipoles. In fact, the conjunction of these two processes, flux cancellation and bipole rotations, is at the origin of a series of events, homologous to the one we analyze in this article, that occurred in AR 11476 from **08 to 10 May 2012**.

## **Global Nature of Solar Coronal Shock Waves shown by Inconsistency between EUV Waves and Type II Radio Bursts**

Aarti [Fulara](#), [Ryun-Young Kwon](#)

ApJLetters 2021

<https://arxiv.org/pdf/2109.01509.pdf>

We re-examine the physical relationship between Extreme-Ultraviolet (EUV) waves and type II radio bursts. It has been often thought that they are two observational aspects of a single coronal shock wave. However, a lack of their speed correlation hampers the understanding of their respective (or common) natures in a single phenomenon. Knowing the uncertainties in identifying true wave components from observations and measuring their speeds, we re-examine the speeds of EUV waves reported in previous literature and compare these with type II radio bursts and Coronal Mass Ejections (CMEs). This confirms the inconsistency between the speeds of EUV waves and their associated type II radio bursts. Second, CME speeds are found to have a better correlation with type II radio bursts than EUV waves. Finally, there exists a tendency for type II speeds and their range to be much greater than those of EUV waves. We demonstrate that the speed inconsistency is in fact an intrinsic tendency and elucidate the nature of a coronal shock wave consisting of both driven and non-driven parts. This suggests that the speed inconsistency would remain even if all other uncertainties were removed. **2013 April 11**

P.T. **Gallagher**, C.A. Young <sup>1, b</sup>, J.P. Byrnea, R.T.J. McAteera

E-print, Apr 2010, *Adv. Space Res.* Volume 47, Issue 12, 15 June 2011, Pages 2118-2126

Coronal mass ejections (CMEs) are large-scale eruptions of plasma and magnetic field that can produce adverse space weather at Earth and other locations in the Heliosphere. Due to the intrinsic multiscale nature of features in coronagraph images, wavelet and multiscale image processing techniques are well suited to enhancing the visibility of CMEs and suppressing noise. However, wavelets are better suited to identifying point-like features, such as noise or background stars, than to enhancing the visibility of the curved form of a typical CME front. Higher order multiscale techniques, such as ridgelets and curvelets, were therefore explored to characterise the morphology (width, curvature) and kinematics (position, velocity, acceleration) of CMEs. Curvelets in particular were found to be well suited to characterizing CME properties in a self-consistent manner. Curvelets are thus likely to be of benefit to autonomous monitoring of CME properties for space weather applications.

### **Rapid acceleration of a coronal mass ejection in the low corona and implications for propagation**

**Gallagher**, P. T., G. R. Lawrence, and B. R. Dennis,  
*ApJL*, 588(1), L53–L56. (2003), **File**

A high-velocity coronal mass ejection (CME) associated with the **2002 April 21 X1.5** flare is studied using a unique set of observations from the *Transition Region and Coronal Explorer (TRACE)*, the Ultraviolet Coronagraph Spectrometer (UVCS), and the Large Angle and Spectroscopic Coronagraph (LASCO). The event is first observed as a rapid rise in *GOES* X-rays, followed by two simultaneous brightenings that appear to be connected by an ascending looplike feature. While expanding, the appearance of the feature remains remarkably constant as it passes through the *TRACE* 195 Å passband and LASCO fields of view, allowing its height-time behavior to be accurately determined. The acceleration is consistent with an exponential rise with an *e*-folding time of ~138 s and peaks at ~1500 m s<sup>-2</sup> when the leading edge is at ~1.7 R<sub>sun</sub> from Sun center. The acceleration subsequently falls off with an *e*-folding time of over 1000 s. At distances beyond ~3.4 R<sub>sun</sub>, the height-time profile is approximately linear with a constant velocity of ~2500 km s<sup>-1</sup>. These results are briefly discussed in light of recent kinematic models of CMEs.

### **Eruptions from Quiet Sun Coronal Bright Points. II. Non-Potential Modeling**

Klaus **Galsgaard**, [Maria S. Madjarska](#), [Duncan H. Mackay](#), [Chaozhou Mou](#)

A&A 623, A78

2019

<https://arxiv.org/pdf/1901.09875.pdf>

Our recent observational study shows that the majority of coronal bright points (CBPs) in the quiet Sun are sources of one or more eruptions during their lifetime. Here, we investigate the non-potential time dependent structure of the magnetic field of the CBP regions with special emphasis on the time evolving magnetic structure at the spatial locations where the eruptions are initiated. The magnetic structure is evolved in time using a Non-Linear Force Free Field (NLFFF) relaxation approach, based on a time series of Helioseismic and Magnetic Imager (HMI) longitudinal magnetograms. This results in a continuous time series of NLFFFs. The time series is initiated with a potential field extrapolation based on a magnetogram taken well before the time of the eruptions. This initial field is then evolved in time in response to the observed changes in the magnetic field distribution at the photosphere. The local and global magnetic field structures from the time series of NLFFF field solutions are analysed in the vicinity of the eruption sites at the approximate times of the eruptions. The analysis shows that many of the CBP eruptions reported in Mou et al. (2018) contain twisted flux tube located at the sites of eruptions. The presence of flux ropes at these locations provides in many cases a direct link between the magnetic field structure, their eruption and the observation of mini coronal mass ejections (mini-CMEs). It is found that all repetitive eruptions are homologous. The NLFFF simulations show that twisted magnetic field structures are created at the locations hosting eruptions in CBPs. These twisted structures are produced by footpoint motions imposed by changes in the photospheric magnetic field observations. The true nature of the micro-flares remains unknown. Further 3D data-driven MHD modelling is required to show how these twisted regions become unstable and erupt. **01-03 Jan 2011**

## Correcting Projection Effects in CMEs using GCS-based Large Statistics of Multi-viewpoint Observations

[Harshita Gandhi](#), [Ritesh Patel](#), [Vaibhav Pant](#), [Satabdwa Majumdar](#), [Sanchita Pal](#), [Dipankar Banerjee](#), [Huw Morgan](#)

Space weather **Volume22, Issue2** e2023SW003805 **2024**

<https://arxiv.org/pdf/2402.07961.pdf>

<https://doi.org/10.1029/2023SW003805>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2023SW003805>

This study addresses the limitations of single-viewpoint observations of Coronal Mass Ejections (CMEs) by presenting results from a 3D catalog of 360 CMEs during solar cycle 24, fitted using the GCS model. The dataset combines 326 previously analyzed CMEs and 34 newly examined events, categorized by their source regions into active region (AR) eruptions, active prominence (AP) eruptions, and prominence eruptions (PE). Estimates of errors are made using a bootstrapping approach. The findings highlight that the average 3D speed of CMEs is  $\sim 1.3$  times greater than the 2D speed. PE CMEs tend to be slow, with an average speed of  $432 \text{ km s}^{-1}$ . AR and AP speeds are higher, at  $723 \text{ km s}^{-1}$  and  $813 \text{ km s}^{-1}$ , respectively, with the latter having fewer slow CMEs. The distinctive behavior of AP CMEs is attributed to factors like overlying magnetic field distribution or geometric complexities leading to less accurate GCS fits. A linear fit of projected speed to width gives a gradient of  $2 \text{ km s}^{-1} \text{ deg}^{-1}$ , which increases to  $5 \text{ km s}^{-1} \text{ deg}^{-1}$  when the GCS-fitted 'true' parameters are used. Notably, AR CMEs exhibit a high gradient of  $7 \text{ km s}^{-1} \text{ deg}^{-1}$ , while AP CMEs show a gradient of  $4 \text{ km s}^{-1} \text{ deg}^{-1}$ . PE CMEs, however, lack a significant speed-width relationship. We show that fitting multi-viewpoint CME images to a geometrical model such as GCS is important to study the statistical properties of CMEs, and can lead to a deeper insight into CME behavior that is essential for improving future space weather forecasting. **2013/04/05**, **2016/04/04**, **2017/09/04**

## The Broken Lane of a Type II Radio Burst Caused by Collision of a Coronal Shock with a Flare Current Sheet

Guannan [Gao](#), Min Wang, Ning Wu, Jun Lin, E. Ebenezer, Baolin Tan

Solar Phys. Volume 291, **Issue 11**, pp 3369–3384 **2016**

<https://arxiv.org/pdf/1612.01784v1.pdf>

We investigated a peculiar metric type II solar radio burst with a broken lane structure, which was observed on **November 13, 2012**. In addition to the radio data, we also studied the data in the other wavelengths. The bursts were associated with two CMEs and two flares that originated from active region AR 11613. A long current sheet was developed in the first CME, and the second CME collided with the current sheet first and then merged with the first one. Combining information revealed by the multi-wavelength data indicated that a coronal shock accounting for the type II radio burst, and that the collision of this shock with the current sheet resulted in the broken lane of the type II radio burst. The type II burst lane resumed after the shock passed through the current sheet. We further estimated the thickness of the current sheet according to the gap on the lane of the type II burst, and found that the result is consistent with previous ones obtained for various events observed in different wavelengths by different instruments. In addition, the regular type II burst associated with the first CME/flare was also studied, and the magnetic field in each source region of the two type II bursts was further deduced in different way.

## Phase Relationships Between the CME-Energy Cycle, the Sunspot-Area Cycle and the Flare-Index Cycle

P. X. [Gao](#), J. L. Xie, J. Zhong

Solar Phys., Volume 289, Issue 5, pp 1831-1841. **2014**

We study the phase relationships between the coronal-mass-ejection (CME) energy cycle, the sunspot-area cycle, and the flare-index cycle from 1996 to 2010. The results show the following: i) The activity cycle of the flare index significantly leads the activity cycle of the sunspot area. ii) The activity cycle of the CME energy is inferred to be almost in phase with the activity cycle of the sunspot area; the activity cycle of the CME energy at low latitudes slightly leads the activity cycle of the sunspot area; the CME energy at high latitudes is shown to significantly lag behind the sunspot area. iii) The CME energy is shown to significantly lag behind the flare index; the CME energy at low latitudes is shown to slightly lag behind the flare index; the CME energy at high latitudes is shown to significantly lag behind the flare index.

### **Radio observations of the fine structure inside a post-CME current sheet**

Guan-Nan **Gao**<sup>1,2,3</sup>, Min Wang<sup>1,3,4</sup>, Jun Lin<sup>1</sup>, Ning Wu<sup>5</sup>, Cheng-Ming Tan<sup>4</sup>, Bernhard Kliem<sup>1,6</sup> and Yang Su<sup>7</sup>

Research in Astronomy and Astrophysics, Volume 14, Number 7, 843-854, **2014**

A solar radio burst was observed in a coronal mass ejection/flare event by the Solar Broadband Radio Spectrometer at the Huairou Solar Observing Station on **2004 December 1**. The data exhibited various patterns of plasma motions, suggestive of the interaction between sunward moving plasmoids and the flare loop system during the impulsive phase of the event. In addition to the radio data, the associated white-light, H $\alpha$ , extreme ultraviolet light, and soft and hard X-rays were also studied.

### **Distributions of Energy and Mass of Coronal Mass Ejections**

P. X. **Gao**, K. J. Li and J. C. Xu

Solar Physics, Volume 273, Number 1, 117-123, **2011**, File

The present study investigates the energy and mass distributions of all (11 322) coronal mass ejections (CMEs), 1406 CMEs associated solely with flares (FL CMEs), and 325 CMEs associated solely with filament eruptions (FE CMEs), all of which were observed by the Large Angle and Spectrometric Coronagraph on board the Solar and Heliospheric Observatory (SOHO/LASCO) from January 1996 to December 2009. The results show the following. i) The mean energy of FL CMEs is significantly lower than that of all CMEs. The mean energy of FE CMEs is significantly higher than those of FL CMEs and all CMEs. ii) The mean mass of FL CMEs is slightly larger than that of all CMEs. The mean mass of FE CMEs is significantly larger than those of FL CMEs and all CMEs. Our results suggest that CMEs should shed excess helicity stored in the corona and that the magnetic complexity determines the likelihood of CMEs.

### **Speed Distributions of CMEs in Cycle 23 at Low and High Latitudes \***

Peng-Xin **Gao** and Ke-Jun Li

Chin. J. Astron. Astrophys. Vol. 8 (**2008**), No. 2, 146–152

<http://www.chjaa.org>

**Abstract** We analyzed the speed ( $v$ ) distributions of 11584 coronal mass ejections (CMEs) observed by the Large Angle and Spectrometric Coronagraph Experiment on board the Solar and Heliospheric Observatory (SOHO/LASCO) in cycle 23 from 1996 to 2006. We find that the speed distributions for high-latitude (HL) and low-latitude (LL) CME events are nearly identical and to a good approximation they can be fitted with a lognormal distribution. This finding implies that statistically the same driving mechanism of a nonlinear nature is acting in both HL and LL CME events, and CMEs are intrinsically associated with the source's magnetic structure on large spatial scales. Statistically, the HL CMEs are slightly slower than the LL CMEs. For HL and LL CME events respectively, the speed distributions for accelerating and decelerating events are nearly identical and also to a good approximation they can be both fitted with a lognormal distribution, thus supplementing the results obtained by Yurchyshyn et al.

### **Photometric Calibration of the LASCO-C2 Coronagraph over 14 Years (1996 – 2009)**

B. **Gardès**, P. Lamy, A. Llebaria

Solar Physics, April **2013**, Volume 283, Issue 2, pp 667-690

We present a photometric calibration of the SOHO/LASCO-C2 coronagraph based on the analysis of all stars down to magnitude  $V=8$  that transited its field of view during the past 14 years of operation (1996–2009), extending the previous work of Llebaria, Lamy, and Danjard (Icarus 182, 281, 2006). The pre-processing of the images incorporates the most recent determination of the evolution of the LASCO-C2 performances. The automatic procedure then analyzes some 260 000 images to detect, locate, and measure those stars. Aperture photometry is performed using four different aperture sizes, and the zero points (ZPs) of the photometric transformations between the LASCO-C2 magnitudes for its orange filter and the standard  $V$  magnitudes are determined after introducing a correction for the color of the stars. A new statistical method (“bootstrap”) is introduced to assess the confidence intervals of the mean yearly value of the ZPs. The correction for finite aperture required to derive the calibration coefficient for the surface photometry of extended sources is based on the reconstructed image of bright saturated stars and a robust model for the growth curve. The

global temporal evolution of the sensitivity of LASCO-C2 is compatible with a continuous decrease at a rate of  $\approx 0.56$  % per year. However, it is better described by two separate linear variations with a discontinuity at the time of the loss of SOHO. After the resumption of normal operations in 1999, the linear decrease of the sensitivity amounts to  $\approx 0.35$  % per year.

## Nonlocal Ohms Law, Plasma Resistivity, and Reconnection During Collisions of Magnetic Flux Ropes

W. [Gekelman](#)<sup>1</sup>, T. DeHaas<sup>1</sup>, P. Pribyl<sup>1</sup>, S. Vincena<sup>1</sup>, B. Van Compernelle<sup>1</sup>, R. Sydora<sup>2</sup>, and S. K. P. Tripathi<sup>1</sup>

2018 ApJ 853 33

<http://sci-hub.tw/http://iopscience.iop.org/0004-637X/853/1/33/>

The plasma resistivity was evaluated in an experiment on the collision of two magnetic flux ropes. Whenever the ropes collide, some magnetic energy is lost as a result of reconnection. Volumetric data, in which all the relevant time-varying quantities were recorded in detail, are presented. Ohm's law is shown to be nonlocal and cannot be used to evaluate the plasma resistivity. The resistivity was instead calculated using the AC Kubo resistivity and shown to be anomalously high in certain regions of space.

<https://doi.org/10.1051/swsc/2021023>

The EU funded the FLARECAST project, that ran from Jan 2015 until Feb 2018. FLARECAST had a R2O focus, and introduced several innovations into the discipline of solar flare forecasting. FLARECAST innovations were: first, the treatment of hundreds of physical properties viewed as promising flare predictors on equal footing, extending multiple previous works; second, the use of fourteen (14) different ML techniques, also on equal footing, to optimize the immense Big Data parameter space created by these many predictors; third, the establishment of a robust, three-pronged communication effort oriented toward policy makers, space-weather stakeholders and the wider public. FLARECAST pledged to make all its data, codes and infrastructure openly available worldwide. The combined use of 170+ properties (a total of 209 predictors are now available) in multiple ML algorithms, some of which were designed exclusively for the project, gave rise to changing sets of best-performing predictors for the forecasting of different flaring levels. At the same time, FLARECAST reaffirmed the importance of rigorous training and testing practices to avoid overly optimistic pre-operational prediction performance. In addition, the project has (a) tested new and revisited physically intuitive flare predictors and (b) provided meaningful clues toward the transition from flares to eruptive flares, namely, events associated with coronal mass ejections (CMEs). These leads, along with the FLARECAST data, algorithms and infrastructure, could help facilitate integrated space-weather forecasting efforts that take steps to avoid effort duplication. In spite of being one of the most intensive and systematic flare forecasting efforts to-date, FLARECAST has not managed to convincingly lift the barrier of stochasticity in solar flare occurrence and forecasting: solar flare prediction thus remains inherently probabilistic. **12 Nov 2012, 2 January 2015, 5 Sep 2017**

## The source and engine of coronal mass ejections Review

Manolis K. [Georgoulis](#), [Alexander Nindos](#), and [Hongqi Zhang](#)

Philosophical Transactions of the Royal Society A: Mathematical, Physical and Engineering Sciences v. 377 Issue 2148 Article ID: 20180094 2019

<https://royalsocietypublishing.org/doi/pdf/10.1098/rsta.2018.0094>

Coronal mass ejections (CMEs) are large-scale expulsions of coronal plasma and magnetic field propagating through the heliosphere. Because CMEs are observed by white-light coronagraphs which, by design, occult the solar disc, supporting disc observations (e.g. in EUV, soft X-rays, Halpha and radio) must be employed for the study of their source regions and early development phases. We review the key properties of CME sources and highlight a certain causal sequence of effects that may occur whenever a strong (flux-massive and sheared) magnetic polarity inversion line develops in the coronal base of eruptive active regions (ARs). Storing non-potential magnetic energy and helicity in a much more efficient way than ARs lacking strong polarity inversion lines, eruptive regions engage in an irreversible course, making eruptions inevitable and triggered when certain thresholds of free energy and helicity are crossed. This evolution favours the formation of pre-eruption magnetic flux ropes. We describe the steps of this plausible path to sketch a picture of the pre-eruptive phase of CMEs that may apply to most events, particularly the ones populating the high end of the energy/helicity distribution, that also tend to have the strongest space-weather implications. **2007/12/05-07, 2012/03/05-06, 2012/07/18, 2015/02/09-10**

## Magnetic Complexity in Eruptive Solar Active Regions and Associated Eruption Parameters

Manolis K. **Georgoulis**

E-print Dec 2007, GRL

Using an efficient magnetic complexity index in the active-region solar photosphere, we quantify the preflare strength of the photospheric magnetic polarity inversion lines in 23 eruptive active regions with flare/CME/ICME events tracked all the way from the Sun to the Earth. We find that active regions with more intense polarity inversion lines host statistically stronger flares and faster, more impulsively accelerated, CMEs. No significant correlation is found between the strength of the inversion lines and the flare soft X-ray rise times, the ICME transit times, and the peak *Dst* indices of the induced geomagnetic storms. Corroborating these and previous results, we speculate on a possible interpretation for the connection between source active regions, flares, and CMEs. Further work is needed to validate this concept and uncover its physical details.

We investigated the interaction of a coronal mass ejection (CME) and a coronal hole (CH) in its vicinity using remote-sensing and 1 AU in situ data. We used extreme-ultraviolet images and magnetograms to identify coronal structures and coronagraph images to analyze the early CME propagation. The Wind spacecraft and the Advanced Composition Explorer (ACE) provide plasma and magnetic field data of near-Earth interplanetary space. We applied various diagnostic tools to the images and to the time-series data. We find that the CME erupts under a streamer and causes the evacuation of material at its far end, which is observable as dimming and subsequent CH formation. The CME is likely deflected in its early propagation and travels southwest of the Sun-Earth line. In situ data lack signatures of a large magnetic cloud, but show a small flux rope at the trailing edge of the interplanetary CME (ICME), followed by an Alfvénic wave. This wave is identified as exhaust from a Petschek-type reconnection region following the successful application of a Walén test. We infer that the two spacecraft at 1 AU most likely traverse the ICME leg that is in the process of reconnection along the heliospheric current sheet that separates the ICME and the high-speed stream outflowing from the CH. **2014: January 25, February 4-10, February 17**

### **Simulating the Formation of a Sigmoidal Flux Rope in AR10977 from SOHO/MDI**

#### **Magnetograms**

G. P. S. **Gibb**<sup>1</sup>, D. H. Mackay<sup>1</sup>, L. M. Green<sup>2</sup>, and K. A. Meyer

**2014** ApJ 782 71

The modeling technique of Mackay et al. is applied to simulate the coronal magnetic field of NOAA active region AR10977 over a seven day period (**2007 December 2-10**). The simulation is driven with a sequence of line-of-sight component magnetograms from SOHO/MDI and evolves the coronal magnetic field through a continuous series of non-linear force-free states. Upon comparison with Hinode/XRT observations, results show that the simulation reproduces many features of the active region's evolution. In particular, it describes the formation of a flux rope across the polarity inversion line during flux cancellation. The flux rope forms at the same location as an observed X-ray sigmoid. After five days of evolution, the free magnetic energy contained within the flux rope was found to be  $3.9 \times 10^{30}$  erg. This value is more than sufficient to account for the B1.4 GOES flare observed from the active region on **2007 December 7**. At the time of the observed eruption, the flux rope was found to contain 20% of the active region flux. We conclude that the modeling technique proposed in Mackay et al.—which directly uses observed magnetograms to energize the coronal field—is a viable method to simulate the evolution of the coronal magnetic field.

Magnetism defines the complex and dynamic solar corona. Twists and tangles in coronal magnetic fields build up energy and ultimately erupt, hurling plasma into interplanetary space. These coronal mass ejections (CMEs) are transient riders on the ever-outflowing solar wind, which itself possesses a three-dimensional morphology shaped by the global coronal magnetic field. Coronal magnetism is thus at the heart of any understanding of the origins of space weather at the Earth. However, we have historically been limited by the difficulty of directly measuring the magnetic fields of the corona, and have turned to observations of coronal plasma to trace out magnetic structure. This approach is complicated by the fact that plasma temperatures and densities vary among coronal magnetic structures, so that looking at any one wavelength of light only shows part of the picture. In fact, in some regimes it is the lack of plasma that is a significant indicator of the magnetic field. Such a case is the coronal cavity: a dark, elliptical region in which strong and twisted magnetism dwells. I will elucidate these enigmatic features by presenting observations of coronal cavities in multiple wavelengths and from a variety of observing vantages, including unprecedented coronal magnetic field measurements now being obtained by the Coronal Multichannel Polarimeter (CoMP). These observations demonstrate the presence of twisted magnetic fields within cavities, and also provide clues to how and why cavities ultimately erupt as CMEs. **5/25/11; 6/14/11; 6/24/11; 7/9/11; 7/14/11; 7/26/11; 7/27/11. <https://arxiv.org/pdf/1702.02214.pdf>

Dark and elliptical, coronal cavities yield important clues to the magnetic structures that cradle prominences, and to the forces that ultimately lead to their eruption. We review observational analyses of cavity morphology, thermal properties (density and temperature), line-of-sight and plane-of-sky flows, substructure including hot cores and central voids, linear polarization signatures, and observational precursors and predictors of eruption. We discuss a magnetohydrodynamic interpretation of these observations which argues that the cavity is a magnetic flux rope, and pose a set of open questions for further study. **July 22 2002, 16 June 2011, March 11-12, 2012, 16 May 2012, 23 July 2012,**

*Astrophysical Journal*, 724:1133–1146, **2010**

We present a three-dimensional density model of coronal prominence cavities, and a morphological fit that has been tightly constrained by a uniquely well-observed cavity. Observations were obtained as part of an International Heliophysical Year campaign by instruments from a variety of space- and ground-based observatories, spanning wavelengths from radio to soft X-ray to integrated white light. From these data it is clear that the prominence cavity is the limb manifestation of a longitudinally extended polar-crown filament channel, and that the cavity is a region of low density relative to the surrounding corona. As a first step toward quantifying density and temperature from campaign spectroscopic data, we establish the three-dimensional morphology of the cavity. This is critical for taking line-of-sight projection effects into account, since cavities are not localized in the plane of the sky and the corona is optically thin. We have augmented a global coronal streamer model to include a tunnel-like cavity with elliptical cross-section and a Gaussian variation of height along the tunnel length. We have developed a semi-automated routine that fits ellipses to cross-sections of the cavity as it rotates past the solar limb, and have applied it to Extreme Ultraviolet Imager observations from the two *Solar Terrestrial Relations Observatory* spacecraft. This defines the morphological parameters of our model, from which we reproduce forward modeled cavity observables. We find that cavity morphology and orientation, in combination with the viewpoints of the observing spacecraft, explain the observed variation in cavity visibility for the east versus west limbs.

### Partially ejected flux ropes: Implications for interplanetary coronal mass ejections,

**Gibson**, S. E., and Y. Fan,

E-print, March 2007; *J. Geophys. Res.*, 113, A09103 (**2008**); **File**

<http://dx.doi.org/10.1029/2008JA013151>

Connecting interplanetary coronal mass ejections (ICMEs) to their solar pre-eruption source requires a clear understanding of how that source may have evolved during eruption. Gibson and Fan (2006a) have presented a three-dimensional numerical magnetohydrodynamic simulation of a CME, which showed how, in the course of eruption, a coronal flux rope may writhe and reconnect both internally and with surrounding fields in a manner that leads to a partial ejection of only part of the rope as a CME. In this paper, we will explicitly describe how the evolution during eruption found in that simulation leads to alterations of the magnetic connectivity, helicity, orientation, and topology of the ejected portion of the rope so that it differs significantly from that of the pre-eruption rope. Moreover, because a significant part of the magnetic helicity remains behind in the lower portion of the rope that survives the eruption, the region is likely to experience further eruptions. These changes would complicate how ICMEs embedded in the solar wind relate to their solar source. In particular, the location and evolution of transient coronal holes, topology of magnetic clouds (“tethered spheromak”), and likelihood of interacting ICMEs would differ significantly from what would be predicted for a CME which did not undergo writhing and partial ejection during eruption.

### Partially-ejected flux ropes: implications for space weather

Sarah E. **Gibson**<sup>1</sup> and Yuhong Fan

Solar Activity and its Magnetic Origin, Proc. IAU Symposium No. 233, **2006**, Volker Bothmer, ed., **File**

The structure and evolution of the sources of solar activity directly affects the nature of space weather disturbances that reach the Earth. We have previously demonstrated that the loss of equilibrium and partial ejection of a coronal magnetic flux rope matches observations of coronal mass ejections (CMEs) and their precursors. In this paper we discuss the significance

of such a partially-ejected rope for space weather. We will consider how the evolution and bifurcation of the rope modifies it from its initial, source configuration. In particular, we will consider how reconnections and writhing motions lead to an escaping rope which has an axis rotated counterclockwise from the original rope axis orientation, and which is rooted in transient coronal holes external to the original source region.

### **Energy release from impacting prominence material following the 2011 June 7 eruption**

H. R. [Gilbert](#), A. R. Inglis, M. L. Mays, L. Ofman, B. J. Thompson, C. A. Young  
E-print, Sept 2013; 2013 ApJL 776 L12

Solar filaments exhibit a range of eruptive-like dynamic activity, ranging from the full or partial eruption of the filament mass and surrounding magnetic structure as a coronal mass ejection (CME), to a fully confined or 'failed' eruption. On **2011 June 7**, a dramatic partial eruption of a filament was observed by multiple instruments on SDO and STEREO. One of the interesting aspects of this event is the response of the solar atmosphere as non-escaping material falls inward under the influence of gravity. The impact sites show clear evidence of brightening in the observed EUV wavelengths due to energy release. Two plausible physical mechanisms explaining the brightening are considered: heating of the plasma due to the kinetic energy of impacting material compressing the plasma, or reconnection between the magnetic field of low-lying loops and the field carried by the impacting material. By analyzing the emission of the brightenings in several SDO/AIA wavelengths, and comparing the kinetic energy of the impacting material ( $7.6 \times 10^{26}$  -  $5.8 \times 10^{27}$  ergs) to the radiative energy ( $1.9 \times 10^{25}$  -  $2.5 \times 10^{26}$  ergs) we find the dominant mechanism of energy release involved in the observed brightening is plasma compression.

### **UVCS/SoHO Catalog of Coronal Mass Ejections from 1996 to 2005: Spectroscopic Proprieties**

S. [Giordano](#), A. Ciaravella, J. Raymond, Y.-K. Ko and R. Suleiman  
E-print, Feb 2013; JGR, 118, Issue 3, pages 967–981, March 2013  
<http://arxiv.org/pdf/1302.1998v2.pdf>

Ultraviolet spectra of the extended solar corona have been routinely obtained by SoHO/UVCS since 1996. Sudden variations of spectral parameters are mainly due to the detection of Coronal Mass Ejections (CMEs) crossing the instrumental slit. We present a catalog of CME ultraviolet spectra based upon a systematic search of events in the LASCO CME catalog, and we discuss their statistical properties. Our catalog includes 1059 events through the end of 2005, covering nearly a full solar cycle. It is online available at the URL [http://solarweb.oato.inaf.it/UVCS\\_CME](http://solarweb.oato.inaf.it/UVCS_CME) and embedded in the online LASCO CME catalog ([http://cdaw.gsfc.nasa.gov/CME\\_list](http://cdaw.gsfc.nasa.gov/CME_list)). The emission lines observed provide diagnostics of CME plasma parameters, such as the light-of-sight velocity, density and temperature and allow to link the CME onset data to the extended corona white-light images. The catalog indicates whether there are clear signatures of features such as shock waves, current sheets, O VI flares, helical motions and which part of the CME structures (front, cavity or prominence material) are detected. The most common detected structure is the cool prominence material (in about 70% of the events). For each event, the catalog also contains movie, images, plots and information relevant to address detailed scientific investigations. The number of events detected in UV is about 1/10 of the LASCO CMEs, and about 1/4 of the halo events. We find that UVCS tends to detect faster, more massive and energetic CME than LASCO and for about 40% of the events it has been possible to determine the plasma light-of-sight velocity. ### **Observation of Heating by Flare-accelerated Electrons in a Solar Coronal Mass Ejection**

Lindsay [Glesener](#), S?m Krucker, Hazel Bain, Robert Lin  
E-print, Dec 2013; 2013 ApJ 779 L29.

We report a Reuven Ramaty High Energy Solar Spectroscopic Imager (RHESSI) observation of flare-accelerated electrons in the core of a coronal mass ejection (CME) and examine their role in heating the CME. Previous CME observations have revealed remarkably high thermal energies that can far surpass the CME's kinetic energy. A joint observation by RHESSI and the Atmospheric Imaging Assembly of a partly occulted flare on **2010 November 3** allows

us to test the hypothesis that this excess energy is collisionally deposited by flare-accelerated electrons. Extreme ultraviolet (EUV) images show an ejection forming the CME core and sheath, with isothermal multifilter analysis revealing temperatures of  $\sim 11$  MK in the core. RHESSI images reveal a large ( $\sim 100 \times 50$  arcsec<sup>2</sup>) hard X-ray (HXR) source matching the location, shape, and evolution of the EUV plasma, indicating that the emerging CME is filled with flare-accelerated electrons. The time derivative of the EUV emission matches the HXR light curve (similar to the Neupert effect observed in soft and HXR time profiles), directly linking the CME temperature increase with the nonthermal electron energy loss, while HXR spectroscopy demonstrates that the **nonthermal electrons contain enough energy to heat the CME**. This is the most direct observation to date of flare-accelerated electrons heating a CME, emphasizing the close relationship of the two in solar eruptive events.

<https://link.springer.com/content/pdf/10.1007%2Fs11207-007-0260-4.pdf>

A series of flares (GOES class M, M and C) and a CME were observed in close succession on **20 January 2004** in NOAA 10540. Radio observations, which took the form of types II, III and N bursts, were associated with these events. We use the combined observations from TRACE, EIT, H $\alpha$  images from Kwasan, MDI magnetograms and GOES to understand the complex development of this event. Contrary to a standard interpretation, we conclude that the first two impulsive flares are part of the CME launch process while the following long-duration event flare represents simply the recovery phase. Observations show that the flare ribbons not only separate but also shift along the magnetic inversion line so that magnetic reconnection progresses stepwise to neighboring flux tubes. We conclude that “tether cutting” reconnection in the sheared arcade progressively transforms it to a twisted flux tube, which becomes unstable, leading to a CME. We interpret the third flare, a long-duration event, as a combination of the classical two-ribbon flare with the relaxation process following forced reconnection between the expanding CME structure and neighboring magnetic fields.

### **Clustering of fast Coronal Mass Ejections during the solar cycles 23 and 24 and implications for CME-CME interactions**

[Jenny M. Rodríguez Gómez](#), [Tatiana Podladchikova](#), [Astrid Veronig](#), [Alexander Ruzmaikin](#), [Joan Feynman](#), [Anatoly Petrukovich](#)

ApJ 899 47 2020

<https://arxiv.org/pdf/2006.10404.pdf>

<https://doi.org/10.3847/1538-4357/ab9e72>

We study the clustering properties of fast Coronal Mass Ejections (CMEs) that occurred during solar cycles 23 and 24. We apply two methods: the Max spectrum method can detect the predominant clusters and the de-clustering threshold time method provides details on the typical clustering properties and time scales. Our analysis shows that during the different phases of solar cycles 23 and 24, CMEs with speed  $\geq 1000$  km/s preferentially occur as isolated events and in clusters with on average two members. However, clusters with more members appear particularly during the maximum phases of the solar cycles. Over the total period and in the maximum phases of solar cycles 23 and 24, about 50% are isolated events, 18% (12%) occur in clusters with 2 (3) members, and another 20% in larger clusters  $\geq 4$ , whereas in solar minimum fast CMEs tend to occur more frequently as isolated events (62%). During different solar cycle phases, the typical de-clustering time scales of fast CMEs are  $\tau_c = 28\text{--}32$  hrs, irrespective of the very different occurrence frequencies of CMEs during solar minimum and maximum. These findings suggest that  $\tau_c$  for extreme events may reflect the characteristic energy build-up time for large flare and CME-prolific active ARs. Associating statistically the clustering properties of fast CMEs with the Disturbance storm index  $\{Dst\}$  at Earth suggests that fast CMEs occurring in clusters tend to produce larger geomagnetic storms than isolated fast CMEs. This may be related to CME-CME interaction producing a more complex and stronger interaction with the Earth magnetosphere. **2000-11-23-25, 2005-08-22-23, 2017-09-09-10**

## SIMULATIONS OF THE

### **Kelvin-Helmholtz instability driven by coronal mass ejections in the turbulent corona**

Daniel O. [Gomez](#), Edward E. DeLuca, Pablo D. Mininni

2016 *ApJ* **818** 126

Recent high-resolution Atmospheric Imaging Assembly/*Solar Dynamics Observatory* images show evidence of the development of the Kelvin–Helmholtz (KH) instability, as coronal mass ejections (CMEs) expand in the ambient corona. A large-scale magnetic field mostly tangential to the interface is inferred, both on the CME and on the background sides. However, the magnetic field component along the shear flow is not strong enough to quench the instability. There is also observational evidence that the ambient corona is in a turbulent regime, and therefore the criteria for the development of the instability are a priori expected to differ from the laminar case. To study the evolution of the KH instability with a turbulent background, we perform three-dimensional simulations of the incompressible magnetohydrodynamic equations. The instability is driven by a velocity profile tangential to the CME–corona interface, which we simulate through a hyperbolic tangent profile. The turbulent background is generated by the application of a stationary stirring force. We compute the instability growth rate for different values of the turbulence intensity, and find that the role of turbulence is to attenuate the growth. The fact that KH instability is observed sets an upper limit on the correlation length of the coronal background turbulence.

### **Numerical simulations of a two-fluid jet at a magnetic null point in a solar arcade**

[J. J. González-Avilés](#), [K. Murawski](#), [T. V. Zaqarashvili](#)

*MNRAS* Volume 515, Issue 4, October 2022, Pages 5094–5105,

<https://doi.org/10.1093/mnras/stac2032>

<https://arxiv.org/pdf/2207.07610.pdf>

We study the formation and evolution of jets in the solar atmosphere using numerical simulations of partially ionized plasma. The two-fluid magnetohydrodynamic equations with ion+electron and neutral hydrogen components are used in two-dimensional (2D) Cartesian geometry. Numerical simulations show that a localized nonlinear Gaussian pulse of ion and neutral pressures initially launched from the magnetic null point of a potential arcade located below the transition region quickly develops into a shock due to the decrease of density with height. The shock propagates upwards into the solar corona and lifts the cold and dense chromospheric plasma behind in the form of a collimated jet with an inverted-Y shape. The inverted-Y shape of jets is connected with the topology of a magnetic null point. The pulse also excites a nonlinear wake in the chromosphere, which leads to quasi-periodic secondary shocks. The secondary shocks lift the chromospheric plasma upwards and create quasi-periodic jets in the lower corona. Ion and neutral fluids show generally similar behavior, but their relative velocity is higher near the upper part of jets, which leads to enhanced temperature or heating due to ion-neutral collisions. Simulations of jets with inverted-Y shape and their heating may explain the properties of some jets observed in the solar atmosphere.

### **Numerical simulations of macrospicule jets under energy imbalance conditions in the solar atmosphere**

[J J González-Avilés](#), [K Murawski](#), [A K Srivastava](#), [T V Zaqarashvili](#), [J A González-Esparza](#)

*MNRAS* , Volume 505, Issue 1, July 2021, Pages 50–64,

<https://doi.org/10.1093/mnras/stab1261>

Using numerical simulations, we study the effects of thermal conduction and radiative cooling on the formation and evolution of solar jets with some macrospicules features. We initially assume that the solar atmosphere is rarely in equilibrium through energy imbalance. Therefore, we test whether the background flows resulting from an imbalance between thermal conduction and radiative cooling influence the jets' behaviour. In this particular scenario, we trigger the formation of the jets by launching a vertical velocity pulse localized at the upper chromosphere for the following test cases: (i) adiabatic case; (ii) thermal conduction case; (iii) radiative cooling case; and (iv) thermal conduction + radiative cooling case. According to the test results, the addition of the thermal conduction results in smaller and hotter jets than in the adiabatic case. On the other hand, the radiative cooling dissipates the jet after reaching the maximum height ( $\approx 5.5$  Mm), making it shorter and colder than in the adiabatic and thermal conduction cases. Besides, the flow generated by the radiative cooling is more substantial than that caused by the thermal conduction. Despite the energy imbalance of the solar atmosphere background, the simulated jet shows morphological features of macrospicules. Furthermore, the velocity pulse steepens into a shock that propagates upward into a solar corona that maintains its initial temperature. The shocks generate the jets with a quasi-periodical behaviour that follows a parabolic path on time–distance plots consistent with macrospicule jets' observed dynamics.

<https://arxiv.org/pdf/1807.04224.pdf>

Within the framework of resistive MHD, implementing the C7 equilibrium atmosphere model and a 3D potential magnetic field realistic configuration, we simulate the formation of a plasma jet with the morphology, upward velocity up to 130 km/s and timescale formation between 60 and 90 s after beginning of simulation, similar to those expected for

Type II spicules. Initial results of this simulation were published in Paper I e.g. \cite{Gonzalez-Aviles\_et\_al\_2018} and present paper is devoted to the analysis of transverse displacements and rotational type motion of the jet. Our results suggest that 3D magnetic reconnection may be responsible for the formation of the jet in Paper I. In this paper, by calculating times series of the velocity components  $v_x$  and  $v_y$  in different points near to the jet for various heights we find transverse oscillations in agreement with spicule observations. We also obtain a time-distance plot of the temperature in a cross-cut at the plane  $x=0.1$  Mm and find significant transverse displacements of the jet. By analyzing temperature isosurfaces of 104 K with the distribution of  $v_x$ , we find that if the line-of-sight (LOS) is approximately perpendicular to the jet axis then there is both motion towards and away from the observer across the width of the jet. This red-blue shift pattern of the jet is caused by rotational motion, initially clockwise and anti-clockwise afterwards, which could be interpreted as torsional motion. From a nearly vertical perspective of the jet the LOS velocity component shows a central blue-shift region surrounded by red-shifted plasma.

## I. Jet Formation and Evolution Due to 3D Magnetic Reconnection

<http://sci-hub.tw/http://iopscience.iop.org/0004-637X/856/2/176/>

<http://iopscience.iop.org/article/10.3847/1538-4357/aab36f/pdf>

Using simulated data-driven, 3D resistive MHD simulations of the solar atmosphere, we show that 3D magnetic reconnection may be responsible for the formation of jets with the characteristics of Type II spicules. We numerically model the photosphere-corona region using the C7 equilibrium atmosphere model. The initial magnetic configuration is a 3D potential magnetic field, extrapolated up to the solar corona region from a dynamic realistic simulation of the solar photospheric magnetoconvection model that mimics the quiet-Sun. In this case, we consider a uniform and constant value of the magnetic resistivity of  $12.56 \Omega \text{ m}$ . We have found that the formation of the jet depends on the Lorentz force, which helps to accelerate the plasma upward. Analyzing various properties of the jet dynamics, we found that the jet structure shows a Doppler shift close to regions with high vorticity. The morphology, the upward velocity covering a range up to  $130 \text{ km s}^{-1}$ , and the timescale formation of the structure between 60 and 90 s, are similar to those expected for Type II spicules.

## Jet formation in solar atmosphere due to magnetic reconnection

J.J. **González-Avilés**, F.S. Guzmán, V. Fedun

ApJ 836 24 2017

<https://arxiv.org/pdf/1609.09422v1.pdf>

Using numerical simulations, we show that jets with features of type II spicules and cold coronal jets corresponding to temperatures 104 K can be formed due to magnetic reconnection in a scenario in presence of magnetic resistivity. For this we model the low chromosphere-corona region using the C7 equilibrium solar atmosphere model and assuming Resistive MHD rules the dynamics of the plasma. The magnetic field configurations we analyze correspond to two neighboring loops with opposite polarity. The separation of the loops' feet determines the thickness of a current sheet that triggers a magnetic reconnection process, and the further formation of a high speed and sharp structure. We analyze the cases where the magnetic field strength of the two loops is equal and different. In the first case, with a symmetric configuration the spicules raise vertically whereas in an asymmetric configuration the structure shows an inclination. With a number of simulations carried out under a 2.5D approach, we explore various properties of excited jets, namely, the morphology, inclination and velocity. The parameter space involves magnetic field strength between 20 and 40 G, and the resistivity is assumed to be uniform with a constant value of the order  $10^{-2} \Omega \text{ m}$

## Speed Evolution of Fast CME/Shocks: Analysis of Kilometric Type II Emissions

J. A. **Gonzalez-Esparza** and E. Aguilar-Rodriguez

Ann. Geophys., 27, 3957-3966, 2009, **File**

Fast CME/shocks propagating in the interplanetary medium can generate kilometric Type II (km-TII) radio emissions at the local plasma frequency and/or its harmonic, so these radio emissions provide a means of remotely tracking CME/shocks. We apply a new analysis technique, using the frequency drift of km-TII spectrum obtained by the Thermal Noise Receiver (TNR) of the WIND/WAVES experiment, to infer, at some adequate intervals, the propagation speed of six CME/shocks. We combine these results with previously reported speeds from coronagraph white light and interplanetary scintillation observations, and in-situ measurements, to study the temporal speed evolution of the six events. The speed values obtained by the km-TII analysis are in a reasonable agreement with the speed measurements obtained by other techniques at different heliocentric distance ranges. The combination of all the speed measurements show a gradual deceleration of the CME/shocks as they propagate to 1 AU. This new technique can be useful in studying the evolution of fast CME/shocks when adequate intervals of km-TII emissions are available.

## CME Classification Based on Wavelet Spectra

D.I. **González-Gómez** · X. Blanco-Cano · A.C. Raga

Solar Phys (2010) 266: 337–347

We study the internal structure of coronal mass ejections (CMEs) using wavelet analysis. We derive wavelet spectra, spatially integrated over regions of interest within LASCO C2 white-light coronagraphic images. These spectra show an inflection point, which we use to characterize each spectrum. In a diagram of flux vs. spatial scale of the inflection point, we find that the analyzed structures fall into two, distinct groups: a low-flux, small-spatial-scale group (which we call the “homogeneous” type), and a high-flux, larger-spatial-scale group (the “collimated” type). Interestingly, if we study different regions of a given image, all of the structures fall into one of the two groups described above. From a qualitative comparison with the images, it is clear that the two groups identified by the wavelet analysis correspond to two types of morphologies, which are seen as either more-homogeneous or more-collimated structures.

### **A morphological study of CMEs using wavelet analysis**

Advances in Space Research

Volume 46, Issue 1, 1 July 2010, Pages 22-30; **File**

The principal objective of this study is to analyze structures of Coronal Mass Ejections (CMEs) using a wavelet technique. We use data measured with the SOHO/LASCO coronagraphs C2–C3, EIT and STEREO COR1A–B, COR2A–B. We have found that different structures show up in a CME at different spatial scales of wavelets. We also study the orientation of the most intense flux and find the orientation of the structures in the CME.

### **Acceleration of Type 2 Spicules in the Solar Chromosphere - 2: Viscous Braking and Upper Bounds on Coronal Energy Input**

Michael L. [Goodman](#)

**2014**

<http://arxiv.org/pdf/1403.2694v1.pdf>

A magnetohydrodynamic model is used to determine conditions under which the Lorentz force accelerates plasma to type 2 spicule speeds in the chromosphere. The model generalizes a previous model to include a more realistic pre-spicule state, and the vertical viscous force. Two cases of acceleration under upper chromospheric conditions are considered. The magnetic field strength for these cases is  $\leq 12.5$  and 25 G. Plasma is accelerated to terminal vertical speeds of 66 and 78 km/s in 100 s, compared with 124 and 397 km/s for the case of zero viscosity. The flows are localized within horizontal diameters  $\sim 80$  and 50 km. The total thermal energy generated by viscous dissipation is  $\sim 10$  times larger than that due to Joule dissipation, but the magnitude of the total cooling due to rarefaction is  $\gg$  this energy. Compressive heating dominates during the early phase of acceleration. The maximum energy injected into the corona by type 2 spicules, defined as the energy flux in the upper chromosphere, may largely balance total coronal energy losses in quiet regions, possibly also in coronal holes, but not in active regions. It is proposed that magnetic flux emergence in inter-granular regions drives type 2 spicules.

Proceedings of IAU Symposium 388 **2024**

<https://arxiv.org/pdf/2407.04165>

This paper provides an update on the coronal mass ejection (CME) catalog maintained at the CDAW Data Center, NASA Goddard Space Flight Center ([this https URL](https://cdaw.gsfc.nasa.gov/)). This is version 2 (v2) of the Catalog that has been made as the default version as of May 1, 2024. The new features of the Catalog v2 are (i) online measurement tool, (ii) combination JavaScript movies from the STEREO and Solar Dynamics Observatory (SDO) missions, and (iii) insertion of newly identified CMEs for the period 1996 to 2004. The CME identification was revisited resulting in a set of  $\sim 3000$  new CMEs added to the Catalog. A vast majority of these CMEs are weak and narrow. The resulting statistical properties of CMEs are not significantly different from those reported using version 1. **2003-01-20, 2012-01-02**

### **Implications of the abundance of halo coronal mass ejections for the strength of solar cycle 25**

[Nat Gopalswamy](#), [Grzegorz Michalek](#), [Seiji Yashiro](#), [Pertti Makela](#), [Sachiko Akiyama](#), [Hong Xie](#)

<https://arxiv.org/pdf/2407.04548>

We assess the relative strength of solar cycle (SC) 25 with respect to SCs 23 and 24 based on the abundance of halo coronal mass ejections (CMEs). We make use of the halo CME database ([this https URL](#)) to compare the halo CME abundance during the first four years in each of SCs 23 to 25. The main result is that in several aspects such as the abundance, occurrence rate, source locations, and halo heights, halo CMEs are similar between SCs 24 and 25 but different from SC 23. This result follows from the fact that weaker cycles have low heliospheric total pressure, whose backreaction on CMEs allows them to expand more and hence enhancing the chance of becoming a halo. The solar cycle variation of halo CME properties is consistent with the precursor-based cycle prediction methods that indicate SC 25 is similar to or only slightly stronger than SC 24.

### What do halo CMEs tell us about solar cycle 25?

[Nat Gopalswamy](#), [Grzegorz Michalek](#), [Seiji Yashiro](#), [Pertti Mäkelä](#), [Sachiko Akiyama](#), [Hong Xie](#)

ApJL 952 L13 2023

<https://arxiv.org/ftp/arxiv/papers/2306/2306.06633.pdf>

<https://iopscience.iop.org/article/10.3847/2041-8213/acdde2/pdf>

It is known that the weak state of the heliosphere due to diminished solar activity in cycle 24 back-reacted on coronal mass ejections (CMEs) to make them appear wider for a given speed. One of the consequences of the weak state of the heliosphere is that more CMEs appear as halo CMEs (HCMEs), and halos are formed at shorter heliocentric distances. Current predictions for the strength of solar cycle (SC) 25 range from half to twice the strength of SC 24. We compare the HCME occurrence rate and other properties during the rise phase of cycles 23, 24, and 25 to weigh in on the strength of SC 25. We find that HCME and solar wind properties in SC 25 are intermediate between SCs 23 and 24, but closer to SC 24. The HCME occurrence rate, normalized to the sunspot number, is higher in SCs 24 and 25 than in SC 23. The solar wind total pressure in SC 25 is ~35% smaller than that in SC 23. Furthermore, the occurrence rates of high-energy solar energetic particle events and intense geomagnetic storms are well below the corresponding values in SC 23, but similar to those in SC 24. We conclude that cycle 25 is likely to be similar to or slightly stronger than cycle 24, in agreement with polar-field precursor methods for cycle 25 prediction.

### What is Unusual about the Third Largest Geomagnetic Storm of Solar Cycle 24?

[N. Gopalswamy](#), [S. Yashiro](#), [S. Akiyama](#), [H. Xie](#), [P. Mäkelä](#), [M.-C. Fok](#), [C. P. Ferradas](#)

JGR Volume 127, Issue 8, article id. e30404 2022

<https://arxiv.org/ftp/arxiv/papers/2207/2207.11630.pdf>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2022JA030404>

We report on the solar and interplanetary (IP) causes of the third largest geomagnetic storm (2018 August 26) in solar cycle 24. The underlying coronal mass ejection (CME) originating from a quiescent filament region becomes a 440 km/s magnetic cloud (MC) at 1 au after ~5 days. The prolonged CME acceleration (for about 24 hrs) coincides with the time profiles of the post-eruption arcade intensity and reconnected flux. Chen et al. (2019) obtain lower speed since they assumed that the CME does not accelerate after about 12 hrs. The presence of multiple coronal holes near the filament channel and the high-speed wind from them seem to have the combined effect of producing complex rotation in the corona and IP medium resulting in a high-inclination MC. The Dst time profile in the main phase steepens significantly (rapid increase in storm intensity) coincident with the density increase (prominence material) in the second half of the MC. Simulations using the Comprehensive Inner Magnetosphere-Ionosphere (CIMI) model shows that a higher ring current energy results from larger dynamic pressure in MCs. Furthermore, the Dst index is highly correlated with the main-phase time integral of the ring current injection that includes density, consistent with the simulations. A complex temporal structure develops in the storm main phase if the underlying MC has a complex density structure during intervals of southward interplanetary magnetic field. We conclude that the high intensity of the storm results from the prolonged CME acceleration, complex rotation, and the high density in the 1-au MC.

### Effect of the Weakened Heliosphere in Solar Cycle 24 on the Properties of Coronal Mass Ejections

[N. Gopalswamy](#), [S. Akiyama](#), [S. Yashiro](#), [G. Michalek](#), [H. Xie](#), [P. Mäkelä](#)

Proc. 19th International Astrophysics Conference held in Santa Fe, New Mexico, March 9 - 13, 2020

<https://arxiv.org/ftp/arxiv/papers/2007/2007.08291.pdf>

Solar cycle (SC) 24 has come to an end by the end of 2019, providing information on two full cycles to understand the manifestations of SC 24, the smallest cycle in the Space Age that has resulted in a weak heliospheric state indicated by the reduced pressure. The backreaction of the heliospheric state is to make the coronal mass ejections (CMEs) appear physically bigger than in SC 23, but their magnetic content has been diluted resulting in a lower geoeffectiveness. The heliospheric magnetic field is also lower in SC 24, leading to the dearth of high-energy solar energetic particle (SEP) events. These space weather events closely follow fast and wide (FW) CMEs. All but FW CMEs are higher in number in SC 24. The CME rate vs. sunspot number (SSN) correlation is high in both cycles but the rate increases faster in SC 24. We revisit the study of limb CMEs (those with source regions within 30 degrees from the limb) previously studied over partial cycles. We find that limb CMEs are slower in SC 24 as in the general population but wider. Limb halo CMEs follow the same trend of slower SC-24 CMEs. However, the SC-24 CMEs become halos at a shorter distance from the Sun. Thus, slower CMEs becoming halos sooner is a clear indication of the backreaction of the weaker

heliospheric state on CMEs. We can further pin down the heliospheric state as the reason for the altered CME properties because the associated flares have similar distributions in the two cycles, unaffected by the heliospheric state. **2002-09-06**

**Table 3.** Halo CMEs originating within  $30^\circ$  from the limb in solar cycles 23 and 24

## The State of the Heliosphere Revealed by Limb Halo Coronal Mass Ejections in Solar Cycles 23 and 24

Nat **Gopalswamy**, [Sachiko Akiyama](#), [Seiji Yashiro](#)

ApJL 897:L1 **2020**

<https://arxiv.org/ftp/arxiv/papers/2006/2006.05844.pdf>

<https://iopscience.iop.org/article/10.3847/2041-8213/ab9b7b/pdf>

We compare the properties of halo coronal mass ejections (CMEs) that originate close to the limb (within a central meridian distance range of 60 to 90 deg) during solar cycles 23 and 24 to quantify the effect of the heliospheric state on CME properties. There are 44 and 38 limb halos in the cycles 23 and 24, respectively. Normalized to the cycle-averaged total sunspot number, there are 42 percent more limb halos in cycle 24. Although the limb halos as a population is very fast (average speed 1464 km s<sup>-1</sup>), cycle-24 halos are slower by 26 percent than the cycle-23 halos. We introduce a new parameter, the heliocentric distance of the CME leading edge at the time a CME becomes a full halo; this height is significantly shorter in cycle 24 (by 20 percent) and has a lower cutoff at 6 Rs. These results show that cycle-24 CMEs become halos sooner and at a lower speed than the cycle-23 ones. On the other hand, the flare sizes are very similar in the two cycles, ruling out the possibility of eruption characteristics contributing to the differing CME properties. In summary, this study reveals the effect of the reduced total pressure in the heliosphere that allows cycle-24 CMEs expand more and become halos sooner than in cycle 23. Our findings have important implications for the space-weather consequences of CMEs in cycle 25 (predicted to be similar to cycle 24) and for understanding the disparity in halo counts reported by automatic and manual catalogs. **2011 September 22**

## A Catalog of Type II Radio Bursts Observed by Wind/WAVES and their Statistical Properties

Nat **Gopalswamy**, [Pertti Mäkelä](#), [Seiji Yashiro](#)

Sun and Geosphere vol.14, no.2, p.111-121 **2019**

<https://arxiv.org/ftp/arxiv/papers/1912/1912.07370.pdf> **File**

Solar type II radio bursts are the signature of particle acceleration by shock waves in the solar corona and interplanetary medium. The shocks originate in solar eruptions involving coronal mass ejections (CMEs) moving at super-Alfvénic speeds. Type II bursts occur at frequencies ranging from hundreds of MHz to tens of kHz, which correspond to plasma frequencies prevailing in the inner heliosphere from the base of the solar corona to the vicinity of Earth. Type II radio bursts occurring at frequencies below the ionospheric cutoff are of particular importance, because they are due to very energetic CMEs that can disturb a large volume of the heliosphere. The underlying shocks accelerate not only electrons that produce the type II bursts, but also protons and heavy ions that have serious implications for space weather. The type II radio burst catalog ([this https URL](#)) presented here provides detailed information on the bursts observed by the Radio and Plasma Wave Experiment (WAVES) on board the Wind Spacecraft. The catalog is enhanced by compiling the associated flares, CMEs, solar energetic particle (SEP) events including their basic properties. We also present the statistical properties of the radio bursts and the associated phenomena, including solar-cycle variation of the occurrence rate of the type II bursts. **2000.11.09, 2005.01.15-16, 2012.07.04**

## Coronal Flux Ropes and their Interplanetary Counterparts

N. **Gopalswamy**, S. Akiyama, S. Yashiro, H. Xie

J. Atmos. Solar-Terr. Phys. Volume 180, Pages 35-45, November **2018** **File (2017)**

<https://arxiv.org/pdf/1705.08912.pdf>

[sci-hub.tw/10.1016/j.jastp.2017.06.004](https://sci-hub.tw/10.1016/j.jastp.2017.06.004)

We report on a study comparing coronal flux ropes inferred from eruption data with their interplanetary counterparts constructed from in situ data. The eruption data include the source-region magnetic field, post-eruption arcades, and coronal mass ejections (CMEs). Flux ropes were fit to the interplanetary CMEs (ICMEs) considered for the 2011 and 2012 Coordinated Data Analysis Workshops (CDAWs). We computed the total reconnected flux involved in each of the associated solar eruptions and found it to be closely related to flare properties, CME kinematics, and ICME properties. By fitting flux ropes to the white-light coronagraph data, we obtained the geometric properties of the flux ropes and added magnetic properties derived from the reconnected flux. We found that the CME magnetic field in the corona is significantly higher than the ambient magnetic field at a given heliocentric distance. The radial dependence of the flux-rope magnetic field strength is faster than that of the ambient magnetic field. The magnetic field strength of the coronal flux rope is also correlated with that in interplanetary flux ropes constructed from in situ data, and with the observed peak magnetic field strength in ICMEs. The physical reason for the observed correlation between the peak field strength in MCs is the higher magnetic field content in faster coronal flux ropes and ultimately the higher reconnected flux in the eruption region. The magnetic flux ropes constructed from the eruption data and coronagraph observations provide a

realistic input that can be used by various models to predict the magnetic properties of ICMEs at Earth and other destination in the heliosphere. **1999 June 24**

We investigate the propagation of the **2015 June 21** CME-driven shock as revealed by the type II bursts at metric and longer wavelengths and coronagraph observations. The CME was associated with the second largest geomagnetic storm of solar cycle 24 and a large solar energetic particle (SEP) event. The eruption consisted of two M-class flares, with the first one being confined, with no metric or interplanetary radio bursts. However, there was intense microwave burst, indicating accelerated particles injected toward the Sun. The second flare was eruptive that resulted in a halo CME. The CME was deflected primarily by an equatorial coronal hole that resulted in the modification of the intensity profile of the associated SEP event and the duration of the CME at Earth. The interplanetary type II burst was particularly intense and was visible from the corona all the way to the vicinity of the Wind spacecraft with fundamental-harmonic structure. We computed the shock speed using the type II drift rates at various heliocentric distances and obtained information on the evolution of the shock that matched coronagraph observations near the Sun and in-situ observations near Earth. The depth of the geomagnetic storm is consistent with the 1-AU speed of the CME and the magnitude of the southward component.

## **Extreme Kinematics of the 2017 September 10 Solar Eruption and the Spectral Characteristics of the Associated Energetic Particles**

<http://sci-hub.tw/http://iopscience.iop.org/article/10.3847/2041-8213/aad86c/meta>

We report on the **2017 September 10** ground level enhancement (GLE) event associated with a coronal mass ejection (CME) whose initial acceleration ( $\sim 9.1 \text{ km s}^{-2}$ ) and initial speed ( $\sim 4300 \text{ km/s}$ ) were among the highest observed in the SOHO era. The GLE event was of low intensity ( $\sim 4.4\%$  above background) and softer-than-average fluence spectrum. We suggest that poor connectivity (longitudinal and latitudinal) of the source to Earth compounded by the weaker ambient magnetic field contributed to these GLE properties. Events with similar high initial speed either lacked GLE association or had softer fluence spectra. The shock-formation height inferred from the metric type II burst was  $\sim 1.4 R_s$ , consistent with other GLE events. The shock height at solar particle release (SPR) was  $\sim 4.4 \pm 0.38 R_s$ , consistent with the parabolic relationship between the shock height at SPR and source longitude. **2012 July 7, 2014 January 7**

## **Coronal mass ejections as a new indicator of the active Sun**

Nat [Gopalswamy](#)

Proc. IAU Symposium 340 on Long-term datasets for the understanding of solar and stellar magnetic cycles, February 19-24, 2018 Jaipur, India. **2018**

<https://arxiv.org/pdf/1804.11112.pdf>

Coronal mass ejections (CMEs) have become one of the key indicators of solar activity, especially in terms of the consequences of the transient events in the heliosphere. Although CMEs are closely related to the sunspot number (SSN), they are also related to other closed magnetic regions on the Sun such as quiescent filament regions. This makes CMEs a better indicator of solar activity. While sunspots mainly represent the toroidal component of solar magnetism, quiescent filaments (and hence CMEs associated with them) connect the toroidal and poloidal components via the rush-to-the-pole (RTTP) phenomenon. Taking the end of RTTP in each hemisphere as an indicator of solar polarity reversal, it is shown that the north-south reversal asymmetry has a quasi-periodicity of 3-5 solar cycles. Focusing on the geospace consequences of CMEs, it is shown that the maximum CME speeds averaged over Carrington rotation period show good correlation with geomagnetic activity indices such as Dst and aa.

## **A new technique to provide realistic input to CME forecasting models**

Nat [Gopalswamy](#), [Sachiko Akiyama](#), [Seiji Yashiro](#), [Hong Xie](#)

IAU Symposium 335: Space Weather of the Heliosphere: Processes and Forecasts **2017**

<https://arxiv.org/pdf/1709.03160.pdf>

We report on a technique to construct a flux rope (FR) from eruption data at the Sun. The technique involves line-of-sight magnetic fields, post-eruption arcades in the corona, and white-light coronal mass ejections (CMEs) so that the FR geometric and magnetic properties can be fully defined in addition to the kinematic properties. We refer to this FR as FRED (Flux Rope from Eruption Data). We illustrate the FRED construction using the **2012 July 12** eruption and

compare the coronal and interplanetary properties of the FR. The results indicate that the FRED input should help make realistic predictions of the components of the FR magnetic field in the heliosphere.

## Extreme Solar Eruptions and their Space Weather Consequences Review

Nat **Gopalswamy**

2017, be published by Elsevier as a chapter in the book, "Extreme Events in the Geospace: Origins, Predictability and Consequences", Ed. Natalia Buzulukova

<https://arxiv.org/ftp/arxiv/papers/1709/1709.03165.pdf> **File**

Solar eruptions generally refer to coronal mass ejections (CMEs) and flares. Both are important sources of space weather. Solar flares cause sudden change in the ionization level in the ionosphere. CMEs cause solar energetic particle (SEP) events and geomagnetic storms. A flare with unusually high intensity and/or a CME with extremely high energy can be thought of examples of extreme events on the Sun. These events can also lead to extreme SEP events and/or geomagnetic storms. Ultimately, the energy that powers CMEs and flares are stored in magnetic regions on the Sun, known as active regions. Active regions with extraordinary size and magnetic field have the potential to produce extreme events. Based on current data sets, we estimate the sizes of one-in-hundred and one-in-thousand year events as an indicator of the extremeness of the events. We consider both the extremeness in the source of eruptions and in the consequences. We then compare the estimated 100-year and 1000-year sizes with the sizes of historical extreme events measured or inferred.

## A Hierarchical Relationship between the Fluence Spectra and CME Kinematics in Large Solar Energetic Particle Events: A Radio Perspective

N **Gopalswamy**, P Mäkelä, S Yashiro, [N Thakur](#), [S Akiyama](#), [H Xie](#)

Journal of Physics: Conference Series (JPCS), Proceedings of the 16th Annual International Astrophysics Conference held in Santa Fe, NM, 2017

<https://arxiv.org/ftp/arxiv/papers/1707/1707.00209.pdf>

We report on further evidence that solar energetic particles are organized by the kinematic properties of coronal mass ejections (CMEs)[1]. In particular, we focus on the starting frequency of type II bursts, which is related to the distance from the Sun where the radio emission starts. We find that the three groups of solar energetic particle (SEP) events known to have distinct values of CME initial acceleration, also have distinct average starting frequencies of the associated type II bursts. SEP events with ground level enhancement (GLE) have the highest starting frequency (107 MHz), while those associated with filament eruption (FE) in quiescent regions have the lowest starting frequency (22 MHz); regular SEP events have intermediate starting frequency (81 MHz). Taking the onset time of type II bursts as the time of shock formation, we determine the shock formation heights measured from the Sun center. We find that the shocks form on average closest to the Sun (1.51 Rs) in GLE events, farthest from the Sun in FE SEP events (5.38 Rs), and at intermediate distances in regular SEP events (1.72 Rs). Finally, we present the results of a case study of a CME with high initial acceleration ( $\sim 3$  km s<sup>-2</sup>) and a type II radio burst with high starting frequency ( $\sim 200$  MHz) but associated with a minor SEP event. We find that the relation between the fluence spectral index and CME initial acceleration continues to hold even for this minor SEP event. **2010 June 12, 2011 November 26, 2012 May 17**

## Estimation of Reconnection Flux using Post-eruption Arcades and Its Relevance to 1-au Magnetic Clouds

N. **Gopalswamy**, S. Yashiro, S. Akiyama, H. Xie

Solar Phys. 292, 65 2017

<https://arxiv.org/pdf/1701.01943v1.pdf> **File**

We report on a new method to compute the flare reconnection (RC) flux from post-eruption arcades (PEAs) and the underlying photospheric magnetic fields. In previous work, the RC flux has been computed using cumulative flare ribbon area. Here we obtain the RC flux as half of that underlying the PEA associated with the eruption using an image in EUV taken after the flare maximum. We apply this method to a set of 21 eruptions that originated near the solar disk center in solar cycle 23. We find that the RC flux from the arcade method ( $\{\Phi\}_rA$ ) has excellent agreement with that from the ribbon method ( $\{\Phi\}_rR$ ) according to:  $\{\Phi\}_rA = 1.24(\{\Phi\}_rR)^{0.99}$ . We also find  $\{\Phi\}_rA$  to be correlated with the poloidal flux ( $\{\Phi\}_P$ ) of the associated magnetic cloud at 1 au:  $\{\Phi\}_P = 1.20(\{\Phi\}_rA)^{0.85}$ . This relation is nearly identical to that obtained by Qiu et al. (2007) using a set of only 9 eruptions. Our result supports the idea that flare reconnection results in the formation of flux rope and PEA as a common process.

## **The 2012 July 23 Backside Eruption: An Extreme Energetic Particle Event?**

Nat **Gopalswamy**, Seiji Yashiro, Neeharika Thakur, Pertti Mäkelä, Hong Xie, Sachiko Akiyama  
ApJ **2016**

<https://arxiv.org/pdf/1610.05790v1.pdf> **File**

The backside coronal mass ejection (CME) of **2012 July 23** had a short Sun to Earth shock transit time (18.5 hours). The associated solar energetic particle (SEP) event had a  $>10$  MeV proton flux peaking at  $\sim 5000$  pfu, and the energetic storm particle (ESP) event was an order of magnitude larger, making it the most intense event in the space era at these energies. By a detailed analysis of the CME, shock, and SEP characteristics, we find that the July 23 event is consistent with a high-energy SEP event (accelerating particles to GeV energies). The time of maximum and fluence spectra in the range 10-100 MeV were very hard, similar to those of ground level enhancement (GLE) events. We found a hierarchical relationship between the CME initial speeds and the fluence spectral indices: CMEs with low initial speeds had SEP events with the softest spectra, while those with highest initial speeds had SEP events with the hardest spectra. CMEs attaining intermediate speeds result in moderately hard spectra. The July 23 event was in the group of hard-spectrum events. During the July 23 event, the shock speed ( $>2000$  km s $^{-1}$ ), the initial acceleration ( $\sim 1.70$  km s $^{-2}$ ), and the shock formation height ( $\sim 1.5$  solar radii) were all typical of GLE events. The associated type II burst had emission components from metric to kilometric wavelengths suggesting a strong shock. These observations confirm that the 2012 July 23 event is likely to be an extreme event in terms of the energetic particles it accelerated.

## **History and Development of Coronal Mass Ejections as a Key Player in Solar Terrestrial Relationship**

**Review**

N. **Gopalswamy**

Geoscience Letters Volume 3, article id.8, 18 pp. **2016** **File**

<http://arxiv.org/pdf/1602.03665v1.pdf>

Coronal mass ejections (CMEs) are relatively a recently-discovered phenomenon, in 1971, some fifteen years into the Space Era. It took another two decades to realize that CMEs are the most important players in solar terrestrial relationship as the root cause of severe weather in Earth's space environment. CMEs are now counted among the major natural hazards because they cause large solar energetic particle (SEP) events and major geomagnetic storms, both of which pose danger to humans and their technology in space and ground. Geomagnetic storms discovered in the 1700s, solar flares discovered in the 1800s, and SEP events discovered in the 1900s are all now found to be closely related to CMEs via various physical processes occurring at various locations in and around CMEs, when they interact with the ambient medium. This article identifies a number of key developments that preceded the discovery of white-light CMEs suggesting that CMEs were waiting to be discovered. The last two decades witnessed an explosion of CME research following the launch of the Solar and Heliospheric Observatory mission in 1995, resulting in the establishment of a full picture of CMEs.

## **Interaction between Coronal Mass Ejections: Limited Spatial Extent Revealed by SOHO Observations**

**Gopalswamy**, Nat; Reiner, Mike J.; Makela, Pertti; Yashiro, Seiji

41st COSPAR Scientific Assembly, abstracts from the meeting that was to be held 30 July - 7 August **2016** at the Istanbul Congress Center (ICC), Turkey, but was cancelled. Abstract D2.1-9-16

A spectacular CME interaction event was observed on **2013 May 22** by the Large Angle and Spectrometric Coronagraph (LASCO) on board the Solar and Heliospheric Observatory (SOHO) mission as confirmed by the radio signature detected by the Radio and Plasma Wave experiment (WAVES) on board the Wind spacecraft. The interaction event was also associated with an intense solar energetic particle event, typical of such events in solar cycles 23 and 24. Detailed height-time plots of the interacting CMEs at various position angles revealed a surprising result: only a limited spatial extent of the primary CME was affected by the interaction. The speed of the primary CME showed a sharp decline in the position angle range where it interacted with the preceding CME. At these position angles, the speed of the preceding CME increased. At position angles away from the interaction region, the speed of the primary CME remained roughly the same except for the usual drag deceleration. This result has important implications to theories on CME collision: treating the interacting CMEs to be rigid bodies and using the whole mass of the CMEs may not be correct.

## **CMEs during the Two Activity Peaks in Cycle 24 and their Space Weather Consequences**

N. **Gopalswamy**, P. Mäkelä, S. Akiyama, S. Yashiro, N. Thakur

Sun and Geosphere, **2015**

<http://arxiv.org/pdf/1509.04216v1.pdf> **File**

We report on a comparison between space weather events that occurred around the two peaks in the sunspot number (SSN) during solar cycle 24. The two SSN peaks occurred in the years 2012 and 2014. Even though SSN was larger during the second peak, we find that there were more space weather events during the first peak. The space weather events we considered are large solar energetic particle (SEP) events and major geomagnetic storms associated with coronal mass ejections (CMEs). We also considered interplanetary type II radio bursts, which are indicative of energetic CMEs driving shocks. When we compared the CME properties between the two SSN peaks, we find that more energetic CMEs occurred during the 2012 peak. In particular, we find that CMEs accompanying IP type II bursts had an average speed of 1543 km/s during the 2012 peak compared to 1201 km/s during the 2014 peak. This result is consistent

with the reduction in the average speed of the general population of CMEs during the second peak. All SEP events were associated with the interplanetary type II bursts, which are better than halo CMEs as indicators of space weather. The comparison between the two peaks also revealed the discordant behavior CME rate and SSN is more pronounced during the second peak. None of the 14 disk-center halo CMEs was associated with a major storm in 2014. The lone major storm in 2014 was due to the intensification of the (southward) magnetic field in the associated magnetic cloud by a shock that caught up and propagated into the magnetic cloud. **23-24 Apr 2012; 18-19 Feb 2014**

## **Short-term variability of the Sun-Earth system: an overview of progress made during the CAWSES-II period**

**Review**

**Gopalswamy**, Nat; Tsurutani, Bruce; Yan, Yihua

Progress in Earth and Planetary Science, Volume 2, article id. #13, 41 pp., **2015**

<http://arxiv.org/pdf/1504.06332v1.pdf> **File**

This paper presents an overview of results obtained during the CAWSES-II period on the short-term variability of the Sun and how it affects the near-Earth space environment. CAWSES-II was planned to examine the behavior of the solar-terrestrial system as the solar activity climbed to its maximum phase in solar cycle 24. After a deep minimum following cycle 23, the Sun climbed to a very weak maximum in terms of the sunspot number in cycle 24 (MiniMax24), so many of the results presented here refer to this weak activity in comparison with cycle 23. The short-term variability that has immediate consequence to Earth and geospace manifests as solar eruptions from closed-field regions and high-speed streams from coronal holes. Both electromagnetic (flares) and mass emissions (coronal mass ejections - CMEs) are involved in solar eruptions, while coronal holes result in high-speed streams that collide with slow wind forming the so-called corotating interaction regions (CIRs). Fast CMEs affect Earth via leading shocks accelerating energetic particles and creating large geomagnetic storms. CIRs and their trailing high-speed streams (HSSs), on the other hand, are responsible for recurrent small geomagnetic storms and extended days of auroral zone activity, respectively. The latter leads to the acceleration of relativistic magnetospheric 'killer' electrons. One of the major consequences of the weak solar activity is the altered physical state of the heliosphere that has serious implications for the shock-driving and storm-causing properties of CMEs. Finally, a discussion is presented on extreme space weather events prompted by the **23 July 2012** super storm event that occurred on the backside of the Sun. Many of these studies were enabled by the simultaneous availability of remote sensing and in situ observations from multiple vantage points with respect to the Sun-Earth line.

## **Kinematic and Energetic Properties of the 2012 March 12 Polar Coronal Mass Ejection**

N. **Gopalswamy**<sup>1</sup>, S. Yashiro<sup>1,2</sup>, and S. Akiyama

**2015** ApJ 809 106

<http://arxiv.org/ftp/arxiv/papers/1507/1507.04057.pdf>

We report on the energetics of the **2012 March 12** polar coronal mass ejection (CME) originating from a southern latitude of  $\sim 60^\circ$ . The polar CME is similar to low-latitude (LL) CMEs in almost all respects: three-part morphology; post-eruption arcade (PEA), CME, and filament kinematics; CME mass and kinetic energy; and the relative thermal energy content of the PEA. From polarized brightness images, we estimate the CME mass, which is close to the average mass of LL CMEs. The CME kinetic energy ( $3.3 \times 10^{30}$  erg) is also typical of the general population of CMEs. From photospheric magnetograms, we estimate the free energy ( $1.8 \times 10^{31}$  erg) in the polar crown source region, which we find is sufficient to power the CME and the PEA. About 19% of the free energy went into the CME kinetic energy. We compute the thermal energy content of the PEA ( $2.3 \times 10^{29}$  erg) and find it to be a small fraction (6.8%) of the CME kinetic energy. This fraction is remarkably similar to that in active region CMEs associated with major flares. We also show that the 2012 March 12 is one among scores of polar CMEs observed during the maximum phase of cycle 24. The cycle 24 polar crown prominence eruptions have the same rate of association with CMEs as those from LLs. This investigation supports the view that all CMEs are magnetically propelled from closed field regions, irrespective of their location on the Sun (polar crown filament regions, quiescent filament regions, or active regions).

### High-energy solar particle events in cycle 24

Nat **Gopalswamy**, [Pertti Makela](#), [Seiji Yashiro](#), [Hong Xie](#), [Sachiko Akiyama](#), [Neeharika Thakur](#)

The 14th International Astrophysics Conference held in Tampa, FL during April 24-29, 2015. Accepted for publication in Journal of Physics: Conference Series (JPCS). edited by G. Zank, **2015**

<http://arxiv.org/ftp/arxiv/papers/1507/1507.06162.pdf>; **File**

The Sun is already in the declining phase of cycle 24, but the paucity of high-energy solar energetic particle (SEP) events continues with only two ground level enhancement (GLE) events as of March 31, 2015. In an attempt to understand this, we considered all the large SEP events of cycle 24 that occurred until the end of 2014. We compared the properties of the associated CMEs with those in cycle 23. We found that the CME speeds in the sky plane were similar, but almost all those cycle-24 CMEs were halos. A significant fraction of (16%) of the frontside SEP events were associated with eruptive prominence events. CMEs associated with filament eruption events accelerate slowly and attain peak speeds beyond the typical GLE release heights. When we considered only western hemispheric events that had good connectivity to the CME nose, there were only 8 events that could be considered as GLE candidates. One turned out to be the first GLE event of cycle 24 (2012 May 17). In two events, the CMEs were very fast (>2000 km/s) but they were launched into a tenuous medium (high Alfvén speed). In the remaining five events, the speeds were well below the typical GLE CME speed (~2000 km/s). Furthermore, the CMEs attained their peak speeds beyond the typical heights where GLE particles are released. We conclude that several factors contribute to the low rate of high-energy SEP events in cycle 24: (i) reduced efficiency of shock acceleration (weak heliospheric magnetic field), (ii) poor latitudinal and longitudinal connectivity), and (iii) variation in local ambient conditions (e.g., high Alfvén speed).

### The dynamics of eruptive prominences

**Review**

Nat **Gopalswamy**

Solar Prominences, edited by J.-C. Vial & O. Engvold, Springer, in press (**2014**), Chapter 15, **File** Astrophysics and Space Science Library Volume 415, **2015**, pp 381-410

<http://arxiv.org/pdf/1407.2594v1.pdf>

[http://link.springer.com/chapter/10.1007/978-3-319-10416-4\\_15](http://link.springer.com/chapter/10.1007/978-3-319-10416-4_15)

This chapter discusses the dynamical properties of eruptive prominences in relation to coronal mass ejections (CMEs). The fact that eruptive prominences are a part of CMEs is emphasized in terms of their physical association and kinematics. The continued propagation of prominence material into the heliosphere is illustrated using in-situ observations. The solar-cycle variation of eruptive prominence locations is discussed with a particular emphasis on the rush-to-the-pole (RTTP) phenomenon. One of the consequences of the RTTP phenomenon is polar CMEs, which are shown to be similar to the low-latitude CMEs. This similarity is important because it provides important clues to the mechanism by which CMEs erupt. The nonradial motion of CMEs is discussed, including the deflection by coronal holes that have important space weather consequences. Finally, the implications of the presented observations for the modeling CME modeling are outlined. **1998-01-25, 24-11-2000, 2001-12-20, 2003-02-18, 2003-08-16-19, 2009-05-05, 2009-11-08, 2013-09-29-30, 2012-03-12,**

### The Peculiar Behavior of Halo Coronal Mass Ejections in Solar Cycle 24

N. **Gopalswamy**, H. Xie, S. Akiyama, P. Mäkelä, S. Yashiro, G. Michalek

ApJL 804 L23 2015

<http://arxiv.org/ftp/arxiv/papers/1504/1504.01797.pdf>

<https://iopscience.iop.org/article/10.1088/2041-8205/804/1/L23/pdf>

We report on a remarkable finding that the halo coronal mass ejections (CMEs) in cycle 24 are more abundant than in cycle 23, although the sunspot number in cycle 24 has dropped by about 40%. We also find that the distribution of halo-CME source locations is different in cycle 24: the longitude distribution of halos is much flatter with the number of halos originating at central meridian distance  $\geq 60$  degrees twice as large as that in cycle 23. On the other hand, the average speed and the associated soft X-ray flare size are the same in the two cycles, suggesting that the ambient medium into which the CMEs are ejected is significantly different. We suggest that both the higher abundance and larger central meridian longitudes of halo CMEs can be explained as a consequence of the diminished total pressure in the heliosphere in cycle 24 (Gopalswamy et al. 2014). The reduced total pressure allows CMEs expand more than usual making them appear as halos.

## **Anomalous Expansion of Coronal Mass Ejections during Solar Cycle 24 and its Space Weather Implications**

Nat **Gopalswamy**, Sachiko Akiyama, Seiji Yashiro, Hong Xie, and Pertti Mäkelä, Grzegorz Michalek  
E-print, April 2014; Geophysical Research Letters, Volume 41, Issue 8, pp. 2673-2680, 2014

<http://arxiv.org/pdf/1404.0252v1.pdf>

The familiar correlation between the speed and angular width of coronal mass ejections (CMEs) is also found in solar cycle 24, but the regression line has a larger slope: for a given CME speed, cycle 24 CMEs are significantly wider than those in cycle 23. The slope change indicates a significant change in the physical state of the heliosphere, due to the weak solar activity. The total pressure in the heliosphere (magnetic + plasma) is reduced by ~40%, which leads to the anomalous expansion of CMEs explaining the increased slope. The excess CME expansion contributes to the diminished effectiveness of CMEs in producing magnetic storms during cycle 24, both because the magnetic content of the CMEs is diluted and also because of the weaker ambient fields. The reduced magnetic field in the heliosphere may contribute to the lack of solar energetic particles accelerated to very high energies during this cycle.

## **Solar Eruptions and Energetic Particles: An Introduction**

**Review**

N. **Gopalswamy**<sup>1</sup>, R. Mewaldt<sup>2</sup>, and J. Torsti<sup>3</sup>

Book Series: [Geophysical Monograph Series](#) Volume 165, 2013

<https://agupubs.onlinelibrary.wiley.com/doi/book/10.1029/GM165>

<http://sci-hub.tw/10.1029/165GM02>

This introductory article highlights current issues concerning two related phenomena involving mass emission from the Sun: solar eruptions and solar energetic particles. A brief outline of the chapters is provided indicating how the current issues are addressed in the monograph. The sections in this introduction roughly group the chapters dealing with coronal mass ejections (CMEs), solar energetic particles (SEPs), shocks, and space weather. The concluding remarks include a brief summary of outstanding issues that drive current and future research on CMEs and SEPs.

## **Testing the empirical shock arrival model using quadrature observations**

N. **Gopalswamy**<sup>1,\*</sup>, P. Mäkelä<sup>1,2</sup>, H. Xie<sup>1,2</sup>, S. Yashiro

Space Weather, Volume 11, Issue 11, pages 661–669, November 2013

[http://cdaw.gsfc.nasa.gov/publications/gopal/gopal2013SW\\_testESA.pdf](http://cdaw.gsfc.nasa.gov/publications/gopal/gopal2013SW_testESA.pdf)

The empirical shock arrival (ESA) model was developed based on quadrature data from Helios (in situ) and P-78 (remote sensing) to predict the Sun-Earth travel time of coronal mass ejections (CMEs). The ESA model requires earthward CME speed as input, which is not directly measurable from coronagraphs along the Sun-Earth line. The Solar Terrestrial Relations Observatory (STEREO) and the Solar and Heliospheric Observatory (SOHO) were in quadrature during 2010–2012, so the speeds of Earth-directed CMEs were observed with minimal projection effects. We identified a set of 20 full halo CMEs in the field of view of SOHO that were also observed in quadrature by STEREO. We used the earthward speed from STEREO measurements as input to the ESA model and compared the resulting travel times with the observed ones from L1 monitors. We find that the model predicts the CME travel time within about 7.3 h, which is similar to the predictions by the ENLIL model. We also find that CME-CME and CME-coronal hole interaction can lead to large deviations from model predictions. **2011 February 15, 2012 July 12**

## **Latitudinal Connectivity of Ground Level Enhancement Events**

N. **Gopalswamy** and P. Mäkelä

Proceedings of: 12th Annual International Astrophysical Conference, ASP Conference Series, ed. Q. Hu and G. Zank, in press, **2013**; **File**

We examined the source regions and coronal environment of the historical ground level enhancement (GLE) events in search of evidence for non-radial motion of the associated coronal mass ejection (CME). For the 13 GLE events that had source latitudes  $>30^\circ$  we found evidence for possible non-radial CME motion due to deflection by large-scale magnetic structures in nearby coronal holes, streamers, or pseudo streamers. Polar coronal holes are the main source of deflection in the rise and declining phases of solar cycles. In the maximum phase, deflection by large-scale streamers or pseudo streamers overlying high-latitude filaments seems to be important. The B0 angle reduced the ecliptic distance of some GLE source regions and increased in others with the net result that the average latitude of GLE events did not change significantly. The non-radial CME motion is the dominant factor that reduces the ecliptic distance of GLE source regions, thereby improving the latitudinal connectivity to Earth. We further infer that the GLE particles must be accelerated at the nose part of the CME-driven shocks, where the shock is likely to be quasi-parallel.

**Table 1. Historical GLE events with flare latitudes  $>30^\circ$**

## **Obscuration of Flare Emission by an Eruptive Prominence**

Nat **Gopalswamy** and Seiji Yashiro

E-print, Sept **2013**, **File**, PASJ

<http://cdaw.gsfc.nasa.gov/publications/gopal/gopal2013PASJ.pdf>

We report on the eclipsing of microwave flare emission by an eruptive prominence from a neighboring region as observed by the Nobeyama Radioheliograph at 17 GHz. The obscuration of the flare emission appears as a dimming feature in the microwave flare light curve. We use the dimming feature to derive the temperature of the prominence and the distribution of heating along the length of the filament. We find that the prominence is heated to a temperature above the quiet Sun temperature at 17 GHz. The duration of the dimming is the time taken by the eruptive prominence in passing over the flaring region. We also find evidence for the obscuration in EUV images obtained by the Solar and Heliospheric Observatory (SOHO) mission. **2002/05/21-22**

## **Height of Shock Formation in the Solar Corona Inferred from Observations of Type II Radio Bursts and Coronal Mass Ejections**

N. **Gopalswamy**, H. Xie, P. Makela, S. Yashiro, S. Akiyama, W. Uddin., A. K. Srivastava, N. C. Joshi, R. Chandra, P. K. Manoharan, K. Mahalakshmi, V. C. Dwivedi, R. Jain and A. K. Awasthi, N. V. Nitta, M. J. Aschwanden, D. P. Choudhary

E-print, Jan **2013**; Adv. Space Res., v. 51, No. 11, p. 1981-1989, **File**

Employing coronagraphic and EUV observations close to the solar surface made by the Solar Terrestrial Relations Observatory (STEREO) mission, we determined the heliocentric distance of coronal mass ejections (CMEs) at the starting time of associated metric type II bursts. We used the wave diameter and leading edge methods and measured the CME heights for a set of 32 metric type II bursts from solar cycle 24. We minimized the projection effects by making the measurements from a view that is roughly orthogonal to the direction of the ejection. We also chose image frames close to the onset times of the type II bursts, so no extrapolation was necessary. We found that the CMEs were located in the heliocentric distance range from 1.20 to 1.93 solar radii (Rs), with mean and median values of 1.43 and 1.38 Rs, respectively. We conclusively find that the shock formation can occur at heights substantially below 1.5 Rs. In a few cases, the CME height at type II onset was close to 2 Rs. In these cases, the starting frequency of the type II bursts was very low, in the range 25–40 MHz, which confirms that the shock can also form at larger heights. The starting frequencies of metric type II bursts have a weak correlation with the measured CME/shock heights and are consistent with the rapid decline of density with height in the inner corona.

## **The Solar Connection of Enhanced Heavy Ion Charge States in the Interplanetary Medium: Implications for the Flux-rope Structure of CMEs**

N. **Gopalswamy**, P. Mäkelä, S. Akiyama, H. Xie, S. Yashiro, and A. A. Reinard

Solar Physics, Volume 284, Issue 1, pp 17-46, **2013**, **File**

We investigated a set of 54 interplanetary coronal mass ejection (ICME) events whose solar sources are very close to the disk center (within  $\pm 15$  degrees from the central meridian). The ICMEs consisted of 23 magnetic cloud (MC) events and 31 non-MC events. Our analyses suggest that the MC and non-MC ICMEs have more or less the same eruption characteristics at the Sun in terms of soft X-ray flares and CMEs. Both types have significant enhancements in charge states, although the non-MC structures have slightly lower levels of enhancement. The overall duration of charge state enhancement is also considerably smaller than that in MCs as derived from solar wind plasma and magnetic signatures. We find very good correlation between the Fe and O charge state measurements and the flare properties such as soft X-ray flare intensity and flare temperature for both MCs and non-MCs. These observations suggest that both MC and non-MC ICMEs are likely to have a flux-rope structure and the unfavorable observational geometry may be

responsible for the appearance of non-MC structures at 1 AU. We do not find any evidence for active region expansion resulting in ICMEs lacking a flux rope structure because the mechanism of producing high charge states and the flux rope structure at the Sun is the same for MC and non-MC events.

## **Observations of CMEs and Models of the Eruptive Corona** Review

N. **Gopalswamy**

E-print, Jan **2013**, **File**; Solar wind 13

[http://arxiv.org/pdf/0903.2776.pdf?origin=publication\\_detail](http://arxiv.org/pdf/0903.2776.pdf?origin=publication_detail)

<http://arxiv.org/pdf/1304.0087v1.pdf>

Current theoretical ideas on the internal structure of CMEs suggest that a flux rope is central to the CME structure, which has considerable observational support both from remote-sensing and in-situ observations. The flux-rope nature is also consistent with the post-eruption arcades with high-temperature plasma and the charge states observed within CMEs arriving at Earth. The model involving magnetic loop expansion to explain CMEs without flux ropes is not viable because it contradicts CME kinematics and flare properties near the Sun. The global picture of CMEs becomes complete if one includes the shock sheath to the CSHKP model.

## **Radio-loud CMEs from the disk center lacking shocks at 1 AU**

N. **Gopalswamy**, P. Makela, S. Akiyama, S. Yashiro, H. Xie, R. J. MacDowall, M. L. Kaiser

E-print, June **2012**, JGR

A coronal mass ejection (CME) associated with a type II burst and originating close to the center of the solar disk typically results in a shock at Earth in 2-3 days and hence can be used to predict shock arrival at Earth. However, a significant fraction (about 28%) of such CMEs producing type II bursts were not associated with shocks at Earth. We examined a set of 21 type II bursts observed by the Wind/WAVES experiment at decameter-hectometric (DH) wavelengths that had CME sources very close to the disk center (within a central meridian distance of 30 degrees), but did not have a shock at Earth. We find that the near-Sun speeds of these CMEs average to ~644 km/s, only slightly higher than the average speed of CMEs associated with radio-quiet shocks. However, the fraction of halo CMEs is only ~30%, compared to 54% for the radio-quiet shocks and 91% for all radio-loud shocks. We conclude that the disk-center radio-loud CMEs with no shocks at 1 AU are generally of lower energy and they drive shocks only close to the Sun and dissipate before arriving at Earth. There is also evidence for other possible processes that lead to the lack of shock at 1 AU: (i) overtaking CME shocks merge and one observes a single shock at Earth, and (ii) deflection by nearby coronal holes can push the shocks away from the Sun-Earth line, such that Earth misses these shocks. The probability of observing a shock at 1 AU increases rapidly above 60% when the CME speed exceeds 1000 km/s and when the type II bursts propagate to frequencies below 1 MHz.

## **Properties of Ground level enhancement events and the associated solar eruptions during solar cycle 23.**

N. **Gopalswamy**, H. Xie, S. Yashiro, S. Akiyama, P. Mäkelä, I.G. Usoskin,

E-print, May **2012**, **File**; Space Sci. Rev., **2012**

Solar cycle 23 witnessed the most complete set of observations of coronal mass ejections (CMEs) associated with the Ground Level Enhancement (GLE) events. We present an overview of the observed properties of the GLEs and those of the two associated phenomena, viz., flares and CMEs, both being potential sources of particle acceleration. Although we do not find a striking correlation between the GLE intensity and the parameters of flares and CMEs, the solar eruptions are very intense involving X-class flares and extreme CME speeds (average ~2000 km/s). An M7.1 flare and a 1200 km/s CME are the weakest events in the list of 16 GLE events. Most (80%) of the CMEs are full halos with the three non-halos having widths in the range 167 to 212 degrees. The active regions in which the GLE events originate are generally large: 1290 msh (median 1010 msh) compared to 934 msh (median: 790 msh) for SEP-producing active regions. For accurate estimation of the CME height at the time of metric type II onset and GLE particle release, we estimated the initial acceleration of the CMEs using flare and CME observations. The initial acceleration of GLE-associated CMEs is much larger (by a factor of 2) than that of ordinary CMEs (2.3 km/s<sup>2</sup> vs. 1 km/s<sup>2</sup>). We confirmed the initial acceleration for two events for which CME measurements are available in the inner corona. The GLE particle release is delayed with respect to the onset of all electromagnetic signatures of the eruptions: type II bursts, low frequency type III bursts, soft X-ray flares and CMEs. The presence of metric type II radio bursts some 17 min (median: 16 min; range: 3 to 48 min) before the GLE onset indicates shock formation well before the particle release. The release of GLE particles occurs when the CMEs reach an average height of ~3.09 Rs (median: 3.18 Rs; range: 1.71 to 4.01 Rs) for well-connected events (source longitude in the range W20 ? W90). For poorly connected events, the average CME height at GLE particle release is ~66% larger (mean: 5.18 Rs; median: 4.61 Rs; range: 2.75 ? 8.49 Rs). The longitudinal dependence is consistent with shock accelerations because the shocks from poorly connected events need to expand more to cross the field lines connecting to an Earth observer. On the other hand, the CME height at metric type II burst onset has no longitudinal dependence because electromagnetic signals do not require magnetic connectivity to the observer. For several events, the GLE particle release is very close to the time of first appearance of the CME in the

coronagraphic field of view, so we independently confirmed the CME height at particle release. The CME height at metric type II burst onset is in the narrow range 1.29 to 1.8 Rs, with mean and median values of 1.53 and 1.47 Rs. The CME heights at metric type II burst onset and GLE particle release correspond to the minimum and maximum in the Alfvén speed profile. The increase in CME speed between these two heights suggests an increase in Alfvénic Mach number from 2 to 3. The CME heights at GLE particle release are in good agreement with those obtained from the velocity dispersion analysis (Reames, 2009a,b) including the source longitude dependence. We also discuss the implications of the delay of GLE particle release with respect to complex type III bursts by ~18 min (median: 16 in; range: 2 to 44 min) for the flare acceleration mechanism. A similar analysis is also performed on the delay of particle release relative to the hard X-ray emission. **6 Nov 1997 , 1998 August 24, 02-Nov-03, 17-Jan-05, 14-Jul-05**

## **The Relationship Between the Expansion Speed and Radial Speed of CMEs Confirmed Using Quadrature Observations of the 2011 February 15 CME**

Nat [Gopalswamy](#)<sup>1</sup>, Pertti Makela<sup>2</sup>, Seiji Yashiro<sup>2</sup>, and Joseph M. Davila<sup>1</sup>

Sun and Geosphere, **2012, File**

It is difficult to measure the true speed of Earth-directed CMEs from a coronagraph located along the Sun-Earth line because of the occulting disk. However, the expansion speed (the speed with which the CME appears to spread in the sky plane) can be measured by such a coronagraph. In order to convert the expansion speed to radial speed (which is important for space weather applications) one can use an empirical relationship between the two that assumes an average width for all CMEs. If we have the width information from quadrature observations, we can confirm the relationship between expansion and radial speeds derived by Gopalswamy et al. (2009a). The STEREO spacecraft were in quadrature with SOHO (STEREO-A ahead of Earth by 87° and STEREO-B 94° behind Earth) on **2011 February 15**, when a fast Earth-directed CME occurred. The CME was observed as a halo by the Large-Angle and Spectrometric Coronagraph (LASCO) on board SOHO. The sky-plane speed was measured by SOHO/LASCO as the expansion speed, while the radial speed was measured by STEREO-A and STEREO-B. In addition, STEREO-A and STEREO-B images provided the width of the CME, which is unknown from Earth view. From the SOHO and STEREO measurements, we confirm the relationship between the expansion speed ( $V_{exp}$ ) and radial speed ( $V_{rad}$ ) derived previously from geometrical considerations (Gopalswamy et al. 2009a):  $V_{rad} = \frac{V_{exp}}{1 + \cot w}$ , where  $w$  is the half width of the CME. STEREO-B images of the CME, we found that CME had a full width of 76°, so  $w = 38°$ . This gives the relation as  $V_{rad} = 1.14 V_{exp}$ . From LASCO observations, we measured  $V_{exp} = 897$  km/s, so we get the radial speed as 1023 km/s. Direct measurement of radial speed yields 945 km/s (STEREO-A) and 1058 km/s (STEREO-B). These numbers are different only by 7.6% and 3.4% (for STEREO-A and STEREO-B, respectively) from the computed value.

## **CORONAL MAGNETIC FIELD MEASUREMENT FROM EUV IMAGES MADE BY THE SOLAR DYNAMICS OBSERVATORY**

Nat [Gopalswamy](#)<sup>1</sup>, Nariaki Nitta<sup>2</sup>, Sachiko Akiyama<sup>1,3</sup>, Pertti Mäkelä<sup>1,3</sup> and Seiji Yashiro

**2012 ApJ 744 72, File**

By measuring the geometrical properties of the coronal mass ejection (CME) flux rope and the leading shock observed on **2010 June 13** by the Solar Dynamics Observatory (SDO) mission's Atmospheric Imaging Assembly we determine the Alfvén speed and the magnetic field strength in the inner corona at a heliocentric distance of ~1.4 Rs. The basic measurements are the shock standoff distance ( $\Delta R$ ) ahead of the CME flux rope, the radius of curvature of the flux rope ( $R_c$ ), and the shock speed. We first derive the Alfvénic Mach number ( $M$ ) using the relationship,  $\Delta R/R_c = 0.81[(\gamma - 1)M^2 + 2]/[(\gamma + 1)(M^2 - 1)]$ , where  $\gamma$  is the only parameter that needed to be assumed. For  $\gamma = 4/3$ , the Mach number declined from 3.7 to 1.5 indicating shock weakening within the field of view of the imager. The shock formation coincided with the appearance of a type II radio burst at a frequency of ~300 MHz (harmonic component), providing an independent confirmation of the shock. The shock compression ratio derived from the radio dynamic spectrum was found to be consistent with that derived from the theory of fast-mode MHD shocks. From the measured shock speed and the derived Mach number, we found the Alfvén speed to increase from ~140 km s<sup>-1</sup> to 460 km s<sup>-1</sup> over the distance range 1.2-1.5 Rs. By deriving the upstream plasma density from the emission frequency of the associated type II radio burst, we determined the coronal magnetic field to be in the range 1.3-1.5 G. The derived magnetic field values are consistent with other estimates in a similar distance range. This work demonstrates that the EUV imagers, in the presence of radio dynamic spectra, can be used as coronal magnetometers.

## **Universal Heliophysical Processes**

[Gopalswamy](#), N.

In: The Sun, the Solar Wind, and the Heliosphere, ed. M. P. Miralles and J. Sanchez Almeida, IAGA Special Sopron Book Series, Vol 4, Chapter 2, Springer, pp 9-20, **2011, File**, DOI: 10.1007/978/90-481-9787-3\_2  
The physical processes in the heliospace are a direct consequence of the influenced by Sun's mass and electromagnetic emissions. There has been enormous progress in studying these processes since the dawn of the space age half a century ago. The heliospace serves as a great laboratory to study numerous physical processes, using the vast array of ground and space-based measurements of various physical quantities. The observational capabilities collectively form the Great Observatory to make scientific investigations not envisioned by individual instrument teams. The International

Heliophysical Year (IHY) program has been promoting scientific investigations on the universality of physical processes such as shocks, particle acceleration, dynamo, magnetic reconnection, magnetic flux ropes, plasma-neutral matter interactions, turbulence, and so on. This paper highlights scientific deliberations on these and related topics that took place during the IAGA sessionon "Universal Heliophysical Processes" in Sopron, Hungary. The session featured several invited and contributed papers that focused on observations, theory and modeling of the universal heliophysical processes.

## **Coronal Mass Ejections and Solar Radio Emissions**

N. [Gopalswamy](#)

Accepted for Publication in the book **Planetary Radio Emissions VII**, Eds. Rucker, H. O., W. S. Kurth, P. Louarn, G. Fischer, Austrian Academy of Sciences Press, Vienna, in press (2011), **File**

Three types of low-frequency nonthermal radio bursts are associated with coronal mass ejections (CMEs): Type III bursts due to accelerated electrons propagating along open magnetic field lines, type II bursts due to electrons accelerated in shocks, and type IV bursts due to electrons trapped in post-eruption arcades behind CMEs. This paper presents a summary of results obtained during solar cycle 23 primarily using the white-light coronagraphic observations from the Solar Heliospheric Observatory (SOHO) and the WAVES experiment on board Wind.

## **The Strength and Radial Profile of Coronal Magnetic Field from the Standoff Distance of a CME-driven Shock**

Nat [Gopalswamy](#) and Seiji Yashiro<sup>2</sup>

E-print, July 2011, **File**

We determine the coronal magnetic field strength in the heliocentric distance range 6 to 23 solar radii ( $R_s$ ) by measuring the shock standoff distance and the radius of curvature of the flux rope during the **2008 March 25** coronal mass ejection (CME) imaged by white-light coronagraphs.

Assuming the adiabatic index, we determine the Alfvén Mach number, and hence the Alfvén speed in the ambient medium using the measured shock speed. By measuring the upstream plasma density using polarization brightness images, we finally get the magnetic field strength upstream of the shock. The estimated magnetic field decreases from ~48 mG around 6  $R_s$  to 8 mG at 23  $R_s$ . The radial profile of the magnetic field can be described by a power law in agreement with other estimates at similar heliocentric distances.

## **Coronal Mass Ejections: a Summary of Recent Results**

N. [Gopalswamy](#), [nat.gopalswamy@nasa.gov](mailto:nat.gopalswamy@nasa.gov)

Proceedings of the 20th Slovak National Solar Physics Workshop, ed. I. Dorotovic, Slovak Central Observatory, pp. 108 - 130, **2010**, **File** [A review](#)

Coronal mass ejections (CMEs) have been recognized as the most energetic phenomenon in the heliosphere, deriving their energy from the stressed magnetic fields on the Sun. This paper summarizes the properties of CMEs and highlights some of the recent results on CMEs. In particular, the morphological, physical, and kinematic properties of CMEs are summarized. The CME consequences in the heliosphere such as interplanetary shocks, type II radio bursts, energetic particles, geomagnetic storms, and cosmic ray modulation are discussed.

## **A Catalog of Halo Coronal Mass Ejections from SOHO**

N. [Gopalswamy](#)<sup>1</sup>, S. Yashiro<sup>2</sup>, G. Michalek<sup>3</sup>, H. Xie<sup>3</sup>, P. Mäkelä<sup>3</sup>, A. Vourlidas<sup>4</sup>, R. A. Howard<sup>4</sup>  
Sun and Geosphere, **2010**; 5(1): 7 – 16, **File**

[http://newserver.stil.bas.bg/SUNGEO/00SGArhiv/SG\\_v5\\_No1\\_2010-pp-7-16.pdf](http://newserver.stil.bas.bg/SUNGEO/00SGArhiv/SG_v5_No1_2010-pp-7-16.pdf)

Coronal mass ejections (CMEs) that appear to surround the occulting disk of the observing coronagraph are known as halo CMEs. Halos constitute a subset of energetic CMEs that have important heliospheric consequences. Here we describe an on-line catalog that contains all the halo CMEs that were identified in the images obtained by the Solar and Heliospheric Observatory (SOHO) mission's Large Angle and Spectrometric Coronagraph (LASCO) since 1996. Until the end of 2007, some 396 halo CMEs were recorded. For each halo CME, we identify the solar source (heliographic coordinates), the soft X-ray flare importance, and the flare onset time. From the sky-plane speed measurements and the solar source information we obtain the space speed of CMEs using a cone model. In addition to the description of the catalog ([http://cdaw.gsfc.nasa.gov/CME\\_list/HALO/halo.html](http://cdaw.gsfc.nasa.gov/CME_list/HALO/halo.html)), we summarize the statistical properties of the halo CMEs. We confirm that halo CMEs are twice faster than ordinary CMEs and are associated with major flares on the average. We also compared the annual rate of halo CMEs with that obtained by automatic detection methods and found that most of these methods have difficulty in identifying full halo CMEs.

## **Large-scale solar eruptions.**

### **THE SOHO/LASCO CME CATALOG**

N. **Gopalswamy**, S. Yashiro, G. Michalek, G. Stenborg, A. Vourlidas, S. Freeland, and R. Howard  
Earth, Moon, and Planets, Volume 104, Issue 1, Page 295, 2009

Coronal mass ejections (CMEs) are routinely identified in the images of the solar corona obtained by the Solar and Heliospheric Observatory (SOHO) mission's Large Angle and Spectrometric Coronagraph (LASCO) since 1996. The identified CMEs are measured and their basic attributes are cataloged in a data base known as the SOHO/LASCO CME Catalog. The Catalog also contains digital data, movies, and plots for each CME, so detailed scientific investigations can be performed on CMEs and the related phenomena such as flares, radio bursts, solar energetic particle events, and geomagnetic storms. This paper provides a brief description of the Catalog and summarizes the statistical properties of CMEs obtained using the Catalog. Data products relevant to space weather research and some CME issues that can be addressed using the Catalog are discussed. The URL of the Catalog is: [http://cdaw.gsfc.nasa.gov/CME\\_list](http://cdaw.gsfc.nasa.gov/CME_list).

### **CME link to the geomagnetic storms**

Nat **Gopalswamy**

Solar and Stellar Variability: Impact on Earth and Planets, Proceedings IAU Symposium No. 264, 2009, p. 326-335, A.G. Kosovichev, A.H. Andrei & J.-P. Rozelot, eds.; **File**

Y:\obridko\otchet09

The coronal mass ejection (CME) link to geomagnetic storms stems from the southward component of the interplanetary magnetic field contained in the CME flux ropes and in the sheath between the flux rope and the CME-driven shock. A typical storm-causing CME is characterized by (i) high speed, (ii) large angular width (mostly halos and partial halos), and (iii) solar source location close to the central meridian. For CMEs originating at larger central meridian distances, the storms are mainly caused by the sheath field. Both the magnetic and energy contents of the storm-producing CMEs can be traced to the magnetic structure of active regions and the free energy stored in them.

### **Relation Between Type II Bursts and CMEs Inferred from STEREO Observations**

**Gopalswamy**, N.; Thompson, W. T.; Davila, J. M.; Kaiser, M. L.; Yashiro, S.; Mäkelä, P.; Michalek, G.; Bougeret, J.-L.; Howard, R. A.

E-print, July 2009; *Solar Phys.* (2009) 259: 227–254; **File**

The inner coronagraph (COR1) of the Solar Terrestrial Relations Observatory (STEREO) mission has made it possible to observe CMEs in the spatial domain overlapping with that of the metric type II radio bursts. The type II bursts were associated with generally weak flares (mostly B and C class soft X-ray flares), but the CMEs were quite energetic.

Using CME data for a set of type II bursts during the declining phase of solar cycle 23, we determine the CME height when the type II bursts start, thus giving an estimate of the heliocentric distance at which CME-driven shocks form. This distance has been determined to be  $\sim 1.5R_s$  (solar radii), which coincides with the distance at which the Alfvén speed profile has a minimum value. We also use type II radio observations from STEREO/WAVES and Wind/WAVES observations to show that CMEs with moderate speed drive either weak shocks or no shock at all when they attain a height where the Alfvén speed peaks ( $\sim 3R_s$ – $4R_s$ ). Thus the shocks seem to be most efficient in accelerating electrons in the heliocentric distance range of  $1.5R_s$  to  $4R_s$ . By combining the radial variation of the CME speed in the inner corona (CME speed increase) and interplanetary medium (speed decrease) we were able to correctly account for the deviations from the universal drift-rate spectrum of type II bursts, thus confirming the close physical connection between type II bursts and CMEs. The average height ( $\sim 1.5R_s$ ) of STEREO CMEs at the time of type II bursts is smaller than that ( $\sim 2.2R_s$ ) obtained for SOHO (Solar and Heliospheric Observatory) CMEs. We suggest that this may indicate, at least partly, the density reduction in the corona between the maximum and declining phases, so a given plasma level occurs closer to the Sun in the latter phase. In two cases, there was a diffuse shock-like feature ahead of the main body of the CME, indicating a standoff distance of  $1R_s$ – $2R_s$  by the time the CME left the LASCO field of view.

## **Erratum to: Relation Between Type II Bursts and CMEs Inferred from STEREO Observations, Solar Physics, Volume 277, Number 2, 459, 2012**

### **LARGE GEOMAGNETIC STORMS ASSOCIATED WITH LIMB HALO CORONAL MASS EJECTIONS**

NAT [GOPALSWAMY](#), SEJI YASHIRO†, HONG XIE, SACHIKO AKIYAMA, and PERTTI MÄKELÄ  
Advances in Geosciences, 2009, File

Solar cycle 23 witnessed the observation of hundreds of halo coronal mass ejections (CMEs), thanks to the high dynamic range and extended field of view of the Large Angle and Spectrometric Coronagraph (LASCO) on board the Solar and Heliospheric Observatory (SOHO) mission. More than two thirds of halo CMEs originating on the front side of the Sun have been found to be geoeffective ( $Dst \leq -50$  nT). The delay time between the onset of halo CMEs and the peak of ensuing geomagnetic storms has been found to depend on the solar source location (Gopalswamy et al., 2007). In particular, limb halo CMEs (source longitude  $> 45^\circ$ ) have a 20% shorter delay time on the average. It was suggested that the geomagnetic storms due to limb halos must be due to the sheath portion of the interplanetary CMEs (ICMEs) so that the shorter delay time can be accounted for. We confirm this suggestion by examining the sheath and ejecta portions of ICMEs from Wind and ACE data that correspond to the limb halos. Detailed examination showed that three pairs of limb halos were interacting events. Geomagnetic storms following five limb halos were actually produced by other disk halos. The storms followed by four isolated limb halos and the ones associated with interacting limb halos, were all due to the sheath portions of ICMEs.

### **Coronal Mass Ejections from Sunspot and non-Sunspot Regions**

N. [Gopalswamy](#)<sup>1</sup>, S. Akiyama<sup>1, 2</sup>, S. Yashiro, and P. Mäkelä<sup>1</sup>

To appear in “Magnetic Coupling between the Interior and the Atmosphere of the Sun”, eds. S. S. Hasan and R. J. Rutten, Astrophysics and Space Science Proceedings, Springer-Verlag, Heidelberg, Berlin, 2009; File. Summary. Coronal mass ejections (CMEs) originate from closed magnetic field regions on the Sun, which are active regions and quiescent filament regions. The energetic populations such as halo CMEs, CMEs associated with magnetic clouds, geoeffective CMEs, CMEs associated with solar energetic particles and interplanetary type II radio bursts, and shock-driving CMEs have been found to originate from sunspot regions. The CME and flare occurrence rates are found to be correlated with the sunspot number, but the correlations are significantly weaker during the maximum phase compared to the rise and declining phases. We suggest that the weaker correlation results from high-latitude CMEs from the polar crown filament regions that are not related to sunspots.

### **Coronal mass ejections and space weather**

Nat [Gopalswamy](#)

Climate and Weather of the Sun-Earth System (CAWSES): Selected Papers from the 2007 Kyoto Symposium, Edited by T. Tsuda, R. Fujii, K. Shibata, and M. A. Geller, pp. 77–120.  
c\_TERRAPUB, Tokyo, 2009, File.

Solar energetic particles (SEPs) and geomagnetic storms are the two primary space weather consequences of coronal mass ejections (CMEs) and their interplanetary counterparts (ICMEs). I summarize the observed properties of CMEs and ICMEs, paying particular attention to those properties that determine the ability of CMEs in causing space weather. Then I provide observational details of two the central issues: (i) for producing geomagnetic storms, the solar source location and kinematics along with the magnetic field structure and intensity are important, and (ii) for SEPs, the shock-driving ability of CMEs, the Alfvén speed in the ambient medium, and the connectivity to Earth are crucial parameters.

### **CME Interaction with Coronal Holes and their Interplanetary Consequences**

N. [Gopalswamy](#)<sup>1</sup>, P. Mäkelä<sup>1,2</sup>, H. Xie<sup>1,2</sup>, S. Akiyama<sup>1,2</sup>, and S. Yashiro<sup>1,2</sup>

JGR, 2009; File; J. Geophys. Res., Vol. 114, No. A3, A00A22

A significant number of interplanetary (IP) shocks (~17%) during cycle 23 were not followed by drivers. The number of such “driverless” shocks steadily increased with the solar cycle with 15%, 33%, and 52% occurring in the rise, maximum, and declining phase of the solar cycle. The solar sources of 15% of the driverless shocks were very close to the central meridian of the Sun (within  $\sim 15^\circ$ ), which is quite unexpected. More interestingly, all the driverless shocks with their solar sources near the solar disk center occurred during the declining phase of solar cycle 23. When we investigated the coronal environment of the source regions of driverless shocks, we found that in each case there was at least one coronal hole nearby suggesting that the coronal holes might have deflected the associated coronal mass ejections (CMEs) away from the Sun-Earth line. The presence of abundant low-latitude coronal holes during the declining phase further explains why CMEs originating close to the disk center mimic the limb CMEs, which normally lead to driverless shocks due to purely geometrical reasons. We also examined the solar source regions of shocks with drivers. For these, the coronal holes were located such that they either had no influence on the CME trajectories, or they deflected the CMEs towards the Sun-Earth line. We also obtained the open magnetic field distribution on the Sun by performing a potential field source surface extrapolation to the corona. It was found that the CMEs generally move

away from the open magnetic field regions. The CME-coronal hole interaction must be widespread in the declining phase, and may have a significant impact on the geoeffectiveness of CMEs.

Cent. Eur. Astrophys. Bull. vol (2008) 1, 1, **File**

We show the relation between radial ( $V_{rad}$ ) and expansion ( $V_{exp}$ ) speeds of coronal mass ejections (CMEs) depends on the CME width. As CME width increases,  $V_{rad}=V_{exp}$  decreases from a value  $>1$  to  $<1$ . For widths approaching  $180^\circ$ , the ratio approaches 0 if the cone has a flat base, while it approaches 0.5 if the base has a bulge (ice cream cone). The speed difference between the limb and disk halos and the spherical expansion of superfast CMEs can be explained by the width dependence.

### **Major Solar Flares without Coronal Mass Ejections**

N. **Gopalswamy**<sup>1</sup>, S. Akiyama<sup>1,2</sup> and S. Yashiro<sup>1,2,3</sup>

Proceedings IAU Symposium No. 257, 2008, N. Gopalswamy, & D. Webb, eds.; **File**

We examine the source properties of X-class soft X-ray flares that were not associated with coronal mass ejections (CMEs). All the flares were associated with intense microwave bursts implying the production of high energy electrons. However, most (85%) of the flares were not associated with metric type III bursts, even though open field lines existed in all but two of the active regions. The X-class flares seem to be truly confined because there was no material ejection (thermal or nonthermal) away from the flaring region.

### **Coronal Mass Ejections, Type II Radio Bursts, and Solar Energetic Particle Events in the SOHO Era**

N. **Gopalswamy**<sup>1</sup>, S. Yashiro<sup>2</sup>, S. Akiyama<sup>2</sup>, P. Makela<sup>2</sup>, H. Xie<sup>2</sup>, M. L. Kaiser<sup>1</sup>, R. A. Howard<sup>3</sup> and J. L. Bougeret<sup>4</sup>

E-print, Feb 2008, **File**; Annales Geophysicae

Using the extensive and uniform data on coronal mass ejections (CMEs), solar energetic particle (SEP) events, and type II radio bursts during the SOHO era, we discuss how the CME properties such as speed, width and solar-source longitude decide whether CMEs are associated with type II radio bursts and SEP events. We discuss why some radio-quiet CMEs are associated with small SEP events while some radio-loud CMEs are not associated with SEP events. We conclude that either some fast and wide CMEs do not drive shocks or they drive weak shocks that do not produce significant levels of particle acceleration. We also infer that the Alfvén speed in the corona and near-Sun interplanetary medium ranges from  $<200$  km/s to  $\sim 1600$  km/s. Radio-quiet fast and wide CMEs are also poor SEP producers and the association rate of type II bursts and SEP events steadily increases with CME speed and width (i.e., energy). If we consider western hemispheric CMEs, the SEP association rate increases linearly from  $\sim 30\%$  for 800 km/s CMEs to 100% for  $\geq 1800$  km/s. Essentially all type II bursts in the decametre-hectometric (DH) wavelength range are associated with SEP events once the source location on the Sun is taken into account. This is a significant result for space weather applications, because if a CME originating from the western hemisphere is accompanied by a DH type II burst, there is a high probability that it will produce an SEP event.

### **Energetic Phenomena on the Sun**

Solar flares, coronal mass ejections (CMEs), solar energetic particles (SEPs), and fast solar wind represent the energetic phenomena on the Sun.

This paper provides an **overview** of the energetic phenomena on the Sun including their origin interplanetary propagation and space weather consequences.

### **Radio Quiet Fast and Wide Coronal Mass Ejections**

N. **Gopalswamy**<sup>1</sup>, S. Yashiro<sup>2</sup>, H. Xie<sup>2</sup>, S. Akiyama<sup>2</sup>, E. Aguilar-Rodriguez<sup>2</sup>, M. L. Kaiser<sup>1</sup>, R. A., Howard<sup>3</sup> and J.-L. Bougeret<sup>4</sup>

E-print, Nov. 2007; Ap. J.

We report on the properties of radio-quiet (RQ) and radio-loud (RL) coronal mass ejections (CMEs) that are fast and wide (FW). RQ CMEs lack of type II radio bursts in the metric and decameterhectometric (DH) wavelengths. RL CMEs are associated with metric or DH type II bursts.

The RQ FW CMEs suggest that the Alfvén speed in the low-latitude outer corona can often exceed 1000 km/s and can vary over a factor of  $\geq 3$ . None of the RQ CMEs was associated with large solar energetic particles, which is

useful information for space weather applications.

## **Coronal Mass Ejections of Solar Cycle 23**

Nat [Gopalswamy](#)

J. Astrophys. Astr. , 2006, File

I summarize the statistical, physical, and morphological properties of coronal mass ejections (CMEs) of solar cycle 23, as observed by the Solar and Heliospheric Observatory (SOHO) mission. The SOHO data is by far the most extensive data, which made it possible to fully establish the properties of CMEs as a phenomenon of utmost importance to Sun-Earth connection as well as to the heliosphere. I also discuss various subsets of CMEs that are of primary importance for impact on Earth.

The coronal mass ejection (CME) phenomenon occurs in closed magnetic field regions on the Sun such as active regions, filament regions, transequatorial interconnection regions, and complexes involving a combination of these. This chapter describes the current knowledge on these closed field structures and how they lead to CMEs. After describing the specific magnetic structures observed in the CME source region, we compare the substructures of CMEs to what is observed before eruption. Evolution of the closed magnetic structures in response to various photospheric motions over different time scales (convection, differential rotation, meridional circulation) somehow leads to the eruption. We describe this pre-eruption evolution and attempt to link them to the observed features of CMEs. Small-scale energetic signatures in the form of electron acceleration (signified by nonthermal radio bursts at metric wavelengths) and plasma heating (observed as compact soft X-ray brightening) may be indicative of impending CMEs. We survey these pre-eruptive energy releases using observations taken before and during the eruption of several CMEs. Finally, we discuss how the observations can be converted into useful inputs to numerical models that can describe the CME initiation.

Abstract

This paper summarizes the extreme solar activity and its space weather implications during the declining phase of the solar cycle 23: October–November 2003 (AR 486), November 2004 (AR 696), January 2005 (AR 720), and September 2005 (AR 808). We have compiled and compared the properties of eruptions and the underlying active regions. All these are super active regions, but the flare and CME productivity varied significantly. While the CMEs from all the regions kept the level of solar energetic particles (SEPs) at storm level for several days, their geoeffectiveness (the ability to produce geomagnetic storms) was significantly different, probably due to the location of the eruptions on the Sun.

A&A 660, A116 2022

<https://arxiv.org/pdf/2202.11375.pdf>

<https://www.aanda.org/articles/aa/pdf/2022/04/aa42995-21.pdf>

Ubiquitous transition region (TR) network jets are considered to be substantial sources of mass and energy to the corona and solar wind. We conduct a case study of a network jet to better understand the nature of mass flows along its length and the energetics involved in its launch. We present an observation of a jet with the Interface Region Imaging Spectrograph (IRIS), while also using data from the Solar Dynamics Observatory (SDO) to provide further context. The jet was located within a coronal hole close to the disk center. We find that a blueshifted secondary component of TR emission is associated with the jet and is persistent along its spire. This component exhibits upward speeds of approximately 20–70 km s<sup>-1</sup> and shows enhanced line broadening. However, plasma associated with the jet in the upper chromosphere shows downflows of 5–10 km s<sup>-1</sup>. Finally, the jet emanates from a seemingly unipolar magnetic footpoint. While a definitive magnetic driver is not discernible for this event, we infer that the energy driving the network jet is deposited at the top of the chromosphere, indicating that TR network jets are driven from the mid-atmospheric layers of the Sun. The energy flux associated with the line broadening indicates that the jet could be powered all the way into the solar wind. **November 23, 2016**

## Brightening and Darkening of the Extended Solar Corona during the Superflares of September 2017

2018 ApJL 856 L38

<http://sci-hub.tw/http://iopscience.iop.org/2041-8205/856/2/L38/>

On **2017 September 6 and 10**, the strongest X9.3 and X8.2 flares of the decade occurred in the active region NOAA Active Region 12673. During these flares, the Sun Watcher with Active Pixels and Image Processing (SWAP) telescope on board the Project for Onboard Autonomy 2 (PROBA2) satellite registered the unusual alternate brightening and darkening of the western corona at the heliocentric distances  $\approx 1.2$ – $1.7 R_{\odot}$ . The X9.3 flare on 2017 September 6 was accompanied by coronal brightening up to 30%–45% at distances  $\approx 1.35$ – $1.7 R_{\odot}$ . Numerical simulations showed that this brightening might be produced by resonant scattering of the flare radiation by the Fe ix–Fexi ions in the coronal plasma at the temperature  $T \sim 0.8$ – $1$  MK, and the densities seriously reduced in comparison with the typical values for the quiet background corona probably moving outward with velocities of 30–40 km s<sup>-1</sup>. At the maximum of the flare and one hour later, two coronal mass ejections (CMEs) originated, which dimmed the coronal emission in the SWAP 174 Å passband above the western limb by 20%–30%. The X8.2 flare on September 10 was accompanied by a CME, which rose up and progressively dimmed the western part of the corona up to 60%. An hour later the darkening, produced by a global rearrangement of the magnetic field structure and an evacuation of a significant part of the coronal plasma, extended over the complete western limb. A differential emission measure (DEM) analysis showed a decrease in the electron density of the background plasma with  $T \sim 1$ – $2$  MK at distances  $1.24$ – $1.33 R_{\odot}$  by 2–3.5 times after the CME. At the same time, an additional DEM peak at  $T \approx 0.8$  MK appeared, which may be associated with an additional emission in the SWAP passband produced by the flare radiation resonantly scattered by the coronal plasma.

## INTERRUPTED ERUPTION OF LARGE QUIESCENT FILAMENT ASSOCIATED WITH A HALO CME

S. **Gosain**<sup>1</sup>, Boris Filippov<sup>2</sup>, Ram Ajor Maurya<sup>3,4</sup>, and Ramesh Chandra

2016 ApJ 821 85 DOI: 10.3847/0004-637X/821/2/85

We analyze the observations of an eruptive quiescent filament associated with a halo Coronal Mass Ejection (CME). We use observations from the Atmospheric Imaging Assembly (AIA) instrument onboard the Solar Dynamics Observatory (SDO), Solar and Heliospheric Observatory (SOHO)/Large Angle and Spectrometric Coronagraph (LASCO), and the Solar Terrestrial Relations Observatory (STEREO A/B) satellites. The filament exhibits a slow-rise phase followed by a gradual acceleration and then completely disappears. The filament could be traced in STEREO observations up to an altitude of about  $1.44 R_{\odot}$ , where its rise speed reached  $\sim 14$  km s<sup>-1</sup> and disappeared completely at about 10:32 UT on **2011 October 21**. The CME associated with the filament eruption and two bright ribbons in the chromosphere both appeared at about 01:30 UT on **October 22**, i.e., 15 hr after the filament eruption was seen in He ii 304 Å filtergrams. We show that this delay is abnormally large even if the slow rise speed and slow acceleration of the filament are taken into account. To understand the cause of this delay, we compute the decay index ( $n$ ) of the overlying coronal magnetic field. The height distribution of the decay index,  $n$ , suggests that the zone of instability ( $n > 1$ ) at a lower altitude, 144–480 Mm, is followed by a zone of stability ( $n < 1$ ) between 540 and 660

Mm. We interpret the observed delay to be due to the presence of the latter zone, i.e., the zone of stability, which could provide a second quasi-equilibrium state to the filament until it finally erupts.

<https://arxiv.org/pdf/2406.02783>

Coronal jets are believed to be the miniature version of large-scale solar eruptions. In particular, the eruption of a mini-filament inside the base arch is suggested to be the trigger and even driver of blowout jets. Here we propose an alternative triggering mechanism, based on high-resolution H-alpha observations of a blowout jet associated with a mini-filament and an M1.2-class flare. The mini-filament remains largely stationary during the blowout jet, except that it is straddled by flare loops connecting two flare ribbons, indicating that the magnetic arcade embedding the mini-filament has been torn into two parts, with the upper part escaping with the blowout jet. In the wake of the flare, the southern end of the mini-filament fans out like neighboring fibrils, indicative of mass and field exchanges between the mini-filament and the fibrils. The blowout jet is preceded by a standard jet. With H-alpha fibrils moving toward the single-strand spire in a sweeping fashion, the standard jet transitions to the blowout jet. The similar pattern of standard-to-blowout jet transition occurs in an earlier C-class flare before the mini-filament forms. The spiraling morphology and sweeping direction of these fibrils are suggestive of their footpoints being dragged by the leading sunspot that undergoes clockwise rotation for over two days. Soon after the sunspot rotation reaches a peak angular speed as fast as 10 deg/hr, the dormant active region becomes flare-productive, and the mini-filament forms through the interaction of moving magnetic features from the rotating sunspot with satellite spots/pores. Hence, we suggest that the sunspot rotation plays a key role in building up free energy for flares and jets and in triggering blowout jets by inducing sweeping motions of fibrils. **2022 November 11**

### **Complete replacement of magnetic flux in a flux rope during a coronal mass ejection**

<https://arxiv.org/pdf/2305.03217.pdf>

<https://www.nature.com/articles/s41550-023-01966-2.pdf>

Solar coronal mass ejections are the most energetic events in the Solar System. In their standard formation model, a magnetic flux rope builds up into a coronal mass ejection through magnetic reconnection that continually converts overlying, untwisted magnetic flux into twisted flux enveloping the pre-existing rope. However, only a minority of coronal mass ejections carry a coherent magnetic flux rope as their core structure, which casts doubt on the universality of this orderly wrapping process. Here we provide observational evidence of a different formation and eruption mechanism of a magnetic flux rope from an S-shaped thread, where its magnetic flux is fully replaced via flare reconnections. One of the footpoints of the sigmoidal feature slipped and expanded during the formation, and then moved to a completely new place, associated with the highly dynamical evolution of flare ribbons and a twofold increase in magnetic flux through the footpoint, during the eruption. Such a configuration is not predicted by standard formation models or numerical simulations and highlights the three-dimensional nature of magnetic reconnections between the flux rope and the surrounding magnetic field. **2014 Sep 10, 12**

<https://arxiv.org/pdf/2006.11707.pdf>

<https://doi.org/10.3847/2041-8213/ab9ec5>

Solar flares and coronal mass ejections (CMEs) are closely coupled through magnetic reconnection. CMEs are usually accelerated impulsively within the low solar corona, synchronized with the impulsive flare energy release. We investigate the dynamic evolution of a fast CME and its associated X2.8 flare occurring on **2013 May 13**. The CME experiences two distinct phases of enhanced acceleration, an impulsive one with a peak value of  $\sim 5 \text{ km s}^{-2}$  followed by an extended phase with accelerations up to  $0.7 \text{ km s}^{-2}$ . The two-phase CME dynamics is associated with a two-episode flare energy release. While the first episode is consistent with the "standard" eruption of a magnetic flux rope, the second episode of flare energy release is initiated by the reconnection of a large-scale loop in the aftermath of the eruption and produces stronger nonthermal emission up to  $\gamma$ -rays. In addition, this long-duration flare reveals clear signs of ongoing magnetic reconnection during the decay phase, evidenced by extended HXR bursts with energies up to 100--300 keV and intermittent downflows of reconnected loops for  $>4$  hours. The observations reveal that the two-step flare reconnection substantially contributes to the two-phase CME acceleration, and the impulsive CME acceleration

precedes the most intense flare energy release. The implications of this non-standard flare/CME observation are discussed.

The Sun's atmosphere is frequently disrupted by coronal mass ejections (CMEs), coupled with flares and energetic particles. In the standard picture, the coupling is explained by magnetic reconnection at a vertical current sheet connecting the flare loops and the CME, with the latter embedding a helical magnetic structure known as flux rope. As it jumps upward due to instabilities or loss of equilibrium, the flux rope stretches the overlying coronal loops so that oppositely directed field is brought together underneath, creating the current sheet. However, both the origin of flux ropes and their nascent paths toward eruption remain elusive. Here we present an observation of how a stellar-sized CME bubble evolves continuously from plasmoids, mini flux ropes that are barely resolved, within half an hour. The eruption initiates when plasmoids springing from a vertical current sheet merge into a leading plasmoid occupying the upper tip of the current sheet. Rising at increasing speed to stretch the overlying loops, this leading plasmoid then expands impulsively into the CME bubble, in tandem with hard X-ray bursts. This observation illuminates for the first time a complete CME evolutionary path that has the capacity to accommodate a wide variety of plasma phenomena by bridging the gap between micro-scale dynamics and macro-scale activities. **2013 May 13**

### Direct Observation of Two-Step Magnetic Reconnection in a Solar Flare

Tingyu [Gou](#), [Astrid M. Veronig](#), [Ewan Dickson](#), [Aaron Hernandez-Perez](#), [Rui Liu](#)

ApJ 845: L1 2017

<https://arxiv.org/pdf/1707.06198.pdf>

We report observations of an eruptive X2.8 flare on **2013 May 13**, which shows two distinct episodes of energy release in the impulsive phase. The first episode is characterized by the eruption of a magnetic flux rope, similar to the energy-release process in most standard eruptive flares. While the second episode, which is stronger than the first normal one and shows enhanced high-energy X-ray and even  $\gamma$ -ray emissions, is closely associated with magnetic reconnection of a large-scale loop in the aftermath of the eruption. The reconnection inflow of the loop leg is observed in the Solar Dynamics Observatory (SDO)/Atmospheric Imaging Assembly (AIA) 304 Å passband and accelerates towards the reconnection region to a speed as high as  $\sim 130$  km/s. Simultaneously the corresponding outflow jets are observed in the AIA hot passbands with a speed of  $\sim 740$  km/s and mean temperature of  $\sim 14$  MK. RHESSI observations show a strong burst of hard X-ray (HXR) and  $\gamma$ -ray emissions with hard electron spectra of  $\delta \approx 3$ , exhibiting a soft-hard-harder behavior. A distinct altitude decrease of the HXR loop-top source coincides with the inward swing of the loop leg observed in the AIA 304 Å passband, which is suggested to be related to the coronal implosion. This fast inflow of magnetic flux contained in the loop leg greatly enhances the reconnection rate and results in very efficient particle acceleration in the second-step reconnection, which also helps to achieve a second higher temperature peak up to  $T \approx 30$  MK.

### Tracking of Coronal White-Light Events by Texture

N. [Goussis](#)<sup>1,2</sup>, G. [Stenborg](#)<sup>3</sup>, A. [Vourlidis](#)<sup>4</sup> and R. [Howard](#)<sup>4</sup>

Solar Phys. 262(2), 481-494, **2010**

The extraction of the kinematic properties of coronal mass ejections (CMEs) from white-light coronagraph images involves a significant degree of user interaction: defining the edge of the event, separating the core from the front or from nearby unrelated structures, *etc.* To contribute towards a less subjective and more quantitative definition, and therefore better kinematic characterization of such events, we have developed a novel image-processing technique based on the concept of “texture of the event”. The texture is defined by the so-called gray-level co-occurrence matrix, and the technique consists of a supervised segmentation algorithm to isolate a particular region of interest based upon its similarity with a pre-specified model. Once the event is visually defined early in its evolution, it is possible to automatically track the event by applying the segmentation algorithm to the corresponding time series of coronagraph images. In this paper we describe the technique, present some examples, and show how the coronal background, the core of the event, and even the associated shock (if one exists) can be identified for different kind of CMEs detected by the LASCO and SECCHI coronagraphs.

The major SOL2001-08-25 event produced a fast coronal mass ejection (CME: 1430 km s<sup>-1</sup>), strong flare emissions in hard X-rays and  $\gamma$ -rays extending to high energies, and neutrons detected both on spacecraft and by a low-latitude neutron monitor. To supplement the probable picture of this outstanding event, we reconstruct kinematic plots of the eruption and the shock-wave history. The hard X-ray and  $\gamma$ -ray emissions exhibited soft-hard-soft evolution. The emissions were strongest and hardest during a two-minute interval soon after the highest change rate of the magnetic flux within the flare ribbons of  $2.6 \times 10^{19}$  Mx s<sup>-1</sup>, which was simultaneous with the reconstructed acceleration of the erupting flux rope. We reveal an indication of accelerated electrons injected into the erupting flux rope that then precipitated far from the main flare site, producing a hard X-ray source that moved along the footprint of a stretching flux-rope leg. These results suggest that the particle acceleration was governed by magnetic reconnection during the eruption. As in a typical situation, a piston shock was excited early in the impulsive phase and gradually transformed into a bow shock later. The frequency drift of a Type-II burst is shown to be proportional to a power of frequency  $f$ ,  $df/dt \propto f^\epsilon$ , with a typical range of  $\epsilon$  being between 5/3 and 2. Overall, the SOL2011-08-25 event was a typical eruptive two-ribbon flare. Its strength was determined mainly by the intensity of the reconnection processes.

## **Reconciliation of Observational Challenges to the Impulsive-Piston Shock-Excitation Scenario.**

### **II. Shock Waves Produced in CME-less Events with a Null-Point Topology.**

Continuing Article [I](#), we revisit challenging events previously identified by different authors, whose analysis led to conclusions about various mechanisms of the shock-wave excitation. Here, we reconsider four events that involved fan-spine coronal configurations with a null-point topology (NPT). The presence of Type-II radio bursts in all events as well as extreme-ultraviolet disturbances (EUV waves) observed in three events evidence the presence of shock waves, whereas no coronal mass ejections (CMEs) were detected in most events. One idea proposed to explain the observations was the shock-wave excitation by the straightening of a postreconnection kinked loop. The Type-II burst in another event appeared in association with a compact flare with a high thermal pressure that looked to be in favor of a flare-generated blast wave. One event was associated with a possible pseudo-CME. All of these challenging events have been reconciled in terms of an impulsively excited piston shock. CME-less filament eruptions in NPT configurations appear to represent a distinct category of events responsible for some of the observed shock waves. **14 November 2005** , **28 February 2011** , **6 March 2014** , **16 April 2014**

## **Reconciliation of Observational Challenges to the Impulsive-Piston Shock-Excitation Scenario.**

### **I. Kinematic Challenges**

**V.V. Grechnev · V.I. Kiselev · A.M. Uralov**

*Solar Phys.* **297**, Article number: 106 **2022** **File** **See movies of 8 December 2007**

Until now, there is no consensus on the origin of coronal shock waves.

Questions also remain about the patterns that govern the propagation of the presumably related disturbances observed in the extreme ultraviolet (EUV waves).

We present arguments in favor of the initial excitation of the waves by the impulsive acceleration of erupting structures. We consider two puzzling events that have been known thanks to the efforts of different research teams. Using recent findings and our methods, we aim to figure out what might actually have happened in these challenging events. In the first event, the expansion of the coronal mass ejection (CME) was determined by gravity starting from the low corona. The previous analysis led the authors to a conclusion about the flare-related origin of the associated shock wave. We also consider another event, in which an EUV wave had a strange kinematics. This was one of the weakest flares accompanied by EUV waves. Both of these challenging events have been reconciled in terms of an impulsively-excited piston shock. **24 December 1996**, **8 December 2007**

## **A Geoeffective CME Caused by the Eruption of a Quiescent Prominence on 29 September 2013**

**V. V. Grechnev & I. V. Kuzmenko**

*Solar Physics* volume 295, Article number: 55 (2020) **File**

<https://link.springer.com/content/pdf/10.1007/s11207-020-01619-x.pdf>

The eruption of a large prominence that occurred away of active regions in the SOL2013-09-29 event produced a fast coronal mass ejection (CME) and a shock wave. The event caused considerable geospace disturbances, including a proton enhancement that have been addressed in previous studies. Continuing with the analysis of this event, we focus on the development of the CME and shock wave, assess an expected geospace impact using simplest considerations, and compare the expectations with in situ measurements near Earth. The high CME speed in this non-flare-associated event was determined by a considerable reconnected flux that corresponds to a pattern established by different authors. Estimations based on a few approaches showed the reconnection flux in this event to be comparable with a typical value in flare-associated eruptions. The shock wave was most likely impulsively excited by the erupting prominence in the

same way as in flare-associated events and changed to the bow-shock regime later. The trajectory calculated for this scenario reproduces the Type II emission observed from 30 MHz to 70 kHz; its interruptions were probably caused by propagation effects. Properties of the near-Earth proton enhancement are discussed considering the results of recent studies

<https://link.springer.com/content/pdf/10.1007%2Fs11207-019-1529-0.pdf>

We study the development of a coronal mass ejection (CME) caused by a prominence eruption on **24 February 2011** and properties of a related interplanetary CME (ICME). The prominence destabilized, accelerated, and produced an M3.5 flare, a fast CME, and a shock wave. The eruption at the east limb was observed in quadrature by the Atmospheric Imaging Assembly (AIA) on board the Solar Dynamics Observatory (SDO) and by the Sun Earth Connection Coronal and Heliospheric Investigation (SECCHI) instrument suite on board the Solar-Terrestrial Relations Observatory (STEREO). The ICME produced by the SOL2011-02-24 event was measured in situ on STEREO-B two days later. The diagnostics made from multi-wavelength SDO/AIA images reveals a pre-eruptive heating of the prominence to about 7 MK and its subsequent heating during the eruption by flare-accelerated particles to about 10 MK. The hot plasma was detected in the related ICME as an enhancement in the ionic charge state of Fe, whose evolution was reproduced in the modeling. The analysis of the solar source region allows for predicting the variations of magnetic components in the ICME, while the flux-rope rotation by about  $40^\circ$  was indicated by observations. The magnetic-cloud propagation appears to be ballistic.

## Multi-instrument view on solar eruptive events observed with the Siberian Radioheliograph: From detection of small jets up to development of a shock wave and CME

The first 48-antenna stage of the Siberian Radioheliograph (SRH) started single-frequency test observations early in 2016, and since August 2016 it routinely observes the Sun at several frequencies in the 4-8 GHz range with an angular resolution of 1-2 arc minutes and an imaging interval of about 12 seconds. With limited opportunities of the incomplete antenna configuration, a high sensitivity of about 100 Jy allows the SRH to contribute to the studies of eruptive phenomena along three lines. First, some eruptions are directly visible in SRH images. Second, some small eruptions are detectable even without a detailed imaging information from microwave depressions caused by screening the background emission by cool erupted plasma. Third, SRH observations reveal new aspects of some events to be studied with different instruments. We focus on an eruptive C2.2 flare on **16 March 2016** around 06:40, one of the first flares observed by the SRH. Proceeding from SRH observations, we analyze this event using extreme-ultraviolet, hard X-ray, white-light, and metric radio data. An eruptive prominence expanded, brightened, and twisted, which indicates a time-extended process of the flux-rope formation together with the development of a large coronal mass ejection (CME). The observations rule out a passive role of the prominence in the CME formation. The abrupt prominence eruption impulsively excited a blast-wave-like shock, which appeared during the microwave burst and was manifested in an "EUV wave" and Type II radio burst. The shock wave decayed and did not transform into a bow shock because of the low speed of the CME. Nevertheless, this event produced a clear proton enhancement near Earth. Comparison with our previous studies of several events confirms that the impulsive-piston shock-excitation scenario is typical of various events. **16 March 2016, 1 May 2017, 3 August 2017, 9 September 2017,**

## The 26 December 2001 Solar Eruptive Event Responsible for GLE63.

### II. Multi-Loop Structure of Microwave Sources in a Major Long-Duration Flare

V.V. [Grechnev](#) . A. M. Uralov, V. I. Kiselev, A.A. Kochanov

[Solar Phys.](#) January 2017, 292:3 **File**

<https://arxiv.org/pdf/1611.08349v1.pdf>

Our analysis of the observations of the SOL2001-12-26 event, which was related to ground-level enhancement of cosmic-ray intensity GLE63, including microwave spectra and images from the *Nobeyama Radioheliograph* at 17 and 34 GHz, from the *Siberian Solar Radio Telescope* at 5.7 GHz, and from the *Transition Region and Coronal Explorer* in 1600 Å, has led to the following results: A flare ribbon overlapped with the sunspot umbra, which is typical of large particle events. Atypical were i) the long duration of the flare, which lasted more than one hour; ii) the moderate intensity of the microwave burst, which was about 104 sfu; iii) the low peak frequency of the gyrosynchrotron spectrum, which was about 6 GHz; and its insensitivity to the flux increase by more than one order of magnitude.

This was accompanied by a nearly constant ratio of the flux emitted by the volume in the high-frequency part of the spectrum to its elevated low-frequency part determined by the area of the source. With the self-similarity of the spectrum, a similarity was observed between the moving microwave sources and the brightest parts of the flare ribbons in 1600 Å images. We compared the 17 GHz and 1600 Å images and confirm that the microwave sources were associated with multiple flare loops, whose footpoints appeared in the ultraviolet as intermittent bright kernels. To understand the properties of the event, we simulated its microwave emission using a system of several homogeneous gyrosynchrotron sources above the ribbons. The scatter between the spectra and the sizes of the individual sources is determined by the inhomogeneity of the magnetic field within the ribbons. The microwave flux is mainly governed by the magnetic flux passing through the ribbons and the sources. The apparent simplicity of the microwave structures is caused by a poorer spatial resolution and dynamic range of the microwave imaging. The results indicate that microwave manifestations of accelerated electrons correspond to the structures observed in thermal emissions, as well-known models predict.

## **A Tiny Eruptive Filament as a Flux-Rope Progenitor and Driver of a Large-Scale CME and Wave**

V.V. [Grechnev](#) (1), A.M. Uralov (1), A.A. Kochanov (1), I.V. Kuzmenko (2), D.V. Prosovetsky (1), Ya.I. Egorov (1), V.G. Fainshtein (1), L.K. Kashapova

Solar Phys., Volume 291, Issue 4, pp 1173-1208 2016

<http://arxiv.org/pdf/1604.00800v1.pdf> File

A solar eruptive event SOL2010-06-13 observed with SDO/AIA has been discussed in the contexts of the CME genesis and an associated EUV transient in terms of a shock driven by the apparent CME rim. We have revealed in this event an erupting flux rope, studied its properties, and detected wave signatures inside the developing CME. These findings have allowed us to establish new features in the genesis of the CME and associated EUV wave and to reconcile all of the episodes into a causally-related sequence. (1) A hot 11 MK flux rope developed from a compact filament, accelerated up to 3 km/s<sup>2</sup> 1 min before a hard X-ray burst and earlier than other structures, reached 420 km/s, and decelerated to 50 km/s. (2) The CME development was driven by the flux rope. Closed structures above the rope got sequentially involved in the expansion from below upwards, came closer together, and disappeared to reveal their envelope, the rim, which became the outer boundary of the cavity. The rim was associated with the separatrix surface of a magnetic domain, which contained the pre-eruptive filament. (3) The rim formation was associated with a successive compression of the upper active-region structures into the CME frontal structure (FS). When the rim was formed, it resembled a piston. (4) The disturbance responsible for the CME formation was excited by the flux rope inside the rim, and then propagated outward. EUV structures at different heights started to accelerate, when their trajectories in the distance-time diagram were crossed by the front of this disturbance. (5) Outside the rim and FS, the disturbance propagated like a blast wave, manifesting in a type II radio burst and a leading part of the EUV transient. Its main, trailing part was the FS, which consisted of swept-up 2 MK loops enveloping the rim. The wave decelerated and decayed soon, being not driven by the trailing piston, which slowed down.

## **Responsibility of a Filament Eruption for the Initiation of a Flare, CME, and Blast Wave, and its Possible Transformation into a Bow Shock**

V. V. [Grechnev](#) (1), A. M. Uralov (1), I. V. Kuzmenko (2), A. A. Kochanov (1), I. M. Chertok (3), S. S. Kalashnikov

Solar Phys., 2015, Volume 290, Issue 1, pp 129-158

<http://arxiv.org/pdf/1410.8696v1.pdf>

Multi-instrument observations of two filament eruptions on **24 February and 11 May 2011** suggest the following updated scenario for eruptive flare, CME and shock wave evolution. An initial destabilization of a filament results in stretching out of magnetic threads belonging to its body and rooted in the photosphere along the inversion line. Their reconnection leads to i) heating of parts of the filament or its environment, ii) initial development of the flare arcade cusp and ribbons, and iii) increasing similarity of the filament to a curved flux rope and its acceleration. Then the pre-eruption arcade enveloping the filament gets involved in reconnection according to the standard model and continues to form the flare arcade and ribbons. The poloidal magnetic flux in the curved rope developing from the filament progressively increases and forces its toroidal expansion. This flux rope impulsively expands and produces an MHD disturbance, which rapidly steepens into a shock. The shock passes through the arcade expanding above the filament and then freely propagates ahead of the CME like a decelerating blast wave for some time. If the CME is slow, then the shock eventually decays. Otherwise, the frontal part of the shock changes into the bow-shock regime. This was observed for the first time in the 24 February 2011 event. When reconnection ceases, the flux rope relaxes and constitutes the CME core-cavity system. The expanding arcade develops into the CME frontal structure. We also found that reconnection in the current sheet of a remote streamer forced by the shock's passage results in a running flare-like process within the streamer responsible for a type II burst. The development of dimming and various associated phenomena are discussed.

## **An Updated View of Solar Eruptive Flares and Development of Shocks and CMEs: History of the 2006 December 13 GLE-Productive Extreme Event**

V. **Grechnev**, V. Kiselev, A. Uralov, N. Meshalkina, A. Kochanov

E-print, Aug **2013**; Publ. Astron. Soc. Japan 65, No SP1, S9 [18 pages] (2013) ), **File**

An extreme **2006 December 13** event marked the onset of the Hinode era being the last major flare in the solar cycle 23 observed with NoRH and NoRP. The event produced a fast CME, strong shock, and big particle event responsible for GLE70. We endeavor to clarify relations between eruptions, shock wave, and the flare, and to shed light on a debate over the origin of energetic protons. One concept relates it with flare processes. Another one associates acceleration of ions with a bow shock driven by a CME at (2-4) $R_{\text{sun}}$ . The latter scenario is favored by a delayed particle release time after the flare. However, our previous studies have established that a shock wave is typically excited by an impulsively erupting magnetic rope (future CME core) during the flare rise, while the outer CME surface evolves from an arcade whose expansion is driven from inside. Observations of the 2006 December 13 event reveal two shocks following each other, whose excitation scenario contradicts the delayed CME-driven bow-shock hypothesis. Actually, the shocks developed much earlier, and could accelerate protons still before the flare peak. Then, the two shocks merged into a single stronger one and only decelerated and dampened long afterwards.

## **Microwave Negative Bursts as Indications of Reconnection between Eruptive Filaments and Large-Scale Coronal Magnetic Environment**

V. **Grechnev**, I. Kuzmenko, A. Uralov, I. Chertok, A. Kochanov

E-print, Aug **2013**, Publ. Astron. Soc. Japan 65, No. SP1, S10 [9 pages] (**2013**)

Low-temperature plasma ejected in solar eruptions can screen active regions as well as quiet solar areas. Absorption phenomena can be observed in microwaves as 'negative bursts' and in different spectral domains. We analyze two very different recent events with such phenomena and present an updated systematic view of solar events associated with negative bursts. Related filament eruptions can be normal, without essential changes of shape and magnetic configuration, and 'anomalous'. The latter are characterized by disintegration of an eruptive filament and dispersal of its remnants as a cloud over a large part of solar disk. Such phenomena can be observed as giant depressions in the He II 304 A line. One of possible scenarios for an anomalous eruption is proposed in terms of reconnection of filament's internal magnetic fields with external large-scale coronal surrounding. **2004 July 13., 2011 June 7, 2011 December 13.**

## **The 26 December 2001 Solar Eruptive Event Responsible for GLE63.**

### **III. CME, Shock Waves, and Energetic Particles**

V.V. **Grechnev** (1), V.I. Kiselev (1), A.M. Uralov (1), K.-L. Klein (2), A.A. Kochanov (1)

Solar Phys. 292:102 **2017**

<https://arxiv.org/pdf/1612.04092v1.pdf>

**File**

The **26 December 2001** moderate solar eruptive event (GOES importance M7.1, microwaves up to 4000 sfu at 9.4 GHz, CME speed 1446 km/s) produced strong fluxes of solar energetic particles (SEPs) and ground-level enhancement of cosmic-ray intensity (GLE63). To find a possible reason for the atypically high proton outcome of this event, we study its multi-wavelength images and dynamic radio spectra, and quantitatively reconcile the findings with each other. An additional eruption probably occurred in the same active region about half an hour before the main eruption, which produced two blast-wave-like shocks during the impulsive phase. Later on, the two shock waves merged around the frontal direction into a single shock, which is traced up to  $25R_{\odot}$  as a halo ahead of the expanding CME body, in agreement with an interplanetary type II event recorded by Wind/WAVES. The shape and kinematics of the halo indicate that the shock wave was in an intermediate regime between the blast wave and bow shock at these distances. The results show that i) the shock wave appeared during the flare rise and could accelerate particles earlier than usually assumed; ii) the particle event could be amplified by the preceding eruption, which stretched closed structures above the developing CME, facilitating its lift-off and escape of flare-accelerated particles, enabling a higher CME speed and a stronger shock ahead; iii) escape of flare-accelerated particles could be additionally facilitated by reconnection of the flux rope, where they were trapped, with a large coronal hole; iv) a rich seed population was provided by the first eruption for the acceleration by a trailing shock wave.

## **A Challenging Solar Eruptive Event of 18 November 2003 and the Causes of the 20 November Geomagnetic Superstorm.**

### **II. CMEs, Shock Waves, and Drifting Radio Bursts**

V.V. **Grechnev**, A.M. Uralov, I.M. Chertok, V.A. Slemzin, B.P. Filippov, Ya.I. Egorov, V.G. Fainshtein, A.N. Afanasyev, N.P. Prestage, M. Temmer

E-print, Aug **2013**; Solar Phys.

We continue our study (Grechnev et al. (2013), doi:10.1007/s11207-013-0316-6; Paper I) on the 18 November 2003 geoeffective event. To understand possible impact on geospace of coronal transients observed on that day, we investigated their properties from solar near-surface manifestations in extreme ultraviolet, LASCO white-light images, and dynamic radio spectra. We reconcile near-surface activity with the expansion of coronal mass ejections (CMEs) and determine their orientation relative to the earthward direction. The kinematic measurements, dynamic radio spectra, and

microwave and X-ray light curves all contribute to the overall picture of the complex event and confirm an additional eruption at 08:07-08:20 UT close to the solar disk center presumed in Paper I. Unusual characteristics of the ejection appear to match those expected for a source of the 20 November superstorm but make its detection in LASCO images hopeless. On the other hand, none of the CMEs observed by LASCO seem to be a promising candidate for a source of the superstorm being able to produce, at most, a glancing blow on the Earth's magnetosphere. Our analysis confirms free propagation of shock waves revealed in the event and reconciles their kinematics with "EUV waves" and dynamic radio spectra up to decameters.

## **A Challenging Solar Eruptive Event of 18 November 2003 and the Causes of the 20 November Geomagnetic Superstorm.**

### **I. Unusual History of an Eruptive Filament**

V. V. **Grechnev**, A. M. Uralov, V. A. Slemzin, I. M. Chertok, B. P. Filippov, G. V. Rudenko, M. Temmer  
E-print, May 2013; Solar Phys.

This is the first of four companion papers, which analyze a complex eruptive event of 18 November 2003 in AR 10501 and the causes of the largest Solar Cycle 23 geomagnetic storm on 20 November 2003. Analysis of a complete data set, not considered before, reveals a chain of eruptions to which hard X-ray and microwave bursts responded. A filament in AR 10501 was not a passive part of a larger flux rope, as usually considered. The filament erupted and gave origin to a CME. The chain of events was as follows: i) an eruption at 07:29 accompanied by a not reported M1.2 class flare associated with the onset of a first southeastern CME1, which is not responsible for the superstorm; ii) a confined eruption at 07:41 (M3.2 flare) that destabilized the filament; iii) the filament acceleration (07:56); iv) the bifurcation of the eruptive filament that transformed into a large cloud; v) an M3.9 flare in AR 10501 associated to this transformation. The transformation of the filament could be due to its interaction with the magnetic field in the neighborhood of a null point, located at a height of about 100 Mm above the complex formed by ARs 10501, 10503, and their environment. The CORONAS-F/SPIRIT telescope observed the cloud in 304 Å as a large Y-shaped darkening, which moved from the bifurcation region to the limb. The masses and kinematics of the cloud and the filament were similar. Remnants of the filament were not observed in the second southwestern CME2, previously regarded as a source of the 20 November superstorm. These facts do not support a simple scenario, in which the interplanetary magnetic cloud is considered as a flux rope formed from a structure initially associated with the pre-eruption filament in AR 10501. Observations suggest a possible additional eruption above the bifurcation region close to solar disk center between 08:07 and 08:17 that could be the source of the superstorm.

### **Coronal Shock Waves, EUV Waves, and Their Relation to CMEs.**

#### **III. Shock-Associated CME/EUV Wave in an Event with a Two-Component EUV Transient**

V. V. **Grechnev**, A. N. Afanasyev, A. M. Uralov, I. M. Chertok, M. V. Eselevich, V. G. Eselevich, G. V. Rudenko and Y. Kubo

Solar Physics, Volume 273, Number 2, 461-477, 2011, **File in Chertok's papers**

On 17 January 2010, STEREO-B observed in extreme ultraviolet (EUV) and white light a large-scale dome-shaped expanding coronal transient with perfectly connected off-limb and on-disk signatures. Veronig et al. (Astrophys. J. Lett. 716, L57, 2010) concluded that the dome was formed by a weak shock wave. We have revealed two EUV components, one of which corresponded to this transient. All of its properties found from EUV, white light, and a metric type II burst match expectations for a freely expanding coronal shock wave, including correspondence with the fast-mode speed distribution, while the transient sweeping over the solar surface had a speed typical of EUV waves. The shock wave was presumably excited by an abrupt filament eruption. Both a weak shock approximation and a power-law fit match kinematics of the transient near the Sun. Moreover, the power-law fit matches the expansion of the CME leading edge up to 24 solar radii. The second, quasi-stationary EUV component near the dimming was presumably associated with a stretched CME structure; no indications of opening magnetic fields have been detected far from the eruption region.

### **Coronal Shock Waves, EUV Waves, and Their Relation to CMEs.**

#### **I. Reconciliation of "EIT Waves", Type II Radio Bursts, and Leading Edges of CMEs**

V. V. **Grechnev**, A. M. Uralov, I. M. Chertok, I. V. Kuzmenko, A. N. Afanasyev, N. S. Meshalkina, S. S. Kalashnikov and Y. Kubo

Solar Physics, Volume 273, Number 2, 433-460, 2011, **File in Chertok's papers**

We show examples of the excitation of coronal waves by flare-related abrupt eruptions of magnetic rope structures. The waves presumably rapidly steepened into shocks and freely propagated afterwards like decelerating blast waves that showed up as Moreton waves and EUV waves. We propose a simple quantitative description for such shock waves to reconcile their observed propagation with drift rates of metric type II bursts and kinematics of leading edges of coronal mass ejections (CMEs). Taking account of different plasma density falloffs for propagation of a wave up and along the solar surface, we demonstrate a close correspondence between drift rates of type II bursts and speeds of EUV waves, Moreton waves, and CMEs observed in a few previously studied events.

## Magnetic Helicity Evolution and Eruptive Activity in NOAA Active Region 11158

L. M. **Green**<sup>1</sup>, J. K. Thalmann<sup>2</sup>, G. Valori<sup>3</sup>, E. Pariat<sup>4</sup>, L. Linan<sup>5</sup>, and K. Moraitis<sup>6</sup>

2022 ApJ 937 59

<https://iopscience.iop.org/article/10.3847/1538-4357/ac88cb/pdf>

Coronal mass ejections are among the Sun's most energetic activity events yet the physical mechanisms that lead to their occurrence are not yet fully understood. They can drive major space weather impacts at Earth, so knowing why and when these ejections will occur is required for accurate space weather forecasts. In this study we use a 4 day time series of a quantity known as the helicity ratio,  $|HJ|/|HV|$  (helicity of the current-carrying part of the active region field to the total relative magnetic helicity within the volume), which has been computed from nonlinear force-free field extrapolations of NOAA active region 11158. We compare the evolution of  $|HJ|/|HV|$  with the activity produced in the corona of the active region and show this ratio can be used to indicate when the active region is prone to eruption. This occurs when  $|HJ|/|HV|$  exceeds a value of 0.1, as suggested by previous studies. We find the helicity ratio variations to be more pronounced during times of strong flux emergence, collision and reconnection between fields of different bipoles, shearing motions, and reconfiguration of the corona through failed and successful eruptions. When flux emergence, collision, and shearing motions have lessened, the changes in helicity ratio are somewhat subtle despite the occurrence of significant eruptive activity during this time. **2011 February 12–15**

Coronal mass ejections (CMEs) were discovered in the early 1970s when space-borne coronagraphs revealed that eruptions of plasma are ejected from the Sun. Today, it is known that the Sun produces eruptive flares, filament eruptions, coronal mass ejections and failed eruptions; all thought to be due to a release of energy stored in the coronal magnetic field during its drastic reconfiguration. This review discusses the observations and physical mechanisms behind this eruptive activity, with a view to making an assessment of the current capability of forecasting these events for space weather risk and impact mitigation. Whilst a wealth of observations exist, and detailed models have been developed, there still exists a need to draw these approaches together. In particular more realistic models are encouraged in order to assess the full range of complexity of the solar atmosphere and the criteria for which an eruption is formed. From the observational side, a more detailed understanding of the role of photospheric flows and reconnection is needed in order to identify the evolutionary path that ultimately means a magnetic structure will erupt. **19 Oct 1994, 19 July 2000, 4th January 2002, 13 Feb 2009**

## Observations of flux rope formation prior to coronal mass ejections

L. M. **Green**, B. Kliem

Proc. IAU Symp. 300, 209, **2013**

<http://arxiv.org/pdf/1312.4388v1.pdf>

Understanding the magnetic configuration of the source regions of coronal mass ejections (CMEs) is vital in order to determine the trigger and driver of these events. Observations of four CME productive active regions are presented here, which indicate that the pre-eruption magnetic configuration is that of a magnetic flux rope. The flux ropes are formed in the solar atmosphere by the process known as flux cancellation and are stable for several hours before the eruption. The observations also indicate that the magnetic structure that erupts is not the entire flux rope as initially formed, raising the question of whether the flux rope is able to undergo a partial eruption or whether it undergoes a transition in specific flux rope configuration shortly before the CME. **19 December 1996, 5-13 December 2006, 11-12 February 2007, 3-7 December 2007**

## Photospheric flux cancellation and associated flux rope formation and eruption

L. M. **Green**<sup>1</sup>, B. Kliem<sup>1,2,3</sup>, and A. J. Wallace<sup>1</sup>

E-print, Nov. **2010**; A&A 526, A2 (**2011**)

**Aims.** We study an evolving bipolar active region that exhibits flux cancellation at the internal polarity inversion line, the formation of a soft X-ray sigmoid along the inversion line and a coronal mass ejection. The aim is to investigate the quantity of flux cancellation that is involved in flux rope formation in the time period leading up to the eruption.  
**Methods.** The active region is studied using its extreme ultraviolet and soft X-ray emissions as it evolves from a sheared arcade to flux rope configuration. The evolution of the photospheric magnetic field is described and used to estimate how much flux is reconnected into the flux rope.

**Results.** About one third of the active region flux cancels at the internal polarity inversion line in the 2.5 days leading up to the eruption. In this period, the coronal structure evolves from a weakly to a highly sheared arcade and then to a sigmoid that crosses the inversion line in the inverse direction. These properties suggest that a flux rope has formed

prior to the eruption. The amount of cancellation implies that up to 60% of the active region flux could be in the body of the flux rope. We point out that only part of the cancellation contributes to the flux in the rope if the arcade is only weakly sheared, as in the first part of the evolution. This reduces the estimated flux in the rope to ~ 30% or less of the active region flux. We suggest that the remaining discrepancy between our estimate and the limiting value of ~10% of the active region flux, obtained previously by the flux rope insertion method, results from the incomplete coherence of the flux rope, due to nonuniform cancellation along the polarity inversion line. A hot linear feature is observed in the active region which rises as part of the eruption and then likely traces out field lines close to the axis of the flux rope. The flux cancellation and changing magnetic connections at one end of this feature suggest that the flux rope reaches coherence by reconnection shortly before and early in the impulsive phase of the associated flare. The sigmoid is destroyed in the eruption but reforms quickly, with the amount of cancellation involved being much smaller than in the course of its original formation.

## **FLUX ROPE FORMATION PRECEDING CORONAL MASS EJECTION ONSET**

L. M. [GREEN](#)<sup>1</sup> AND B. KLIEM<sup>1,2,3</sup>

E-print, June **2009**, *File*; ApJL, 700, Number 2, L83-L87, **2009**.

We analyse the evolution of a sigmoidal (S shaped) active region toward eruption, which includes a coronal mass ejection (CME) but leaves part of the filament in place. The X-ray sigmoid is found to trace out three different magnetic topologies in succession: a highly sheared arcade of coronal loops in its long-lived phase, a bald-patch separatrix surface (BPSS) in the hours before the CME, and the first flare loops in its major transient intensity enhancement. The coronal evolution is driven by photospheric changes which involve the convergence and cancellation of flux elements under the sigmoid and filament. The data yield unambiguous evidence for the existence of a BPSS, and hence a flux rope, in the corona prior to the onset of the CME.

## **HOW ARE EMERGING FLUX, FLARES AND CMES RELATED TO MAGNETIC POLARITY IMBALANCE IN MDI DATA?**

L.M. [GREEN](#)<sup>1</sup>, P. D'EMOULIN<sup>2</sup>, C.H. MANDRINI<sup>3</sup>, L. VAN DRIEL-GESZTELYI<sup>1,2,4,5</sup>

*Solar Physics*, v. 215, Issue 2, p. 307-325 (**2003**), *File*

In order to understand whether major flares or coronal mass ejections (CMEs) can be related to changes in the longitudinal photospheric magnetic field, we study 4 young active regions during seven days of their disc passage. This time period precludes any biases which may be introduced in studies that look at the field evolution during the short-term flare or CME period only. Data from the Michelson Doppler Imager (MDI) with a time cadence of 96 minutes are used. Corrections are made to the data to account for area foreshortening and angle between line of sight and field direction, and also the underestimation of the flux densities. We make a systematic study of the evolution of the longitudinal magnetic field, and analyze flare and CME occurrence in the magnetic evolution. We find that the majority of CMEs and flares occur during or after new flux emergence. The flux in all four active regions is observed to have deviations from polarity balance both on the long-term (solar rotation) and on the short term (few hours). The long-term imbalance is not due to linkage outside the active region; it is primarily related to the east-west distance from central meridian, with the sign of polarity closer to the limb dominating. The sequence of short term imbalances are not closely linked to CMEs and flares and no permanent imbalance remains after them. We propose that both kinds of imbalance are due to the presence of a horizontal field component (parallel to the photospheric surface) in the emerging flux.

## **MULTI-WAVELENGTH OBSERVATIONS OF AN X-CLASS FLARE WITHOUT A CORONAL MASS EJECTION.**

Developments in our knowledge of coronal mass ejections (CMEs) have shown that many of these transients occur in association with solar flares. On the occasions when there is a common occurrence of the eruption and the flare, it is most likely that the flare is of high intensity and/or long-duration (Burkepile, Hundhausen, and Webb, 1994; Munro *et al.*, 1979; Webb and Hundhausen, 1987). A model for the relationship between the long-duration event and eruption has been developed (Carmichael, 1964; Sturrock, 1966; Hirayama, 1974; Kopp and Pneuman, 1976), but not so for the high-intensity flares and eruptions. This work investigates the magnetic topology changes that occur for a X1.2 GOES classification flare which has no associated CME. It is found that the flare is likely to result from the interaction between two pre-existing loops low in the corona, producing a confined flare. Slightly higher in the corona, a loop is observed which exhibits an outward motion as a result of the reconfiguration during reconnection. The objective of this work is to gain insight on the magnetic topology of the event which is critical in order to determine whether a high-intensity flare is likely to be related to a CME or not. **30 Sept 2000**.

### **The Post-Eruptive Arcade Formation in The Limb Event on July 31, 2004 From Microwave Solar Observations with the RATAN-600 Radio Telescope.**

Irina Yu. [Grigoryeva](#)<sup>1</sup>, Larisa K. Kashapova<sup>2</sup>, Valery N. Borovik<sup>1</sup>, Moisey A. Livshits<sup>3</sup>  
Sun and Geosphere, 2010; 5(2): 58-60

[http://www.shao.az/SG/v5n2/SG\\_v5\\_No2\\_2010-pp-58-60.pdf](http://www.shao.az/SG/v5n2/SG_v5_No2_2010-pp-58-60.pdf)

A CME/flare event occurred at the western limb on 31 July 2004. Five successive multi-wavelength scans in centimeter range were obtained with the RATAN-600 radio telescope starting at the early stage of post-eruptive arcade formation (24 min after a C8.3 flare peak) and lasting for 4 hours. Microwave radio emission of the arcade was rather intense at initial stage indicating a predominant contribution of thermal emission and then considerably decreased during the decay phase. Its maximum was co-spatial with the 195 E Fe XII loop tops. At the end of microwave observations the contribution of the emission from accelerated particles became significant. The similarity of microwave characteristics of two eruptive events (on 31 July 2004 at the western limb and on 25 January 2007 at the eastern limb) is shown.

### **CONSTRAINTS ON CORONAL MASS EJECTION EVOLUTION FROM IN SITU OBSERVATIONS OF IONIC CHARGE STATES**

Jacob R. [Gruesbeck](#)<sup>1</sup>, Susan T. Lepri<sup>1</sup>, Thomas H. Zurbuchen<sup>1</sup>, and Spiro K. Antiochos<sup>2</sup>

Astrophysical Journal, 730:103 (9pp), 2011 April; **File**

We present a novel procedure for deriving the physical properties of coronal mass ejections (CMEs) in the corona. Our methodology uses in situ measurements of ionic charge states of C, O, Si, and Fe in the heliosphere and interprets them in the context of a model for the early evolution of interplanetary CME (ICME) plasma, between 2 and 5R<sub>⊙</sub>. We find that the data are best fit by an evolution that consists of an initial heating of the plasma, followed by an expansion that ultimately results in cooling. The heating profile is consistent with a compression of coronal plasma due to flare reconnection jets and an expansion cooling due to the ejection, as expected from the standard CME/flare model. The observed frozen-in ionic charge states reflect this time history and, therefore, provide important constraints for the heating and expansion timescales, as well as the maximum temperature the CME plasma is heated to during its eruption. Furthermore, our analysis places severe limits on the possible density of CME plasma in the corona. We discuss the implications of our results for CME models and for future analysis of ICME plasma composition.

### **Testing predictors of eruptivity using parametric flux emergence simulations**

Chloé [Guennou](#), Etienne Pariat, Nicole Vilmer, [James E. Leake](#)

2017 J. Space Weather Space Clim., 7, A17

<https://arxiv.org/pdf/1706.04915.pdf>

<https://www.swsc-journal.org/articles/swsc/pdf/2017/01/swsc160047.pdf>

Solar flares and coronal mass ejections (CMEs) are among the most energetic events in the solar system, impacting the near-Earth environment. Flare productivity is empirically known to be correlated with the size and complexity of active regions. Several indicators, based on magnetic-field data from active regions, have been tested for forecasting in recent years. None of these indicators, or combinations thereof, have yet demonstrated an unambiguous eruption or are criterion. Furthermore, numerical simulations have been only barely used to test the predictability of these parameters. In this context, we used the 3D parametric MHD numerical simulations of the self-consistent formation of the flux emergence of a twisted ux tube, inducing the formation of stable and unstable magnetic flux ropes of Leake (2013, 2014). We use these numerical simulations to investigate the eruptive signatures observable in various magnetic scalar parameters and provide highlights on data analysis processing. Time series of 2D photospheric-like magnetograms are used from parametric simulations of stable and unstable flux emergence, to compute a list of about 100 different indicators. This list includes parameters previously used for operational forecasting, physical parameters used for the first time, as well as new quantities specifically developed for this purpose. Our results indicate that only parameters measuring the total non-potentiality of active regions associated with magnetic inversion line properties, such as the Falconer parameters Lss, WLss, Lsg and WLsg, as well as the new current integral WLsc and length Lsc parameters, present a significant ability to distinguish the eruptive cases of the model from the non-eruptive cases, possibly indicating that they are promising are and eruption predictors. A preliminary study about the effect of noise on the detection of the eruptive signatures is also proposed.

### **FLARES OF M-STARS IN UPPER SCORPIUS REGION AND FLARES AND CMES OF THE ACTIVE M-STAR AD LEO**

E. W. [Guenther](#)<sup>1</sup>, D. Wöckel<sup>1</sup> and P. Muheki<sup>2</sup>

Stars and their variability observed from space 2019

<https://arxiv.org/pdf/1911.09922.pdf>

Using the Kepler K2 data, we studied the flare-activity of young K- and M-stars in the Upper Sco region and found that they have 10000 to 80000 times as many super-flares with ( $E \geq 5 \times 10^{34}$  erg) than solar like stars. The power-law index for flares is  $N/dE \sim E^{-1.2}$  for K-stars,  $N/dE \sim E^{-1.4}$  for early M-star and  $dN/dE \sim E^{-1.3}$  for late M-stars, which is about the same as that of the Sun. We also observed the active M-star AD Leo spectroscopy for 222 hours, detected 22 flares but no coronal mass ejections.

### **IRIS observations of magnetic interactions in the solar atmosphere between pre-existing and emerging magnetic fields. I. Overall evolution**

Salvo L. [Guglielmino](#), [Francesca Zuccarello](#), [Peter R. Young](#), [Mariariata Murabito](#), [Paolo Romano](#)  
ApJ 2018

<https://arxiv.org/pdf/1802.05657.pdf>

We report multi-wavelength ultraviolet observations taken with the IRIS satellite, concerning the emergence phase in the upper chromosphere and transition region of an emerging flux region (EFR) embedded in the pre-existing field of active region NOAA 12529. IRIS data are complemented by full-disk observations of the Solar Dynamics Observatory satellite, relevant to the photosphere and the corona. The photospheric configuration of the EFR is also analyzed by measurements taken with the spectropolarimeter aboard the Hinode satellite, when the EFR was fully developed. Recurrent intense brightenings that resemble UV bursts, with counterparts in all coronal passbands, are identified at the edges of the EFR. Jet activity is also observed at chromospheric and coronal levels, near the observed brightenings. The analysis of the IRIS line profiles reveals the heating of dense plasma in the low solar atmosphere and the driving of bi-directional high-velocity flows with speed up to 100 km/s at the same locations. Compared with previous observations and numerical models, these signatures suggest evidence of several long-lasting, small-scale magnetic reconnection episodes between the emerging bipole and the ambient field. This process leads to the cancellation of a pre-existing photospheric flux concentration and appears to occur higher in the atmosphere than usually found in UV bursts, explaining the observed coronal counterparts. **April 13 and 14 2016**

### **Penumbral-like Filaments in the Solar Photosphere as a Manifestation of Flux Emergence**

Salvo L. [Guglielmino](#)<sup>1</sup>, [Francesca Zuccarello](#)<sup>1</sup>, and [Paolo Romano](#)  
**2014** ApJ 786 L22.

Rare observations of the solar photosphere show the appearance of orphan penumbrae, filamentary structures very similar to a bundle of sunspot penumbral filaments not connected to any umbra. Lim et al. found an orphan penumbra in active region NOAA 11391 near a mature sunspot. We analyze a different data set to study the same structure using the Solar Optical Telescope on board the Hinode satellite. Spectropolarimetric measurements along the Fe I 630.2 nm pair, complemented by G-band and Ca II H filtergrams, show the evolution of this penumbral-like structure and reveal that an emerging flux region is its ancestor. We find new evidence for the interaction between the emerging flux and the pre-existing field that leads to a brightening observed near the base of the chromosphere. Our analysis suggests that as a result of the combination of photospheric flux emergence and magneto-convection in inclined fields the horizontal component of the emerging field can be trapped in the photosphere by the overlying fields and form a structure resembling penumbral filaments.

### **Quantitative Analysis of CME Deflections in the Corona**

Bin [Gui](#), Chenglong Shen, Yuming Wang, Pinzhong Ye and Jijia Liu, Shui Wang and Xuepu Zhao  
Solar Physics, Volume 271, Numbers 1-2, 111-139, **2011**

In this paper, ten CME events viewed by the STEREO twin spacecraft are analyzed to study the deflections of CMEs during their propagation in the corona. Based on the three-dimensional information of the CMEs derived by the graduated cylindrical shell (GCS) model (Thernisien, Howard, and Vourlidas in *Astrophys. J.* 652, 1305, 2006), it is found that the propagation directions of eight CMEs had changed. By applying the theoretical method proposed by Shen et al. (*Solar Phys.* 269, 389, 2011) to all the CMEs, we found that the deflections are consistent, in strength and direction, with the gradient of the magnetic energy density. There is a positive correlation between the deflection rate and the strength of the magnetic energy density gradient and a weak anti-correlation between the deflection rate and the CME speed. Our results suggest that the deflections of CMEs are mainly controlled by the background magnetic field and can be quantitatively described by the magnetic energy density gradient (MEDG) model.

### **Characterizing Coronal Mass Ejections in Solar Cycle Analysis**

[Ryan Manuel D. Guido](#)

**2018**

<https://arxiv.org/ftp/arxiv/papers/1804/1804.10870.pdf>

The Sun is the major source of heat and light in our solar system. The solar cycle is the 11-year cycle of solar activity that can be determined by the rise and fall in the numbers and surface area of sunspots. Solar activity is associated with several factors including radio flux, solar irradiance, magnetic field, solar flares, coronal mass ejections, and solar cycles. This study attempts to determine the Sun's activity specifically for the coronal mass ejection, its trend during solar cycle 23, and its apparent difference. A time series analysis was used to measure the CME data for larger cases

and to see the apparent difference and trends of the CMEs. The result shows that a decreasing trend of coronal mass ejection from the year 1996 to 2016. It is therefore concluded that the coronal mass ejection data are normally distributed while coronal mass ejections are distributed and curved normally as fluctuation was found in the intensity of the disturbed storm time index as the number of great geomagnetic storms undeniably increased in the ascending and descending phases of the cycle. This reveals that eventhough the Sun has cycles and trends, it shows its inherent characteristics. The Sun still possess getting more dynamic through time which showcases through the limited parameters involved in this study.

## **Coronal Mass Ejections during Geomagnetic Storms on Earth.**

## **Magnetic-Island Contraction and Particle Acceleration in Simulated Eruptive Solar Flares**

S. E. **Guidoni**, C. R. DeVore, J. T. Karpen, B. J. Lynch

ApJ 2016

<http://arxiv.org/pdf/1603.01309v1.pdf>

The mechanism that accelerates particles to the energies required to produce the observed high-energy impulsive emission in solar flares is not well understood. Drake et al. (2006) proposed a mechanism for accelerating electrons in contracting magnetic islands formed by kinetic reconnection in multi-layered current sheets. We apply these ideas to sunward-moving flux ropes (2.5D magnetic islands) formed during fast reconnection in a simulated eruptive flare. A simple analytic model is used to calculate the energy gain of particles orbiting the field lines of the contracting magnetic islands in our ultrahigh-resolution 2.5D numerical simulation. We find that the estimated energy gains in a single island range up to a factor of five. This is higher than that found by Drake et al. for islands in the terrestrial magnetosphere and at the heliopause, due to strong plasma compression that occurs at the flare current sheet. In order to increase their energy by two orders of magnitude and plausibly account for the observed high-energy flare emission, the electrons must visit multiple contracting islands. This mechanism should produce sporadic emission because island formation is intermittent. Moreover, a large number of particles could be accelerated in each magnetohydrodynamic-scale island, which may explain the inferred rates of energetic-electron production in flares. We conclude that island contraction in the flare current sheet is a promising candidate for electron acceleration in solar eruptions.

## **Dependence of coronal mass ejections on the morphology and toroidal flux of their source magnetic flux ropes**

A&A 690, A189 2024

<https://arxiv.org/pdf/2407.09457>

<https://www.aanda.org/articles/aa/pdf/2024/10/aa49731-24.pdf>

Context. Coronal mass ejections (CMEs) stand as intense eruptions of magnetized plasma from the Sun, playing a pivotal role in driving significant changes of the heliospheric environment. Deducing the properties of CMEs from their progenitors in solar source regions is crucial for space weather forecasting.

Aims. The primary objective of this paper is to establish a connection between CMEs and their progenitors in solar source regions, enabling us to infer the magnetic structures of CMEs before their full development.

Methods. We create a dataset comprising a magnetic flux rope series with varying projection shapes (S-, Z- and toroid-shaped), sizes and toroidal fluxes, using the Regularized Biot-Savart Laws (RBSL). These flux ropes are inserted into solar quiet regions, aimed at imitating the eruptions of quiescent filaments. Thereafter, we simulate the propagation of these flux ropes from the solar surface to a distance of  $25R_{\odot}$  with our global coronal magnetohydrodynamic (MHD) model which is named COCONUT.

Results. Our parametric survey reveals significant impacts of source flux ropes on the consequent CMEs. Regarding the flux-rope morphology, we find that the projection shape (e.g., sigmoid or torus) can influence the magnetic structures of CMEs at  $20R_{\odot}$ , albeit with minimal impacts on the propagation speed. However, these impacts diminish as source flux ropes become fat. In terms of toroidal flux, our simulation results demonstrate a pronounced correlation with the propagation speed of CMEs, as well as the successfulness in erupting.

Conclusions. This work builds the bridge between the CMEs in the outer corona and their progenitors in solar source regions. Our parametric survey suggests that the projection shape, cross-section radius and toroidal flux of source flux ropes are crucial parameters in predicting magnetic structures and propagation speed of CMEs, providing valuable insights for space weather prediction. On the one hand, the conclusion drawn here could be instructive in identifying the high-risk eruptions with the potential to induce stronger geomagnetic effects ( $B_z$  and propagation speed). On the other hand, our findings hold practical significance for refining the parameter settings of launched CMEs at  $21.5R_{\odot}$  in heliospheric simulations, such as with EUHFORIA, based on observations for their progenitors in solar source regions.

## **Formation and Evolution of Transient Prominence Bubbles Driven by Erupting Mini-filaments**

**Yilin Guo**, **Yijun Hou**, **Ting Li**, **Yuandeng Shen**, **Jincheng Wang**, **Jun Zhang**, **Jianchuan Zheng**, **Dong Wang**, **Lin Mei**

ApJ 970 110 2024

<https://arxiv.org/pdf/2405.04725>

<https://iopscience.iop.org/article/10.3847/1538-4357/ad54b8/pdf>

Prominence bubbles, the dark arch-shaped "voids" below quiescent prominences, are generally believed to be caused by the interaction between the prominences and the slowly-emerging or quasi-stable underlying magnetic loops. However, this scenario could not explain some short-lived bubbles with extremely dynamic properties of evolution. Based on high-resolution H $\alpha$  observations, here we propose that bubbles should be classified into two categories according to their dynamic properties: quasi-steady (Type-I) bubbles and transient (Type-II) bubbles. Type-I bubbles could remain relatively stable and last for several hours, indicating the existence of a quasi-stable magnetic topology, while Type-II bubbles grow and collapse quickly within one hour without stability duration, which are usually associated with erupting mini-filaments. Analysis of several typical Type-II bubbles from different views, especially including an on-disk event, reveals that Type-II bubbles quickly appear and expand at a velocity of  $\sim 5\text{--}25$  km s $^{-1}$  accompanied by an erupting mini-filament below. The mini-filament's rising velocity is slightly larger than that of the Type-II bubbles' boundary, which will lead to the collision with each other in a short time, subsequent collapse of Type-II bubbles, and formation of a large plume into the above prominence. We also speculate that only if the angle between the axis of the erupting mini-filament and the line-of-sight is large enough, the interaction between the erupting mini-filament and the overlying prominence could trigger a Type-II bubble with a typical arch-shaped but quickly-expanding bright boundary. 7-Nov-2018, 10-Nov-2018, 19-May-2019, 9-Mar-2023

### **Modelling the propagation of coronal mass ejections with COCONUT: implementation of the Regularized Biot-Savart Laws flux rope model**

[Jinhan Guo](#), [L. Linan](#), [S. Poedts](#), [Y. Guo](#), [A. Lani](#), [B. Schmieder](#), [M. Brchneleva](#), [B. Perri](#), [T. Baratashvili](#), [Y. W. Ni](#), [P. F. Chen](#)

A&A 2023

<https://arxiv.org/pdf/2311.13432.pdf>

Context: Coronal mass ejections (CMEs) are rapid eruptions of magnetized plasma that occur on the Sun, which are known as the main drivers of adverse space weather. Accurately tracking their evolution in the heliosphere in numerical models is of utmost importance for space weather forecasting. Aims: The main objective of this paper is to implement the Regularized Biot-Savart Laws (RBSL) method in a new global corona model COCONUT. This approach has the capability to construct the magnetic flux rope with an axis of arbitrary shape. Methods: We present the implementation process of the RBSL flux rope model in COCONUT, which is superposed onto a realistic solar wind reconstructed from the observed magnetogram around the minimum of solar activity. Based on this, we simulate the propagation of an S-shaped flux rope from the solar surface to a distance of 25 solar radii. Results: Our simulation successfully reproduces the birth process of a CME originating from a sigmoid in a self-consistent way. The model effectively captures various physical processes and retrieves the prominent features of the CMEs in observations. In addition, the simulation results indicate that the magnetic topology of the CME flux rope at around 20 solar radii deviates from a coherent structure, and manifests as a mix of open and closed field lines with diverse footpoints. Conclusions: This work demonstrates the potential of the RBSL flux rope model in reproducing CME events that are more consistent with observations. Moreover, our findings strongly suggest that magnetic reconnection during the CME propagation plays a critical role in destroying the coherent characteristic of a CME flux rope. 2007-02-11, 2011-03-08

### **Data-driven Modeling of a Coronal Magnetic Flux Rope: from Birth to Death**

[J. H. Guo](#), [Y. W. Ni](#), [Y. Guo](#), [C. Xia](#), [B. Schmieder](#), [S. Poedts](#), [Z. Zhong](#), [Y. H. Zhou](#), [F. Yu](#), [P. F. Chen](#)

ApJ 961 140 2024

<https://arxiv.org/pdf/2310.19617.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ad088d/pdf>

Magnetic flux ropes are a bundle of twisted magnetic field lines produced by internal electric currents, which are responsible for solar eruptions and are the major drivers of geomagnetic storms. As such, it is crucial to develop a numerical model that can capture the entire evolution of a flux rope, from its birth to death, in order to predict whether adverse space weather events might occur or not. In this paper, we develop a data-driven modeling that combines a time-dependent magneto-frictional approach with a thermodynamic magnetohydrodynamic model. Our numerical modeling successfully reproduces the formation and confined eruption of an observed flux rope, and unveils the physical details behind the observations. Regarding the long-term evolution of the active region, our simulation results indicate that the flux cancellation due to collisional shearing plays a critical role in the formation of the flux rope, corresponding to a substantial increase in magnetic free energy and helicity. Regarding the eruption stage, the deformation of the flux rope during its eruption can cause an increase in the downward tension force, which suppresses it from further rising. This finding may shed light on why some torus-unstable flux ropes lead to failed eruptions after large-angle rotations. Moreover, we find that twisted fluxes can accumulate during the confined eruptions, which would breed the subsequent eruptive flares. 2017 September 4-10

<https://iopscience.iop.org/article/10.3847/1538-4357/acf75b/pdf>

Solar eruptive activities could occur in weak magnetic field environments and over large spatial scales, which are especially relevant to eruptions involving intermediate or quiescent solar filaments. To handle the large scales, we implement and apply a flux rope embedding method using regularized Biot–Savart laws in the spherical coordinate system. Combined with a potential field source surface model and a magneto–frictional method, a nonlinear force-free field comprising a flux rope embedded in a potential field is constructed. Using the combined nonlinear force-free field as the initial condition, we then perform a zero- $\beta$  data-constrained magnetohydrodynamic (MHD) simulation for an M8.7 flare at 03:38 UT on **2012 January 23**. The MHD model reproduces the eruption process, flare ribbon evolution (represented by the quasi-separatrix layer evolution), and kinematics of the flux rope. This approach could potentially model global-scale eruptions from weak field regions.

## Understanding the Lateral Drifting of an Erupting Filament with a Data-constrained Magnetohydrodynamic Simulation

Solar filaments often exhibit rotation and deflection during eruptions, which would significantly affect the geoeffectiveness of the corresponding coronal mass ejections (CMEs). Therefore, understanding the mechanisms that lead to such rotation and lateral displacement of filaments is a great concern to space weather forecasting. In this paper, we examine an intriguing filament eruption event observed by the Chinese H $\alpha$  Solar Explorer (CHASE) and the Solar Dynamics Observatory (SDO). The filament, which eventually evolves into a CME, exhibits significant lateral drifting during its rising. Moreover, the orientation of the CME flux rope axis deviates from that of the pre-eruptive filament observed in the source region. To investigate the physical processes behind these observations, we perform a data-constrained magnetohydrodynamic (MHD) simulation. Many prominent observational features in the eruption are reproduced by our numerical model, including the morphology of the eruptive filament, eruption path, and flare ribbons. The simulation results reveal that the magnetic reconnection between the flux-rope leg and neighboring low-lying sheared arcades may be the primary mechanism responsible for the lateral drifting of the filament material. Such a reconnection geometry leads to flux-rope footpoint migration and a reconfiguration of its morphology. As a consequence, the filament material hosted in the flux rope drifts laterally, and the CME flux rope deviates from the pre-eruptive filament. This finding underscores the importance of external magnetic reconnection in influencing the orientation of a flux rope axis during eruption. **2022 August 18**

## Dynamical Evolution of an Active-region Filament Driven by Magnetic Reconnection

Yilin [Guo](#)<sup>1,2</sup>, Yijun Hou<sup>4,1,2</sup>, Ting Li<sup>1,2</sup>, and Jun Zhang<sup>4,3</sup>

2021 ApJ 920 77

<https://doi.org/10.3847/1538-4357/ac1ac6>

Studying solar filament dynamical evolutions is an important approach to reveal the driving mechanism of solar eruptions, which seriously impact on the Sun–Earth system and could cause disastrous space weather. To better understand the evolution process of solar filaments, here we investigate an active-region filament by employing observations from the New Vacuum Solar Telescope (NVST), Solar Dynamics Observatory, and Interface Region Imaging Spectrograph. The high-resolution NVST H $\alpha$  images show that the northern footpoint of the filament gradually moved northward. Near the northern footpoint, there is an arch filament system (AFS). Between adjacent footpoints of the filament and the AFS, transient brightening, underlying magnetic cancellation, and bidirectional flows were detected, which jointly imply that it could be the magnetic reconnection between the filament and the AFS that changes the connection of filament threads and drives its footpoint to move northward. In addition, during the footpoint evolution, the filament with highly twisted structure underwent several untwisting motions. Meanwhile, transient brightenings were also observed and appeared as bright knots around several positions where filament threads might braid with each other. And some bright blobs were also detected to propagate outward from the brightening region. These observations suggest that magnetic reconnection might be responsible for the untwisting motion. This work exposes us to a dynamical scenario of the filament evolution driven by magnetic reconnection, which will promote our understanding of the formation and eruption of the filaments.

## Data-constrained Magnetohydrodynamic Simulation of a Long Duration Eruptive Flare

[Yang Guo](#), [Ze Zhong](#), [M. D. Ding](#), [P. F. Chen](#), [Chun Xia](#), [Rony Keppens](#)

ApJ **919** 39 **2021**

<https://arxiv.org/pdf/2106.15080.pdf>

<https://doi.org/10.3847/1538-4357/ac10c8>

We perform a zero- $\beta$  magnetohydrodynamic simulation for the C7.7 class flare initiated at 01:18 UT on **2011 June 21** using the Message Passing Interface Adaptive Mesh Refinement Versatile Advection Code (MPI-AMRVAC). The initial condition for the simulation involves a flux rope which we realize through the regularized Biot-Savart laws, whose parameters are constrained by observations from the Atmospheric Imaging Assembly (AIA) on the Solar

Dynamics Observatory (SDO) and the Extreme Ultraviolet Imager (EUVI) on the twin Solar Terrestrial Relations Observatory (STEREO). This data-constrained initial state is then relaxed to a force-free state by the magneto-frictional module in MPI-AMRVAC. The further time-evolving simulation results reproduce the eruption characteristics obtained by SDO/AIA 94 Å, 304 Å, and STEREO/EUVI 304 Å observations fairly well. The simulated flux rope possesses similar eruption direction, height range, and velocities to the observations. Especially, the two phases of slow evolution and fast eruption are reproduced by varying the density distribution in light of the filament material draining process. Our data-constrained simulations also show other advantages, such as a large field of view (about 0.76 solar radii). We study the twist of the magnetic flux rope and the decay index of the overlying field, and find that in this event, both the magnetic strapping force and the magnetic tension force are sufficiently weaker than the magnetic hoop force, thus allowing the successful eruption of the flux rope. We also find that the anomalous resistivity is necessary in keeping the correct morphology of the erupting flux rope.

## **Observations and modeling of the onset of fast reconnection in the solar transition region**

[L.-J. Guo](#), [B. De Pontieu](#), [Y.-M. Huang](#), [H. Peter](#), [A. Bhattacharjee](#)

ApJ 2020

<https://arxiv.org/pdf/2009.11475.pdf>

Magnetic reconnection is a fundamental plasma process that plays a critical role not only in energy release in the solar atmosphere, but also in fusion, astrophysical, and other space plasma environments. One of the challenges in explaining solar observations in which reconnection is thought to play a critical role is to account for the transition of the dynamics from a slow quasi-continuous phase to a fast and impulsive energetic burst of much shorter duration. Despite the theoretical progress in identifying mechanisms that might lead to rapid onset, a lack of observations of this transition has left models poorly constrained. High-resolution spectroscopic observations from NASA's Interface Region Imaging Spectrograph (IRIS) now reveal tell-tale signatures of the abrupt transition of reconnection from a slow phase to a fast, impulsive phase during UV bursts or explosive events in the Sun's atmosphere. Our observations are consistent with numerical simulations of the plasmoid instability, and provide evidence for the onset of fast reconnection mediated by plasmoids and new opportunities for remote-sensing diagnostics of reconnection mechanisms on the Sun. **13-Aug-2013, 4-Feb-2014, 15-Apr-2014, 2014 May 04-05**

## **The Magnetic Flux Rope Structure of a Triangulated Solar Filament**

2019 ApJL 884 L1

<https://doi.org/10.3847/2041-8213/ab4514>

Solar magnetic flux ropes are core structures driving solar activities. We construct a magnetic flux rope for a filament/prominence observed at 01:11 UT on **2011 June 21** in AR 11236 with a combination of state-of-the-art methods, including triangulation from multiperspective observations, the flux rope embedding method, the regularized Biot–Savart laws, and the magnetofrictional method. First, the path of the filament is reconstructed via the triangulation with 304 Å images observed by the Atmospheric Imaging Assembly on board Solar Dynamics Observatory (SDO) and by the Extreme Ultraviolet Imager on board the twin Solar Terrestrial Relations Observatory. Then, a flux rope is constructed with the regularized Biot–Savart laws using the information of its axis. Next, it is embedded into a potential magnetic field computed from the photospheric radial magnetic field observed by the Helioseismic and Magnetic Imager on board SDO. The combined magnetic field is finally relaxed by the magnetofrictional method to reach a nonlinear force-free state. It is found that both models constructed by the regularized Biot–Savart laws and after the magnetofrictional relaxation coincide with the 304 Å images. The distribution of magnetic dips coincides with part of the filament/prominence material, and the quasi-separatrix layers wrap the magnetic flux ropes, displaying hyperbolic flux tube structures. These models have the advantages of constructing magnetic flux ropes in the higher atmosphere and weak magnetic field regions, which could be used as initial conditions for magnetohydrodynamic simulations of coronal mass ejections.

## **The Role of a Magnetic Topology Skeleton in a Solar Active Region**

[sci-hub.se/10.3847/1538-4357/ab0aed](https://doi.org/10.3847/1538-4357/ab0aed)

We investigate the 3D magnetic topology in the active region NOAA 11719 nine hours before and after a flare–coronal mass ejection (CME) event on **2013 April 11**. The extrapolated 3D coronal magnetic field is computed employing a boundary integrated model, and a complex magnetic topology skeleton comprising five fairly robust null points and their relevant structures are revealed with a mathematical method based on a Poincaré index of isolated 3D null points. Comparative analyses show that the magnetic topology skeleton in this active region determines geometries of post-flare loops and flare ribbons, and characterizes the initial stage of the CME. The present work demonstrates that the magnetic topology skeleton plays an important role in the process of the flare–CME eruption.

## **Solar Magnetic Flux Rope Eruption Simulated by a Data-Driven Magnetohydrodynamic Model**

[sci-hub.tw/10.3847/2041-8213/aafabf](https://sci-hub.tw/10.3847/2041-8213/aafabf)

The combination of magnetohydrodynamic (MHD) simulation and multi-wavelength observations is an effective way to study mechanisms of magnetic flux rope eruption. We develop a data-driven MHD model using the zero- $\beta$  approximation. The initial condition is provided by nonlinear force-free field derived by the magneto-frictional method based on vector magnetic field observed by the Helioseismic and Magnetic Imager (HMI) aboard the Solar Dynamics Observatory (SDO). The bottom boundary uses observed time series of the vector magnetic field and the vector velocity derived by the Differential Affine Velocity Estimator for Vector Magnetograms (DAVE4VM). We apply the data-driven model to active region 11123 observed from 06:00 UT on **2011 November 11** to about 2 hours later. The evolution of the magnetic field topology coincides with the flare ribbons observed in the 304 and 1600 Å wavebands by the Atmospheric Imaging Assembly. The morphology, propagation path, and propagation range of the flux rope are comparable with the observations in 304 Å. We also find that a data-constrained boundary condition, where the bottom boundary is fixed to the initial values, reproduces a similar simulation result. This model can reproduce the evolution of a magnetic flux rope in its dynamic eruptive phase.

## Origin and Structures of Solar Eruptions II: Magnetic Modeling (Invited Review)

The topology and dynamics of the three-dimensional magnetic field in the solar atmosphere govern various solar eruptive phenomena and activities, such as flares, coronal mass ejections, and filaments/prominences. We have to observe and model the vector magnetic field to understand the structures and physical mechanisms of these solar activities. Vector magnetic fields on the photosphere are routinely observed via the polarized light, and inferred with the inversion of Stokes profiles. To analyze these vector magnetic fields, we need first to remove the 180° ambiguity of the transverse components and correct the projection effect. Then, the vector magnetic field can be served as the boundary conditions for a force-free field modeling after a proper preprocessing. The photospheric velocity field can also be derived from a time sequence of vector magnetic fields. Three-dimensional magnetic field could be derived and studied with theoretical force-free field models, numerical nonlinear force-free field models, magnetohydrostatic models, and magnetohydrodynamic models. Magnetic energy can be computed with three-dimensional magnetic field models or a time series of vector magnetic field. The magnetic topology is analyzed by pinpointing the positions of magnetic null points, bald patches, and quasi-separatrix layers. As a well conserved physical quantity, magnetic helicity can be computed with various methods, such as the finite volume method, discrete flux tube method, and helicity flux integration method. This quantity serves as a promising parameter characterizing the activity level of solar active regions.

## Slow Patchy Extreme-ultraviolet Propagating Fronts Associated With Fast Coronal Magneto-acoustic Waves In Solar Eruptions

Y. [Guo](#), M. D. Ding, P. F. Chen

Astrophysical Journal Supplement Series 219(2) 36 2015

Using the high spatiotemporal resolution extreme ultraviolet (EUV) observations of the Atmospheric Imaging Assembly on board the Solar Dynamics Observatory, we conduct a statistical study of the observational properties of the coronal EUV propagating fronts. We find that it might be a universal phenomenon for two types of fronts to coexist in a large solar eruptive event. It is consistent with the hybrid model of EUV propagating fronts, which predicts that coronal EUV propagating fronts consist of both a fast magneto-acoustic wave and a nonwave component. We find that the morphologies, propagation behaviors, and kinematic features of the two EUV propagating fronts are completely different from each other. The fast magneto-acoustic wave fronts are almost isotropic. They travel continuously from the flaring region across multiple magnetic polarities to global distances. On the other hand, the slow nonwave fronts appear as anisotropic and sequential patches of EUV brightening. Each patch propagates locally in the magnetic domains where the magnetic field lines connect to the bottom boundary and stops at the magnetic domain boundaries. Within each magnetic domain, the velocities of the slow patchy nonwave component are an order of magnitude lower than that of the fast-wave component. However, the patches of the slow EUV propagating front can jump from one magnetic domain to a remote one. The velocities of such a transit between different magnetic domains are about one-third to one-half of those of the fast-wave component. The results show that the velocities of the nonwave component, both within one magnetic domain and between different magnetic domains, are highly nonuniform due to the inhomogeneity of the magnetic field in the lower atmosphere.

## Rayleigh-Taylor Type Instabilities in the Reconnection Exhaust Jet as a Mechanism for Supra-arcade Downflows in the Sun

L.-J. [Guo](#)<sup>1,2,3,4</sup>, Y.-M. Huang<sup>1,2,3</sup>, A. Bhattacharjee<sup>1,2,3</sup>, and D. E.

2014 ApJ 796 L29

<http://arxiv.org/pdf/1406.3305v1.pdf>

Supra-arcade downflows (hereafter referred to as SADs) are low-emission, elongated, finger-like features usually observed in active-region coronae above post-eruption flare arcades. Observations exhibit downward moving SADs intertwined with bright upward moving spikes. Whereas SADs are dark voids, spikes are brighter, denser structures. Although SADs have been observed for decades, the mechanism of formation of SADs remains an open issue. In our three-dimensional resistive magnetohydrodynamic simulations, we demonstrate that secondary Rayleigh-Taylor type instabilities develop in the downstream region of a reconnecting current sheet. The instability results in the formation of low-density coherent structures that resemble SADs, and high-density structures that appear to be spike-like. Comparison between the simulation results and observations suggests that secondary Rayleigh-Taylor type instabilities in the exhaust of reconnecting current sheets provide a plausible mechanism for observed SADs and spikes.

## **Twist Accumulation and Topology Structure of a Solar Magnetic Flux Rope**

Y. **Guo**, M. D. Ding, X. Cheng, J. Zhao, E. Pariat

E-print, Nov **2013**; **2013 ApJ** 779 157

To study the build up of a magnetic flux rope before a major flare and coronal mass ejection (CME), we compute the magnetic helicity injection, twist accumulation, and the topology structure of the three dimensional magnetic field, which is derived by the nonlinear force-free field model. The Extreme-ultraviolet Imaging Telescope on board the Solar and Heliospheric Observatory observed a series of confined flares without any CME before a major flare with a CME at 23:02 UT on **2005 January 15** in active region NOAA 10720. We derive the vector velocity at eight time points from 18:27 UT to 22:20 UT with the differential affine velocity estimator for vector magnetic fields, which were observed by the Digital Vector Magnetograph at Big Bear Solar Observatory. The injected magnetic helicity is computed with the vector magnetic and velocity fields. The helicity injection rate was  $(-16.47 \text{ pm } 3.52) \times 1040 \text{ Mx}^2/\text{hr}$ . We find that only about 1.8% of the injected magnetic helicity became finally the internal helicity of the magnetic flux rope, whose twist increasing rate was  $-0.18 \text{ pm } 0.08 \text{ Turns/hr}$ . The quasi-separatrix layers (QSLs) of the three dimensional magnetic field are computed by evaluating the squashing degree,  $Q$ . We find that the flux rope was wrapped by QSLs with large  $Q$  values, where the magnetic reconnection induced by the continuously injected magnetic helicity further produced the confined flares. We suggest that the flux rope was built up and heated by the magnetic reconnection in the QSLs.

## **DISTRIBUTION OF PLASMOIDS IN POST-CORONAL MASS EJECTION CURRENT SHEETS**

L.-J. **Guo**<sup>1,2,3,4</sup>, A. Bhattacharjee<sup>1,2,3,4</sup>, and Y.-M. Huang

**2013 ApJ** 771 L14

Recently, the fragmentation of a current sheet in the high-Lundquist-number regime caused by the plasmoid instability has been proposed as a possible mechanism for fast reconnection. In this work, we investigate this scenario by comparing the distribution of plasmoids obtained from Large Angle and Spectrometric Coronagraph (LASCO) observational data of a coronal mass ejection event with a resistive magnetohydrodynamic simulation of a similar event. The LASCO/C2 data are analyzed using visual inspection, whereas the numerical data are analyzed using both visual inspection and a more precise topological method. Contrasting the observational data with numerical data analyzed with both methods, we identify a major limitation of the visual inspection method, due to the difficulty in resolving smaller plasmoids. This result raises questions about reports of log-normal distributions of plasmoids and other coherent features in the recent literature. Based on nonlinear scaling relations of the plasmoid instability, we infer a lower bound on the current sheet width, assuming the underlying mechanism of current sheet broadening is resistive diffusion.

## **Recurrent coronal jets induced by repetitively accumulated electric currents\***

Y. **Guo**<sup>1,2</sup>, P. Démoulin<sup>3</sup>, B. Schmieder<sup>3</sup>, M. D. Ding<sup>1,2</sup>, S. Vargas Domínguez<sup>4</sup> and Y. Liu

*A&A* 555, A19 (**2013**)

Context. Jets of plasma are frequently observed in the solar corona. A self-similar recurrent behavior is observed in a fraction of them.

Aims. Jets are thought to be a consequence of magnetic reconnection; however, the physics involved is not fully understood. Therefore, we study some jet observations with unprecedented temporal and spatial resolutions.

Methods. The extreme-ultraviolet (EUV) jets were observed by the Atmospheric Imaging Assembly on board the Solar Dynamics Observatory (SDO). The Helioseismic and Magnetic Imager (HMI) on board SDO measured the vector magnetic field, from which we derive the magnetic flux evolution, the photospheric velocity field, and the vertical electric current evolution. The magnetic configuration before the jets is derived by the nonlinear force-free field extrapolation.

Results. Three EUV jets recurred in about one hour on **17 September 2010** in the following magnetic polarity of active region 11106. We derive that the jets are above a pair of parasitic magnetic bipoles that are continuously driven by photospheric diverging flows. The interaction drove the buildup of electric currents, which we observed as elongated patterns at the photospheric level. For the first time, the high temporal cadence of the HMI allows the evolution of such small currents to be followed. In the jet region, we found that the integrated absolute current peaks repetitively in phase with the 171 Å flux evolution. The current buildup and its decay are both fast, about ten minutes each, and the current maximum precedes the 171 Å also by about ten minutes. Then, the HMI temporal cadence is marginally fast enough to detect such changes.

Conclusions. The photospheric current pattern of the jets is found to be associated with the quasi-separatrix layers deduced from the magnetic extrapolation. From previous theoretical results, the observed diverging flows are expected to continuously build such currents. We conclude that the magnetic reconnection occurs periodically, in the current layer created between the emerging bipoles and the large-scale active region field. The periodic magnetic reconnection induced the observed recurrent coronal jets and the decrease of the vertical electric current magnitude.

### **Driving Mechanism and Onset Condition of a Confined Eruption**

Y. [Guo](#)<sup>1,2,3</sup>, M. D. Ding<sup>1,2</sup>, B. Schmieder<sup>3</sup>, H. Li<sup>4</sup>, T. Torok<sup>3,5</sup>, T. Wiegelmann<sup>6</sup>  
E-print, Nov **2010**, ApJL

We study a confined eruption accompanied by an M1.1 flare in solar active region (AR) NOAA 10767 on **2005 May 27**, where a pre-eruptive magnetic flux rope was reported in a nonlinear force-free field (NLFFF) extrapolation. The observations show a strong writhing motion of the erupting structure, suggesting that a flux rope was indeed present and converted some of its twist into writhe in the course of the eruption. Using the NLFFF extrapolation, we calculate the twist of the pre-eruptive flux rope and find that it is in very good agreement with thresholds of the helical kink instability found in numerical simulations. We conclude that the activation and rise of the flux rope were triggered and driven by the instability. Using a potential field extrapolation, we also estimate the height distribution of the decay index of the external magnetic field in the AR one hour prior to the eruption. We find that the decay index stays below the threshold for the torus instability for a significant height range above the erupting flux rope. This provides a possible explanation for the confinement of the eruption to the low corona.

### **A FLUX ROPE ERUPTION TRIGGERED BY JETS**

Astrophysical Journal, 711:1057–1061, **2010** March, [File](#)

We present an observation of a filament eruption caused by recurrent chromospheric plasma injections (surges/jets) on **2006 July 6**. The filament eruption was associated with an M2.5 two-ribbon flare and a coronal mass ejection (CME). There was a light bridge in the umbra of the main sunspot of NOAA 10898; one end of the filament was terminated at the region close to the light bridge, and recurrent surges were observed to be ejected from the light bridge. The surges occurred intermittently for about 8 hr before the filament eruption, and finally a clear jet was found at the light bridge to trigger the filament eruption. We analyzed the evolutions of the relative darkness of the filament and the loaded mass by the continuous surges quantitatively. It was found that as the occurrence of the surges, the relative darkness of the filament body continued growing for about 3–4 hr, reached its maximum, and kept stable for more than 2 hr until it erupted. If suppose 50% of the ejected mass by the surges could be trapped by the filament channel, then the total loaded mass into the filament channel will be about  $0.574 \times 10^{16}$  g with a momentum of  $0.574 \times 10^{22}$  g cm s<sup>-1</sup> by 08:08 UT, which is a non-negligible effect on the stability of the filament. Based on the observations, we present a model showing the important role that recurrent chromospheric mass injection play in the evolution and eruption of a flux rope. Our study confirms that the surge activities can efficiently supply the necessary material for some filament formation. Furthermore, our study indicates that the continuous mass with momentum loaded by the surge activities to the filament channel could make the filament unstable and cause it to erupt.

### **Magnetic properties of flare-CME productive active regions and CME speed:**

A&A 462 (2007) 1121-1126 (Section 'The Sun')  
<http://www.aanda.org/10.1051/0004-6361:20065888>

Four measures, including the tilt angle (Tilt), total flux (Ft), length of the strong-field and strong-gradient main neutral line (Lsg) and effective distance (dE), are used to quantify the properties of the magnetic field of flare-CME productive active regions.

### **Stability of the coronal magnetic field around large confined and eruptive solar flares**

[Manu Gupta](#), [J. K. Thalmann](#), [A. M. Veronig](#)  
A&A **2024**

<https://arxiv.org/pdf/2402.12254.pdf>

Context. The coronal magnetic field, which overlies the current-carrying field of solar active regions, straps the magnetic configuration below. The characteristics of this overlying field are crucial in determining if a flare will be eruptive and accompanied by a coronal mass ejection (CME), or if it will remain confined without a CME.

Aims. In order to improve our understanding on the pre-requisites of eruptive solar flares, we study and compare different measures that characterize the eruptive potential of solar active regions — the critical height for torus instability as a local measure and the helicity ratio as a global measure — with the structural properties of the underlying magnetic field, namely the altitude of the center of the current-carrying magnetic structure.

Methods. Using time series of 3D optimization-based nonlinear force-free magnetic field models for 10 different active regions (ARs) around the time of large solar flares, we determine the altitudes of the current-weighted centers of the

non-potential model structures. Based on the potential magnetic field, we inspect the decay index,  $n$ , in multiple vertical planes oriented along of or perpendicular to the flare-relevant polarity inversion line, and estimate the critical height ( $h_{crit}$ ) for torus instability (TI) using different thresholds of  $n$ . The critical heights are interpreted with respect to the altitudes of the current-weighted centers of the associated non-potential structures, as well as the eruptive character of the associated flares, and the eruptive potential of the host AR, as characterized by the helicity ratio.

Results. Our most important findings are that (i)  $h_{crit}$  is more segregated in terms of flare type than the helicity ratio, and that (ii) coronal field configurations with a higher eruptive potential (in terms of the helicity ratio) also appear to be more prone to TI. Furthermore, we find no pronounced differences in the altitudes of the non-potential structures prior to confined and eruptive flares. An aspect which requires further investigation is that, quite generally, the modeled non-potential structures hardly reside in a torus-unstable regime, requiring further assessment regarding the applicability of the chosen NLFF modeling approach when targeted at the structural properties of the coronal magnetic field. **2011-02-15, 2011-03-09, 2011-09-26, 2011-11-05, 2012-03-07, 2014-10-24, 2015-01-30, 2015-03-11, 2017-09-06**

## **Magnetic helicity and energy budget around large confined and eruptive solar flares**

[Manu Gupta](#), [J. K. Thalmann](#), [A. M. Veronig](#)

A&A 653, A69 2021

<https://arxiv.org/pdf/2106.08781.pdf>

<https://www.aanda.org/articles/aa/pdf/2021/09/aa40591-21.pdf>

<https://doi.org/10.1051/0004-6361/202140591>

We investigate the coronal magnetic energy and helicity budgets of ten solar ARs, around the times of large flares. In particular, we are interested in a possible relation of the derived quantities to the particular type of the flares that the AR produces, i.e., whether they are associated with a CME or they are confined. Using an optimization approach, we employ time series of 3D nonlinear force-free magnetic field models of ten ARs, covering a time span of several hours around the time of occurrence of large solar flares (GOES class M1.0 and larger). We subsequently compute the 3D magnetic vector potentials associated to the model 3D coronal magnetic field using a finite-volume method. This allows us to correspondingly compute the coronal magnetic energy and helicity budgets, as well as related (intensive) quantities such as the relative contribution of free magnetic energy,  $EF/E$  (energy ratio), the fraction of non-potential (current-carrying) helicity,  $|HJ|/|HV|$  (helicity ratio), and the normalized current-carrying helicity,  $|HJ|/\phi^2$ . The total energy and helicity budgets of flare-productive ARs (extensive parameters) cover a broad range of magnitudes, with no obvious relation to the eruptive potential of the individual ARs, i.e., whether or not a CME is produced in association with the flare. The intensive eruptivity proxies,  $EF/E$  and  $|HJ|/|HV|$ , and  $|HJ|/\phi^2$ , however, seem to be distinctly different for ARs that produced CME-associated large flares compared to those which produced confined flares. For the majority of ARs in our sample, we are able to identify characteristic pre-flare magnitudes of the intensive quantities, clearly associated to subsequent CME-productivity. **2011-02-15, 2011-03-09, 2011-09-26, 2011-11-05, 2012-03-07, 2013-11-08, 2014-10-24, 2015-01-30, 2015-03-11, 2017-09-06**

PASJ 2021

<https://arxiv.org/pdf/2101.08575.pdf>

We present a detailed three-dimensional (3D) view of a prominence eruption, coronal loop expansion, and coronal mass ejections (CMEs) associated with an M4.4 flare that occurred on **2011 March 8** in the active region NOAA 11165. Full-disk  $H\alpha$  images of the flare and filament ejection were successfully obtained by the Flare Monitoring Telescope (FMT) following its relocation to Ica University, Peru. Multiwavelength observation around the  $H\alpha$  line enabled us to derive the 3D velocity field of the  $H\alpha$  prominence eruption. Features in extreme ultraviolet were also obtained by the Atmospheric Imager Assembly onboard the *Solar Dynamic Observatory* and the Extreme Ultraviolet Imager on board the *Solar Terrestrial Relations Observatory - Ahead* satellite. We found that, following collision of the erupted filament with the coronal magnetic field, some coronal loops began to expand, leading to the growth of a clear CME. We also discuss the succeeding activities of CME driven by multiple interactions between the expanding loops and the surrounding coronal magnetic field.

## **Short term topological changes of coronal holes associated with prominence eruptions and subsequent CMEs**

H. [Gutiérrez](#), L. Taliashvili, Z. Mouradian

Advances in Space Research, Volume 51, Issue 10, 2013, pp. 1824-1833

[sci-hub.se/10.1016/j.asr.2012.03.008](https://doi.org/10.1016/j.asr.2012.03.008)

We study the short-term topological changes of equatorial and polar coronal hole (CH) boundaries, such as a variation of their area and disintegration, associated to reconnection with nearby (within  $15^\circ$  distance) quiescent prominence magnetic fields leading to eruptions and subsequent Coronal Mass Ejections (CMEs). The examples presented here correspond to the recent solar minimum years 2008 and 2009. We consider a temporal window of one day between the CH topological changes and the start and end times of prominence eruptions and onset of CMEs. To establish this

association we took into account observational conditions related to the instability of prominence/filaments, the occurrence of a CME, as well as the subsequent evolution after the CME. We found an association between short-term local topological changes in CH boundaries and the formation/disappearance of bright points near them, as well as, between short-term topological changes within the whole CH and eruptions of nearby quiescent prominences followed by the appearance of one or more CMEs. **2008/08/29, 2008/12/12, 2009/05/29**

## **Predicting the Loci of Solar Eruptions**

N. Gyenge, R. Erdélyi

**2017** Space Weather of the Heliosphere: Processes and Forecasts Proceedings IAU Symposium No. 335

<https://arxiv.org/pdf/1710.06196.pdf>

The longitudinal distribution of solar active regions shows non-homogeneous spatial behaviour, which is often referred to as Active Longitude (AL). Evidence for a significant statistical relationships between the AL and the longitudinal distribution of flare and coronal mass ejections (CME) occurrences is found in Gyenge et al, 2017 (ApJ, 838, 18). The present work forecasts the spatial position of AL, hence the most flare/CME capable active regions are also predictable. Our forecast method applies Autoregressive Integrated Moving Average model for the next 2 years time period. We estimated the dates when the solar flare/CME capable longitudinal belts face towards Earth.

## **Active longitude and CME occurrences**

N. Gyenge, T. Singh, T. S. Kiss, A. K. Srivastava, R. Erdélyi

**2017**

<https://arxiv.org/pdf/1702.06664.pdf>

The spatial inhomogeneity of the distribution of coronal mass ejection (CME) occurrences in the solar atmosphere could provide a tool to estimate the longitudinal position of the most probable CME-capable active regions in the Sun. The anomaly in the longitudinal distribution of active regions themselves is often referred to as active longitude (AL). In order to reveal the connection between the AL and CME spatial occurrences, here we investigate the morphological properties of active regions. The first morphological property studied is the separateness parameter, which is able to characterise the probability of the occurrence of an energetic event, such as solar flare or CME. The second morphological property is the sunspot tilt angle. The tilt angle of sunspot groups allows us to estimate the helicity of active regions. The increased helicity leads to a more complex built-up of the magnetic structure and also can cause CME eruption. We found that the most complex active regions appear near to the AL and the AL itself is associated with the most tilted active regions. Therefore, the number of CME occurrences is higher within the AL. The origin of the fast CMEs is also found to be associated with this region. We concluded that the source of the most probably CME-capable active regions is at the AL. By applying this method we can potentially forecast a flare and/or CME source several Carrington rotations in advance. This finding also provides new information for solar dynamo modelling.

## **Laboratory demonstration of slow rise to fast acceleration of arched magnetic flux ropes**

Bao N. Ha\* and Paul M. Bellan

Geophysical Research Letters **2016**

<http://sci-hub.cc/10.1002/2016GL069744>

We demonstrate the slow rise to fast acceleration of an arched plasma-filled magnetic flux rope. The flux rope expansion is inhibited by an externally applied customizable strapping field. When the strapping field is not too strong and not too weak, expansion forces build up while the flux rope is in the strapping field region. When the flux rope moves to a critical height beyond the peak strapping field region, the plasma accelerates quickly corresponding to the observed slow rise to fast acceleration of solar eruptions. This behavior is in agreement with the predictions of the torus instability.

The solar flare and Coronal Mass Ejections (CMEs) are well known as one of the most massive eruptions which potentially create major disturbances in the interplanetary medium and initiate severe magnetic storms when they collide with the Earth's magnetosphere. However, how far the solar flare can contribute to the formation of the CMEs is still not easy to be understood. These phenomena are associated with II and III burst it also divided by sub-type of burst depending on the physical characteristics and different mechanisms. In this work, we used a Compound Astronomical

Low-cost Low-frequency Instrument for Spectroscopy in Transportable Observatories (CALLISTO) system. The aim of the present study is to reveal dynamical properties of solar burst type II and III due to several mechanisms. Most of the cases of both solar radio bursts can be found in the range less than 400 MHz. Based on solar flare monitoring within 24 hours, the CMEs that have the potential to explode will dominantly be a class of M1 solar flare. Overall, the tendencies of SRBT III burst form the solar radio burst type III at 187 MHz to 449 MHz. Based on solar observations, it is evident that the explosive, short time-scale energy release during flares and the long term, gradual energy release expressed by CMEs can be reasonably understood only if both processes are taken as common and probably not independent signatures of a destabilization of pre-existing coronal magnetic field structures. The configurations of several active regions can be sourced regions of CMEs formation. The study of the formation, acceleration and propagation of CMEs requires advanced and powerful observational tools in different spectral ranges as many „stages“ as possible between the photosphere of the Sun and magnetosphere of the Sun and magnetosphere of the Earth. In conclusion, this range is a current regime of solar radio bursts during CMEs events. **9th March 2012, 13th November 2012, 23rd October 2012, 30th March 2013,**

## **Solar Coronal Jets Extending to High Altitudes Observed During the 2017 August 21 Total Eclipse**

[Yoichiro Hanaoka](#), [Ryuichi Hasuo](#), [Tsukasa Hirose](#), [Akiko C. Ikeda](#), [Tsutomu Ishibashi](#), [Norihiro Manago](#), [Yukio Masuda](#), [Sakuhiro Morita](#), [Jun Nakazawa](#), [Osamu Ohgoe](#), [Yoshiaki Sakai](#), [Kazuhiro Sasaki](#), [Koichi Takahashi](#), [Toshiyuki Toi](#)

ApJ **860** 142 **2018**

<https://arxiv.org/pdf/1805.04251.pdf>

Coronal jets, which extend from the solar surface to beyond  $2 R_{\odot}$ , were observed in the polar coronal hole regions during the total solar eclipse on **2017 August 21**. In a time-series of white-light images of the corona spanning 70 minutes taken with our multi-site observations of this eclipse, six jets were found as narrow structures upwardly ejected with the apparent speed of about  $450 \text{ km s}^{-1}$  in polar plumes. On the other hand, extreme-ultraviolet (EUV) images taken with the Atmospheric Image Assembly of the Solar Dynamics Observatory show that all of the eclipse jets were preceded by EUV jets. Conversely, all the EUV jets whose brightness is comparable to ordinary soft X-ray jets and which occurred in the polar regions near the eclipse period were observed as eclipse jets. These results suggest that ordinary polar jets generally reach high altitudes and escape from the Sun as part of the solar wind.

## **Coronal Mass Ejections Observed at the Total Solar Eclipse on 13 November 2012**

Yoichiro [Hanaoka](#), Jun Nakazawa, Osamu Ohgoe, Yoshiaki Sakai, Kazuo Shiota

Solar Physics, **2014**, Volume 289, Issue 7, pp 2587-2599

<http://arxiv.org/pdf/1309.3718v1.pdf>

<http://sci-hub.cc/10.1007/s11207-014-0476-z>

White-light observations of the total solar eclipse on **13 November 2012** were made at two sites, where the totality occurred 35 min apart. The structure of the corona from the solar limb to a couple of solar radii was observed with a wide dynamic range and a high signal-to-noise ratio. An ongoing coronal mass ejection (CME) and a pre-CME loop structure just before the eruption were observed in the height range between  $1 - 2 R_{\odot}$ . The source region of CMEs was revealed to be in this height range, where the material and the magnetic field of CMEs were located before the eruption. This height range includes the gap between the extreme ultraviolet observations of the low corona and the spaceborne white-light observations of the high corona, but the eclipse observation shows that this height range is essential for the study of CME initiation. The eclipse observation is basically just a snapshot of CMEs, but it indicates the importance of a continuous coverage of CME observations in this height range in the future.

## **Multi-thermal dynamics and energetics of a coronal mass ejection in the low solar atmosphere\***

I. G. [Hannah](#) and E. P. Kontar

A&A 553, A10 (**2013**); **File**

<http://arxiv.org/pdf/1212.5529v1.pdf>

**Aims.** The aim of this work is to determine the multi-thermal characteristics and plasma energetics of an eruptive plasmoid and occulted flare observed by the Solar Dynamics Observatory's Atmospheric Imaging Assembly (SDO/AIA).

**Methods.** We study a **2010 Nov. 3** event (peaking at 12:20 UT in GOES soft X-rays) of a coronal mass ejection and occulted flare that demonstrates the morphology of a classic erupting flux rope. The high spatial and time resolution and six coronal channels of the SDO/AIA images allows the dynamics of the multi-thermal emission during the initial phases of eruption to be studied in detail. The differential emission measure is calculated, using an optimized version of a regularized inversion method, for each pixel across the six channels at different times, resulting in emission measure maps and movies in a variety of temperature ranges.

**Results.** We find that the core of the erupting plasmoid is hot (8–11, 11–14 MK) with a similarly hot filamentary “stem” structure connecting it to the lower atmosphere, which could be interpreted as the current sheet in the flux rope model, though is wider than these models suggest. The velocity of the leading edge of the eruption is  $597\text{--}664 \text{ km s}^{-1}$  in the

temperature range  $\geq 3\text{--}4$  MK and between  $1029\text{--}1246$  km s<sup>-1</sup> for  $\leq 2\text{--}3$  MK. We estimate the density (in  $11\text{--}14$  MK) of the erupting core and stem during the impulsive phase to be about  $3 \times 10^9$  cm<sup>-3</sup>,  $6 \times 10^9$  cm<sup>-3</sup>,  $9 \times 10^8$  cm<sup>-3</sup> in the plasmoid core, stem, and surrounding envelope of material. This gives thermal energy estimates of  $5 \times 10^{29}$  erg,  $1 \times 10^{29}$  erg, and  $2 \times 10^{30}$  erg. The kinetic energy for the core and envelope is slightly lower. The thermal energy of the core and current sheet grows during the eruption, suggesting continuous influx of energy presumably via reconnection. Conclusions. The combination of the optimized regularized inversion method and SDO/AIA data allows the multi-thermal characteristics (i.e. velocity, density, and thermal energies) of the plasmoid eruption to be determined.

### **Emission measure maps of a CME seen by SDO/AIA**

Iain **Hannah** and Eduard Kontar

UKSP nugget: 31, 2013

<http://www.uksolphys.org/?p=5790>

Mapping dynamical heating in a CME.

The spectacular images from the Atmospheric Imaging Assembly on the Solar Dynamics Observatory (SDO/AIA) show a range of highly energetic phenomena in the solar corona like flares and coronal mass ejections (CMEs). These observations not only permit the dynamics to be studied but the different wavelength filters, particularly the six sensitive to coronal temperatures, also allow the heated plasma parameters to be investigated. In this nugget we demonstrate a regularized approach to recovering the underlying temperature distribution of the emitting material from a CME low in the solar corona. The SDO/AIA images show the CME formation which broadly matches the classic CSHKP model of an erupting plasmoid, stretching the magnetic field to produce a current sheet behind it. However in reality this event is considerably more complicated: this CME featured in a earlier nugget. **03-Nov-2010**

### **Simultaneous Near-Sun Observations of a Moving Type IV Radio Burst and the Associated White-Light Coronal Mass Ejection**

K. **Hariharan**, R. Ramesh, C. Kathiravan, T. J. Wang

Solar Phys. Volume 291, Issue 5, pp 1405-1416 **2016** DOI: 10.1007/s11207-016-0918-x

<http://sci-hub.cc/10.1007/s11207-016-0918-x>

We present rare contemporaneous low-frequency ( $< 100$  MHz) imaging, spectral, and polarimetric observations of a moving type IV radio burst that had close spatio-temporal association with a white-light coronal mass ejection (CME) near the Sun. We estimate the electron density near the burst region from white-light coronagraph polarized brightness (pB) images of the CME as well as the two-dimensional radio imaging observations of the thermal free-free emission at a typical radio frequency such as 80 MHz. We analyze the burst properties such as the degree of circular polarization, the spectral index, and fine structures using the radio polarimeter and the radio spectral observations. The obtained results suggest that second harmonic plasma emission from the enhanced electron density in the leading edge of the CME is the cause of the radio burst. We determine the strength of the coronal magnetic field ( $B$ ) for the first time based on this interpretation. The estimated value ( $B \approx 1$  gauss) in the CME leading edge at a heliocentric distance of ( $\approx 2.2 R_{\odot}$ ) agrees well with the similar  $B$  values reported earlier based on other types of observations. **31 March 2014**

### **Measuring Velocities in the Early Stage of an Eruption: Using "Overlappogram" Data from Hinode EIS**

Louise K. **Harra**<sup>1</sup>, Hirohisa Hara<sup>2</sup>, George A. Doschek<sup>3</sup>, Sarah Matthews<sup>1</sup>, Harry Warren<sup>3</sup>, J. Leonard Culhane<sup>1</sup>, and Magnus M. Woods<sup>1</sup>

**2017** ApJ 842 58

<http://sci-hub.cc/10.3847/1538-4357/aa7411>

In order to understand the onset phase of a solar eruption, plasma parameter measurements in the early phases are key to constraining models. There are two current instrument types that allow us to make such measurements: narrow-band imagers and spectrometers. In the former case, even narrow-band filters contain multiple emission lines, creating some temperature confusion. With imagers, however, rapid cadences are achievable and the field of view can be large. Velocities of the erupting structures can be measured by feature tracking. In the spectrometer case, slit spectrometers can provide spectrally pure images by "rastering" the slit to build up an image. This method provides limited temporal resolution, but the plasma parameters can be accurately measured, including velocities along the line of sight. Both methods have benefits and are often used in tandem. In this paper we demonstrate for the first time that data from the wide slot on the Hinode EUV Imaging Spectrometer, along with imaging data from AIA, can be used to deconvolve velocity information at the start of an eruption, providing line-of-sight velocities across an extended field of view. Using He ii 256 Å slot data at flare onset, we observe broadening or shift(s) of the emission line of up to  $\pm 280$  km s<sup>-1</sup>. These are seen at different locations—the redshifted plasma is seen where the hard X-ray source is later seen (energy deposition site). In addition, blueshifted plasma shows the very early onset of the fast rise of the filament. **2011-07-15, 2012-03-09, 2013-12-31**

### **The Characteristics of Solar X-Class Flares and CMEs: A Paradigm for Stellar Superflares and Eruptions?**

Louise K. [Harra](#), Carolus J. Schrijver, Miho Janvier, Shin Toriumi, Hugh Hudson, Sarah Matthews, Magnus M. Woods, Hirohisa Hara, Manuel Guedel, Adam Kowalski, Rachel Osten, Kanya Kusano, Theresa Lueftinger

Solar Phys. Volume 291, [Issue 6](#), pp 1761–1782 **2016** [Open Access File](#)

This paper explores the characteristics of 42 solar X-class flares that were observed between February 2011 and November 2014, with data from the Solar Dynamics Observatory (SDO) and other sources. This flare list includes nine X-class flares that had no associated CMEs. In particular our aim was to determine whether a clear signature could be identified to differentiate powerful flares that have coronal mass ejections (CMEs) from those that do not. Part of the motivation for this study is the characterization of the solar paradigm for flare/CME occurrence as a possible guide to the stellar observations; hence we emphasize spectroscopic signatures. To do this we ask the following questions: Do all eruptive flares have long durations? Do CME-related flares stand out in terms of active-region size vs. flare duration? Do flare magnitudes correlate with sunspot areas, and, if so, are eruptive events distinguished? Is the occurrence of CMEs related to the fraction of the active-region area involved? Do X-class flares with no eruptions have weaker non-thermal signatures? Is the temperature dependence of evaporation different in eruptive and non-eruptive flares? Is EUV dimming only seen in eruptive flares? We find only one feature consistently associated with CME-related flares specifically: coronal dimming in lines characteristic of the quiet-Sun corona, i.e. 1–2 MK. We do not find a correlation between flare magnitude and sunspot areas. Although challenging, it will be of importance to model dimming for stellar cases and make suitable future plans for observations in the appropriate wavelength range in order to identify stellar CMEs consistently. **19-03-2011, 24-Sept-2011, 03-11-2011, 07-03-2012, 12-07-2012, 23-10-2012, 08-11-2013, 24-02-2014, 22-10-2014**

### **The Impact of a Filament Eruption on Nearby High-lying Cool Loops**

L. K. [Harra](#)<sup>1</sup>, S. A. Matthews<sup>1</sup>, D. M. Long<sup>1</sup>, G. A. Doschek<sup>2</sup>, and B. De Pontieu

**2014** ApJ 792 93

<http://fr.arxiv.org/pdf/1409.0377v1>

<http://arxiv.org/pdf/1409.0377v1.pdf>

The first spectroscopic observations of cool Mg II loops above the solar limb observed by NASA's Interface Region Imaging Spectrograph (IRIS) are presented. During the observation period, IRIS is pointed off-limb, allowing the observation of high-lying loops, which reach over 70 Mm in height. Low-lying cool loops were observed by the IRIS slit-jaw camera for the entire four-hour observing window. There is no evidence of a central reversal in the line profiles, and the Mg II h/k ratio is approximately two. The Mg II spectral lines show evidence of complex dynamics in the loops with Doppler velocities reaching  $\pm 40$  km s<sup>-1</sup>. The complex motions seen indicate the presence of multiple threads in the loops and separate blobs. Toward the end of the observing period, a filament eruption occurs that forms the core of a coronal mass ejection. As the filament erupts, it impacts these high-lying loops, temporarily impeding these complex flows, most likely due to compression. This causes the plasma motions in the loops to become blueshifted and then redshifted. The plasma motions are seen before the loops themselves start to oscillate as they reach equilibrium following the impact. The ratio of the Mg h/k lines also increases following the impact of the filament.

### **The Solar Source of a Magnetic Cloud Using a Velocity Difference Technique**

L.K. [Harra](#), · C.H. Mandrini, · S. Dasso, A.M. Gulisano, · K. Steed, · S. Imada

E-print, Nov 2010; Solar Phys. (**2011**) 268: 213–230, **File**

For large eruptions on the Sun, it is often a problem that the core dimming region cannot be observed due to the bright emission from the flare itself. However, spectroscopic data can provide the missing information through the measurement of Doppler velocities. In this paper we analyse the well-studied flare and coronal mass ejection that erupted on the Sun on **13 December 2006** and reached the Earth on 14 December 2006. In this example, although the imaging data were saturated at the flare site itself, we could extract information on the core dimming region through velocity measurements, as well as on the remote dimmings. The purpose of this paper is to determine more accurately the magnetic flux of the solar source region, potentially involved in the ejection, through a new technique. The results of its application are compared to the flux in the magnetic cloud observed at 1AU, as a way to check the reliability of this technique. We analysed data from the {it Hinode} EUV Imaging Spectrometer to estimate the Doppler velocity in the active region and its surroundings before and after the event. This allowed us to determine a Doppler velocity 'difference' image. We used the velocity difference image overlaid on a Michelson Doppler Imager magnetogram to identify the regions in which the blue-shifts were more prominent after the event; the magnetic flux in these regions was used as a proxy for the ejected flux and compared to the magnetic cloud flux. This new method provides a more accurate flux determination in the solar source region.

### **Spectroscopic observations of coronal waves and coronal mass ejections**

L.K. [Harra](#)

[Advances in Space Research](#)

[Volume 41, Issue 1](#), **2008**, Pages 138-143, **File**

It is common to use imaging instruments such as EUV and X-ray imagers and coronagraphs to study large-scale phenomena such as coronal mass ejections and coronal waves. Although high resolution spectroscopy is generally

limited to a small field of view, its importance in understanding global phenomena should not be under-estimated. I will review current spectroscopic observations of large-scale dynamic phenomena such as global coronal waves and coronal mass ejections. The aim is to determine plasma parameters such as flows, temperatures and densities to obtain a physical understanding of these phenomena.

### **How Does Large Flaring Activity from the Same Active Region Produce Oppositely Directed Magnetic Clouds?**

Louise K. [Harra](#) · Nancy U. Crooker · Cristina H. Mandrini · Lidia van Driel-Gesztelyi · Sergio Dasso · Jingxiu Wang · Heather Elliott · Gemma Attrill · Bernard V. Jackson · Mario M. Bisi  
Solar Phys, DOI 10.1007/s11207-007-9002-x, **2007**

We describe the interplanetary coronal mass ejections (ICMEs) that occurred as a result of a series of solar flares and eruptions from 4 to 8 November 2004. Two ICMEs/magnetic clouds occurring from these events had opposite magnetic orientations. This was despite the fact that the major flares related to these events occurred within the same active region that maintained the same magnetic configuration.

### **MATERIAL OUTFLOWS FROM CORONAL INTENSITY “DIMMING REGIONS” DURING CORONAL MASS EJECTION ONSET**

Louise K. [Harra](#), Alphonse C. Sterling  
Astrophysical Journal, 561:L215–L218, **2001**

<https://iopscience.iop.org/article/10.1086/324767/pdf>

One signature of expulsion of coronal mass ejections (CMEs) from the solar corona is the appearance of transient intensity dimmings in coronal images. These dimmings have generally been assumed to be due to discharge of CME material from the corona, and thus the “dimming regions” are thought of as an important signature of the sources of CMEs. We present spectral observations of two dimming regions at the time of expulsion of CMEs, using the Coronal Diagnostic Spectrometer (CDS) on the SOHO satellite. One of the dimming regions is at the solar limb and associated with a CME traveling in the plane of the sky, while the other region is on the solar disk and associated with an Earth-directed “halo” CME. From the limb event, we see Doppler signatures of  $\sim 30$  km s<sup>-1</sup> in coronal (Fe XVI and Mg IX) emission lines, where the enhanced velocities coincide with the locations of coronal dimming. This provides direct evidence that the dimmings are associated with outflowing material. We also see larger ( $\sim 100$  km s<sup>-1</sup>) Doppler velocities in transition region (O V and He I) emission lines, which are likely to be associated with motions of a prominence and loops at transition region temperatures. An “EIT wave” accompanies the disk event, and a dimming region behind the wave shows strong blueshifted Doppler signatures of  $\sim 100$  km s<sup>-1</sup> in O V, suggesting that material from the dimming regions behind the wave may be feeding the CME.

We present a statistical analysis of coronal mass ejections (CMEs) imaged by the Heliospheric Imager (HI) instruments aboard NASAs twin-spacecraft STEREO mission between April 2007 and August 2017 for STEREO-A and between April 2007 and September 2014 for STEREO-B. The analysis exploits a catalogue that was generated within the FP7 HELCATS project. Here, we focus on the observational characteristics of CMEs imaged in the heliosphere by the inner (HI-1) cameras. More specifically, in this paper we present distributions of the basic observational parameters - namely occurrence frequency, central position angle (PA) and PA span - derived from nearly 2000 detections of CMEs in the heliosphere by HI-1 on STEREO-A or STEREO-B from the minimum between Solar Cycles 23 and 24 to the maximum of Cycle 24; STEREO-A analysis includes a further 158 CME detections from the descending phase of Cycle 24, by which time communication with STEREO-B had been lost. We compare heliospheric CME characteristics with properties of CMEs observed at coronal altitudes, and with sunspot number. As expected, heliospheric CME rates correlate with sunspot number, and are not inconsistent with coronal rates once instrumental factors/differences in cataloguing philosophy are considered. As well as being more abundant, heliospheric CMEs, like their coronal counterparts, tend to be wider during solar maximum. Our results confirm previous coronagraph analyses suggesting that CME launch sites don't simply migrate to higher latitudes with increasing solar activity. At solar minimum, CMEs tend to be launched from equatorial latitudes while, at maximum, CMEs appear to be launched over a much wider latitude range; this has implications for understanding the CME/solar source association. Our analysis provides some supporting evidence for the systematic dragging of CMEs to lower latitude as they propagate outwards. **2008-12-13, 2009-09-01, 2010-06-02, 2011-07-03, 2011-12-01, 2013-12-15**

2012 ApJ 750 45, [File](#)

On 2010 August 1, the northern solar hemisphere underwent significant activity that involved a complex set of active regions near central meridian with, nearby, two large prominences and other more distant active regions. This activity culminated in the eruption of four major coronal mass ejections (CMEs), effects of which were detected at Earth and other solar system bodies. Recognizing the unprecedented wealth of data from the wide range of spacecraft that were available—providing the potential for us to explore methods for CME identification and tracking, and to assess issues regarding onset and planetary impact—we present a comprehensive analysis of this sequence of CMEs. We show that, for three of the four major CMEs, onset is associated with prominence eruption, while the remaining CME appears to be closely associated with a flare. Using instrumentation on board the Solar Terrestrial Relations Observatory spacecraft, three of the CMEs could be tracked out to elongations beyond 50°; their directions and speeds have been determined by various methods, not least to assess their potential for Earth impact. The analysis techniques that can be applied to the other CME, the first to erupt, are more limited since that CME was obscured by the subsequent, much faster event before it had propagated far from the Sun; we discuss the speculation that these two CMEs interact. The consistency of the results, derived from the wide variety of methods applied to such an extraordinarily complete data set, has allowed us to converge on robust interpretations of the CME onsets and their arrivals at 1 AU.

### Coronal mass ejection: key issues

[Review](#)

Richard [Harrison](#)

Proceedings of the International Astronomical Union (2008), *N. Gopalswamy & D.F. Webb, eds*, .  
4: 191-200, 2009, [File](#)

Coronal Mass Ejections (CMEs) have been addressed by a particularly active research community in recent years. With the advent of the International Heliophysical Year and the new STEREO and Hinode missions, in addition to the on-going SOHO mission, CME research has taken centre stage in a renewed international effort. This [review](#) aims to touch on some key observational areas, and their interpretation. First, we consider coronal dimming, which has become synonymous with CME onsets, and stress that recent advances have heralded a move from a perceived association between the two phenomena to a firm, well-defined physical link. What this means for our understanding of CME modeling is discussed. Second, with the new STEREO observations, and noting the on-going SMEI observations, it is important to review the opening field of CME studies in the heliosphere. Finally, we discuss some specific points with regard to EIT-waves and the flare-CME relationship. In the opinion of the author, these issues cover key hot topics which need consideration for significant progress in the field.

### Pre-CME Onset Fuses – Do the STEREO Heliospheric Imagers Hold the Clues to the CME Onset Process?

Richard A. [Harrison](#) · Christopher J. Davis · Jackie A. Davies

Solar Phys (2009) 259: 277–296, [File](#)

Understanding the onset of coronal mass ejections (CMEs) is surely one of the holy grails of solar physics today. Inspection of data from the Heliospheric Imagers (HI), which are part of the SECCHI instrument suite aboard the two NASA STEREO spacecraft, appears to have revealed pre-eruption signatures which may provide valuable evidence for identifying the CME onset mechanism. Specifically, an examination of the HI images has revealed narrow rays comprised of a series of outward-propagating plasma blobs apparently forming near the edge of the streamer belt prior to many CME eruptions. In this pilot study, we inspect a limited dataset to explore the significance of this phenomenon, which we have termed a pre-CME ‘fuse’. Although, the enhanced expulsion of blobs may be consistent with an increase in the release of outward-propagating blobs from the streamers themselves, it could also be interpreted as evidence for interchange reconnection in the period leading to a CME onset. Indeed, it is argued that the latter could even have implications for the end-of-life of CMEs. Thus, the presence of these pre-CME fuses provides evidence that the CME onset mechanism is either related to streamer reconnection processes or the reconnection between closed field lines in the streamer belt and adjacent, open field lines. We investigate the nature of these fuses, including their timing and location with respect to CME launch sites, as well as their speed and topology.

**25 Jan 2007** We show for the first time images of solar coronal mass ejections (CMEs) viewed using the **Heliospheric Imager (HI)** instrument aboard the NASA **STEREO** spacecraft. The HI instruments are wide-angle imaging systems designed to detect CMEs in the heliosphere, in particular, for the first time, observing the propagation of such events along the Sun–Earth line, that is, those directed towards Earth. At the time of writing the STEREO spacecraft are still close to the Earth and the full advantage of the HI dual-imaging has yet to be realised. However, even these early results show that despite severe technical challenges in their design and implementation, the HI instruments can successfully detect CMEs in the heliosphere, and this is an extremely important milestone for CME research. For the principal event being analysed here we demonstrate an ability to track a CME from the corona to over 40 degrees. The time–altitude history shows a constant speed of ascent over at least the first 50 solar radii and some evidence for deceleration at distances of over 20 degrees.

An analysis is presented of solar X-ray flares associated with coronal mass ejections through the period 1986–1987. The nature of the flares apparently associated with mass ejection is explored. In particular the relationships between flare duration and intensity and the association with mass ejection are investigated. We believe that this study tackles the flare–CME analysis in a way that is uniquely unbiased. Past studies of a similar nature are discussed and a criticism of their approach is given. In particular, the author believes that the continual bias toward the so-called Long Duration Events and the brightest flares is misleading. The analysis supports the view that the flare and CME are signatures of the same magnetic "disease", that is, they represent the responses in different parts of the magnetic structure, to a particular activity; they do not drive one another but are closely related. The present statistical analysis allows a chance association to be given for a mass ejection event when an X-ray flare is observed. The use of such information in the prediction of geomagnetic activity generated when mass ejecta interact with the Earth is discussed.

### **Recurrent Coronal Mass Ejections and Their Geomagnetic Storms Association on 2012**

#### **January 19: Solar Surface to Upper Earth's Atmosphere Analyses**

A. **Hassanin**<sup>1</sup>, Amira Shimeis<sup>2</sup>, Hadeer F. Sabeha<sup>1</sup>, and F. N. Minta<sup>3</sup>

**2024** ApJ 974 301

<https://iopscience.iop.org/article/10.3847/1538-4357/ad77d4/pdf>

In this study, we have conducted an analysis of space weather disruptions that occurred on **19 January 2012**. Our analysis identified three coronal mass ejections (CMEs), CME1, CME2, and CME3—which were ejected at 09:48:05 universal time (UT), 14:36:05 UT, and 16:12:06 UT, respectively. Nonrecurrent disturbances in space weather, such as geomagnetic storms, result from CMEs originating from the Sun and traveling toward Earth. We assess the contribution of CME–CME interactions on 2012 January 19 and the volume emission rate of nitric oxide (NO) near the Earth's upper atmosphere in prolonging the geomagnetic disturbances observed on 2012 January 23. The findings suggest an increase in intensity at the interacting boundaries of CME1 and CME2, indicating an increase in pressure and density, leading to the compression of the magnetosphere. The 3D reconstructions of the CMEs provide evidence of unequal expansion and rotations within coronagraphic frames attributed to structural variability in the background solar wind during the eruptions. Furthermore, highlights from the in situ observations suggest that the impact of the recurrent CMEs on the geomagnetic disturbance was more pronounced within the auroral region synchronizing with a significant increase in NO volume emission rate on 2012 January 23, near the upper Earth's atmosphere. Our

focus is on exploring the interactions between these CMEs to understand their potential contribution to the extended duration of the observed geomagnetic disturbance.

## **A Model of Homologous Confined and Ejective Eruptions Involving Kink Instability and Flux Cancellation**

Alshaimaa **Hassanin**<sup>1</sup>, Bernhard Kliem<sup>2</sup>, Norbert Seehafer<sup>2</sup>, and Tibor Török<sup>3</sup>

2022 ApJL 929 L23

<https://iopscience.iop.org/article/10.3847/2041-8213/ac64a9/pdf>

<https://arxiv.org/pdf/2204.11767>

In this study, we model a sequence of a confined and a full eruption, employing the relaxed end state of the confined eruption of a kink-unstable flux rope as the initial condition for the ejective one. The full eruption, a model of a coronal mass ejection, develops as a result of converging motions imposed at the photospheric boundary, which drive flux cancellation. In this process, parts of the positive and negative external flux converge toward the polarity inversion line, reconnect, and cancel each other. Flux of the same amount as the canceled flux transfers to a flux rope, increasing the free magnetic energy of the coronal field. With sustained flux cancellation and the associated progressive weakening of the magnetic tension of the overlying flux, we find that a flux reduction of  $\approx 11\%$  initiates the torus instability of the flux rope, which leads to a full eruption. These results demonstrate that a homologous full eruption, following a confined one, can be driven by flux cancellation.

## **Helical Kink Instability in the confined Solar Eruption on 2002 May 27**

Alshaimaa **Hassanin**, Bernhard Kliem, Norbert Seehafer

Astron. Nachr. (Astron. News; AN) 337, 1082, 2016

<https://arxiv.org/pdf/1611.01008v1.pdf>

This paper presents an improved MHD modeling of the confined filament eruption in solar active region NOAA-9957 on **2002 May-27** by extending the parametric studies of the event in Torok & Kliem 2005 and Hassanin & Kliem 2016. Here the initial flux rope equilibrium is chosen to possess a small apex height identical to the observed initial filament height, which implies a more realistic inclusion of the photospheric line tying. The model matches the observations as closely as in the preceding studies, with the closest agreement again being obtained for an initial average flux rope twist of about  $4\pi$ . Thus, the model for strongly writhing confined solar eruptions, which assumes that a kink-unstable flux rope in the stability domain of the torus instability exists at the onset of the eruption's main acceleration phase, is further substantiated.

## **Helical Kink Instability in a Confined Solar Eruption**

Alshaimaa **Hassanin**, Bernhard Kliem

ApJ 832 106 2016

<http://arxiv.org/pdf/1609.00673v1.pdf>

A model for strongly writhing confined solar eruptions suggests an origin in the helical kink instability of a coronal flux rope which remains stable against the torus instability. This model is tested against the well observed filament eruption on **2002 May 27** in a parametric MHD simulation study which comprises all phases of the event. Good agreement with the essential observed properties is obtained. These include the confinement, terminal height, writhing, distortion, and dissolution of the filament, and the flare loops. The agreement is robust against variations in a representative range of parameter space. Careful comparisons with the observation data constrain the ratio of the external toroidal and poloidal field components to  $B_{\theta}/B_{\phi} \approx 1$  and the initial flux rope twist to  $\Phi \approx 4\pi$ . Different from ejective eruptions, two distinct phases of strong magnetic reconnection can occur. First, the erupting flux is cut by reconnection with overlying flux in the helical current sheet formed by the instability. If the resulting flux bundles are linked as a consequence of the erupting rope's strong writhing, they subsequently reconnect in the vertical current sheet between them. This reforms the overlying flux and a far less twisted flux rope, offering a pathway to homologous eruptions.

## **Reverse Current Model for Coronal Mass Ejection Cavity Formation**

Magnus A. **Haw**<sup>1</sup>, Pakorn Wongwaitayakornkul<sup>1</sup>, Hui Li<sup>2</sup>, and Paul M. Bellan<sup>1</sup>

2018 ApJL 862 L15

<http://sci-hub.tw/http://iopscience.iop.org/article/10.3847/2041-8213/aad33c/meta>

We report here a new model for explaining the three-part structure of coronal mass ejections (CMEs). The model proposes that the cavity in a CME forms because a rising electric current in the core prominence induces an oppositely directed electric current in the background plasma; this eddy current is required to satisfy the frozen-in magnetic flux condition in the background plasma. The magnetic force between the inner-core electric current and the oppositely directed induced eddy current propels the background plasma away from the core, creating a cavity and a density pileup at the cavity edge. The cavity radius saturates when an inward restoring force from magnetic and hydrodynamic pressure in the region outside the cavity edge balances the outward magnetic force. The model is supported by (i) laboratory experiments showing the development of a cavity as a result of the repulsion of an induced reverse current by a rising inner-core flux-rope current, (ii) 3D numerical magnetohydrodynamic (MHD) simulations that reproduce the laboratory experiments in quantitative detail, and (iii) an analytic model that describes cavity formation as a result of the plasma containing the induced reverse current being repelled from the inner core. This analytic model has broad

applicability because the predicted cavity widths are relatively independent of both the current injection mechanism and the injection timescale. **2011 October 4**

## **MHD simulations of the global solar corona around the Halloween event in 2003 using the synchronic frame format of the solar photospheric magnetic field**

Keiji [Hayashi](#), Xue Pu Zhao, Yang Liu

JOURNAL OF GEOPHYSICAL RESEARCH, VOL. 113, A07104, doi:10.1029/2007JA012814, **2008**

<http://dx.doi.org/10.1029/2007JA012814>

We performed two time-relaxation magnetohydrodynamics (MHD) simulations of the solar corona: one uses the boundary map representing the solar surface magnetic field distribution before the **Halloween event in 2003**, and the other uses map representing the postevent distribution. The aims of this study are to test a new concept of a solar surface magnetic field map capable of representing a particular time of interest and to examine the coronal responses to the solar photospheric magnetic field changes occurring over a few days. We used a new mapping scheme named “synchronic frame” that can include the longitudinal shift caused by the solar differential rotation and the solar surface variations occurring at the time of interest. These two time-relaxation MHD simulations using the two maps are separately performed to numerically obtain the quasi steady states of the solar corona before and after the Halloween event. Comparisons of the simulated coronal magnetic field structures to the SOHO/EIT measurements show that the combinations of our mapping method and simulation model reproduce the changes of the coronal structures well. We also find that the consequences of solar surface variations can be seen in the plasma quantities in the solar corona. These results show the capability and importance of the solar surface magnetic field mapping scheme for better reconstruction of global coronal structures, parts of which are sensitive to the solar surface magnetic field variations.

## **High-Energy Insights from an Escaping Coronal Mass Ejection with Solar Orbiter/STIX Observations**

[Laura A. Hayes](#), [Säm Krucker](#), [Hannah Collier](#), [Daniel Ryan](#)

A&A 691, A190 **2024**

<https://arxiv.org/pdf/2408.14194>

<https://www.aanda.org/articles/aa/pdf/2024/11/aa50882-24.pdf>

Solar eruptive events, including solar flares and coronal mass ejections (CMEs), are typically characterised by energetically significant X-ray emissions from flare-accelerated electrons and hot thermal plasmas. Occulted events, where the main flare is blocked by the solar limb, provide an opportunity to observe and analyse the X-ray emissions specifically associated with CMEs. This study investigates the X-ray and extreme ultraviolet (EUV) emissions associated with a large filament eruption and CME that occurred on **February 15, 2022**. This event was highly occulted from the three vantage points of Solar Orbiter, STEREO-A, and Earth. We utilised X-ray observations from the Spectrometer/Telescope for Imaging X-rays (STIX) and EUV observations from the Full Sun Imager (FSI) of the Extreme Ultraviolet Imager (EUI) on-board Solar Orbiter, supplemented by multi-viewpoint observations from STEREO-A/EUVI. This enabled a comprehensive analysis of the X-ray emissions in relation to the filament structure observed in EUV. We used STIX's imaging and spectroscopy capabilities to characterise the X-ray source associated with the eruption. Our analysis reveals that the X-ray emissions associated with the occulted eruption originated from an altitude exceeding 0.3R<sub>sun</sub> above the main flare site. The X-ray time-profile showed a sharp increase and exponential decay, and consisted of both a hot thermal component at 17 MK and non-thermal emissions (>11.4 keV) characterised by an electron spectral index of 3.9. Imaging analysis showed an extended X-ray source that coincided with the EUV emission as observed from EUI, and was imaged until the source grew to a size larger than the imaging limit of STIX (180 arcsec). The findings demonstrate that STIX combined with EUI provides a unique and powerful tool for examining the energetic properties of the CME component of solar energetic eruptions.

## **Quantitative Characterization of Magnetic Flux Rope Properties for Two Solar Eruption Events**

[Wen He](#), [Qiang Hu](#), [Chaowei Jiang](#), [Jiong Qiu](#), [Avijeet Prasad](#)

ApJ 934 103 **2022**

<https://arxiv.org/pdf/2201.03149.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac78df/pdf>

In order to bridge the gap between heliospheric and solar observations of coronal mass ejections (CMEs), one of the key steps is to improve the understanding of their corresponding magnetic structures like the magnetic flux ropes (MFRs). But it remains a challenge to confirm the existence of a coherent MFR before or upon the CME eruption on the Sun and to quantitatively characterize the CME-MFR due to the lack of direct magnetic field measurement in the corona. In this study, we investigate the MFR structures, originating from two active regions (ARs), AR 11719 and AR 12158, and estimate their magnetic properties quantitatively. We perform the nonlinear force-free field extrapolations with preprocessed photospheric vector magnetograms. In addition, remote-sensing observations are employed to find indirect evidence of MFRs on the Sun and to analyze the time evolution of magnetic reconnection flux associated with the flare ribbons during the eruption. A coherent “pre-existing” MFR structure prior to the flare eruption is identified quantitatively for one event from the combined analysis of the extrapolation and observation. Then the characteristics of MFRs for two events on the Sun before and during the eruption, forming the CME-MFR, including the axial magnetic flux, field-line twist, and reconnection flux, are estimated and compared with the corresponding in situ modeling

results. We find that the magnetic reconnection associated with the accompanying flares for both events injects significant amount of flux into the erupted CME-MFRs. **2013 April 11, 2014 September 10**

### **Electric Currents through J-shaped and Non-J-shaped Flare Ribbons**

[Yuwei He](#), [Rui Liu](#), [Lijuan Liu](#), [Jun Chen](#), [Wensi Wang](#), [Yuming Wang](#)

ApJ **2020**

<https://arxiv.org/pdf/2007.05693.pdf>

Recently solar flares exhibiting a double J-shaped ribbons in the lower solar atmosphere have been paid increasing attention in the context of extending the two-dimensional standard flare model to three dimensions, as motivated by the spatial correlation between photospheric current channels and flare ribbons. Here we study the electric currents through the photospheric area swept by flare ribbons (termed synthesized ribbon area or SRA), with a sample of 71 two-ribbon flares, of which 36 are J-shaped. Electric currents flowing through one ribbon are highly correlated with those through the other, therefore belonging to the same current system. The non-neutrality factor of this current system is independent of the flare magnitude, implying that both direct and return currents participate in flares. J-shaped flares are distinct from non-J-shaped flares in the following aspects: 1) Electric current densities within J-shaped SRA are significantly smaller than those within non-J-shaped SRA, but J-shaped SRA and its associated magnetic flux are also significantly larger. 2) Electric currents through SRA are positively correlated with the flare magnitude, but J-shaped flares show stronger correlation than non-J-shaped flares. 3) The majority (75%) of J-shaped flares are eruptive, while the majority (86%) of non-J-shaped flares are confined; accordingly, hosting active regions of J-shaped flares are more likely to be sigmoidal than non-J-shaped flares. Thus, J-shaped flares constitute a distinct subset of two-ribbon flares, probably the representative of eruptive ones. Further, we found that combining SRA and its associated magnetic flux has the potential to differentiate eruptive from confined flares. **2013 April 12, 2013 August 12**

### **Data-driven MHD Simulation of the Formation and Initiation of a Large-scale Pre-flare Magnetic Flux Rope in Solar Active Region 12371**

Wen [He](#), [Chaowei Jiang](#), [Peng Zou](#), [Aiyang Duan](#), [Xueshang Feng](#), [Pingbing Zuo](#), [Yi Wang](#)

ApJ **892 9 2020**

<https://arxiv.org/pdf/2002.04837.pdf>

Solar eruptions are the most powerful drivers of space weather. To understand their cause and nature, it is crucial to know how the coronal magnetic field evolves before eruption. Here we study the formation process of a relatively large-scale magnetic flux rope (MFR) in active region NOAA~12371 that erupts with a major flare and coronal mass ejection on **2015 June 21**. A data-driven numerical magnetohydrodynamic model is employed to simulate three-dimensional coronal magnetic field evolution of one-day duration before the eruption. Comparison between the observed features and our modeled magnetic field discloses how the pre-eruption MFR forms. Initially, the magnetic field lines were weakly twisted as being simple sheared arcades. Then a long MFR was formed along the polarity inversion line due to the complex photospheric motion, which is mainly shearing rather than twisting. The presence of the MFR is evidenced by a coherent set of magnetic field lines with twist number above unity. Below the MFR a current sheet is shown in the model, suggesting that tether-cutting reconnection plays a key role in the MFR formation. The MFR's flux grows as more and more field lines are twisted due to continuous injection of magnetic helicity by the photospheric motions. Meanwhile, the height of the MFR's axis increases monotonely from its formation. By an analysis of the decay index of its overlying field, we suggest that it is because the MFR runs into the torus instability regime and becomes unstable that finally triggers the eruption.

### **A Stealth CME Bracketed between Slow and Fast Wind Producing Unexpected Geoeffectiveness**

Wen [He](#), [Ying D.Liu](#), [Huidong Hu](#), [Rui Wang](#), [Xiaowei Zhao](#)

ApJ **860 78 2018**

<https://arxiv.org/pdf/1805.03128.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/aac381/pdf>

We investigate how a weak coronal mass ejection (CME) launched on **2016 October 8** without obvious signatures in the low corona produced a relatively intense geomagnetic storm. Remote sensing observations from SDO, STEREO and SOHO and in situ measurements from WIND are employed to track the CME from the Sun to the Earth. Using a graduated cylindrical shell (GCS) model, we estimate the propagation direction and the morphology of the CME near the Sun. CME kinematics are determined from the wide-angle imaging observations of STEREO A and are used to predict the CME arrival time and speed at the Earth. We compare ENLIL MHD simulation results with in situ measurements to illustrate the background solar wind where the CME was propagating. We also apply a Grad-Shafranov technique to reconstruct the flux rope structure from in situ measurements in order to understand the geoeffectiveness associated with the CME magnetic field structure. Key results are obtained concerning how a weak CME can generate a relatively intense geomagnetic storm: (1) there were coronal holes at low latitudes, which could produce high speed streams (HSSs) to interact with the CME in interplanetary space; (2) the CME was bracketed between a slow wind ahead and a HSS behind, which enhanced the southward magnetic field inside the CME and gave rise to the unexpected geomagnetic storm.

### **Tracking the Source of Solar Type II Bursts through Comparisons of Simulations and Radio Data**

[Alexander M. Hegedus](#) (1), [Ward B. Manchester IV](#) (1), [Justin C. Kasper](#) (1)

ApJ **2021**

<https://arxiv.org/pdf/2102.07875.pdf>

The most intense solar energetic particle events are produced by coronal mass ejections (CMEs) accompanied by intense type II radio bursts below 15 MHz. Understanding where these type II bursts are generated relative to an erupting CME would reveal important details of particle acceleration near the Sun, but the emission cannot be imaged on Earth due to distortion from its ionosphere. Here, a technique is introduced to identify the likely source location of the emission by comparing the observed dynamic spectrum observed from a single spacecraft against synthetic spectra made from hypothesized emitting regions within a magnetohydrodynamic (MHD) numerical simulation of the recreated CME. The radio-loud **2005 May 13** CME was chosen as a test case, with Wind/WAVES radio data used to frame the inverse problem of finding the most likely progression of burst locations. An MHD recreation is used to create synthetic spectra for various hypothesized burst locations. A framework is developed to score these synthetic spectra by their similarity to the type II frequency profile derived from Wind/WAVES data. Simulated areas with 4x enhanced entropy and elevated de Hoffmann Teller velocities are found to produce synthetic spectra similar to spacecraft observations. A geometrical analysis suggests that the eastern edge of the entropy derived shock around (-30, 0) degrees in heliocentric coordinates was emitting in the first hour of the event before ceasing emission, and that the western/southwestern edge of the shock centered around (6, -12) degrees was a dominant area of radio emission for the 2 hours of simulation data out to 20 solar radii. **2012-01-19**

<https://arxiv.org/pdf/1908.10161.pdf>

In a thorough study, we investigate the origin of a remarkable plasma and magnetic field configuration observed in situ on **June 22, 2011**, near L1, which appears to be a magnetic ejecta (ME) and a shock signature engulfed by a solar wind high-speed stream (HSS). We identify the signatures as an Earth-directed coronal mass ejection (CME), associated with a C7.7 flare on **June 21, 2011**, and its interaction with a HSS, which emanates from a coronal hole (CH) close to the launch site of the CME. The results indicate that the major interaction between the CME and the HSS starts at a height of 1.3  $R_{\odot}$  up to 3  $R_{\odot}$ . Over that distance range, the CME undergoes a strong north-eastward deflection of at least 30° due to the open magnetic field configuration of the CH. We perform a comprehensive analysis for the CME–HSS event using multi-viewpoint data (from the Solar TERrestrial RELations Observatories, the Solar and Heliospheric Observatory and the Solar Dynamics Observatory), and combined modeling efforts (nonlinear force-free field modeling, Graduated Cylindrical Shell CME modeling, and the Forecasting a CME’s Altered Trajectory – ForeCAT model). We aim at better understanding its early evolution and interaction process as well as its interplanetary propagation and related in situ signatures, and finally the resulting impact on the Earth’s magnetosphere.

### **Hot prominence detected in the core of a coronal mass ejection: Analysis of SOHO/UVCS $L\alpha$ and SOHO/LASCO visible-light observations**

P. [Heinzel](#)<sup>1,4</sup>, R. Susino<sup>2</sup>, S. Jejić<sup>3,1</sup>, A. Bemporad<sup>2</sup> and U. Anzer<sup>4</sup>

A&A 589, A128 (**2016**)

Context. The paper deals with the physics of erupting prominences in the core of coronal mass ejections (CME).

Aims. We determine the physical parameters of an erupting prominence embedded in the core of a CME using SOHO/UVCS hydrogen  $L\alpha$  and  $L\beta$  lines and SOHO/LASCO visible light observations. In particular we analyze the CME event observed on **August 2, 2000**. We develop the non-LTE (NLTE; i.e. considering departures from the local thermodynamic equilibrium – LTE) spectral diagnostics based on  $L\alpha$  and visible light observations.

Methods. Our method is based on 1D NLTE modeling of eruptive prominences and takes into account the effect of large flow velocities, which reach up to 300 km s<sup>-1</sup> for the studied event (the so-called Doppler dimming). The NLTE radiative-transfer method can be used for both optically thin and thick prominence structures. We combine spectroscopic UVCS observations of an erupting prominence in the core of a CME with visible light images from LASCO-C2 in order to derive the geometrical parameters like projected thickness and velocity, together with the effective temperature and column density of electrons. These are then used to constrain our NLTE radiative transfer modeling which provides the kinetic temperature, microturbulent velocity, gas pressure, ionization degree, the line opacities, and the prominence effective thickness (geometrical filling factor).

Results. Analysis was made for 69 observational points (spatial pixels) inside the whole erupting prominence. Roughly one-half of them show a non-negligible  $L\alpha$  optical thickness for flow velocity 300 km s<sup>-1</sup> and about one-third for flow velocity 150 km s<sup>-1</sup>. All pixels with  $L\alpha\tau_0 \leq 0.3$  have been considered for further analysis, which is presented in the form of statistical distributions (histograms) of various physical quantities such as the kinetic temperature, gas pressure, and electron density for two representative flow velocities (150 and 300 km s<sup>-1</sup>) and non-zero microturbulence. For two pixels co-temporal LASCO visible-light data are also available, which further constrains the diagnostics of the electron density and effective thickness. Detailed NLTE modeling is presented for various sets of input parameters.

Conclusions. The studied CME event shows that the erupting prominence expands to large volumes, meaning that it is a low-pressure structure with low electron densities and high temperatures. This analysis provides a basis for future diagnostics using the METIS coronagraph on board the Solar Orbiter mission.

## From Starspots to Stellar Coronal Mass Ejections—Revisiting Empirical Stellar Relations

Konstantin [Herbst](#)<sup>1</sup>, Athanasios Papaioannou<sup>2</sup>, Vladimir S. Airapetian<sup>3,4</sup>, and Dimitra Atri<sup>5</sup>

2021 ApJ 907 89

<https://doi.org/10.3847/1538-4357/abcc04>

Upcoming missions, including the James Webb Space Telescope, will soon characterize the atmospheres of terrestrial-type exoplanets in habitable zones around cool K- and M-type stars by searching for atmospheric biosignatures. Recent observations suggest that the ionizing radiation and particle environment from active cool planet hosts may be detrimental to exoplanetary habitability. Since no direct information on the radiation field is available, empirical relations between signatures of stellar activity, including the sizes and magnetic fields of starspots, are often used. Here, we revisit the empirical relation between the starspot size and the effective stellar temperature and evaluate its impact on estimates of stellar flare energies, coronal mass ejections, and fluxes of the associated stellar energetic particle events.

## Pre-eruption processes: heating, particle acceleration and the formation of a hot channel before the 2012 October 20 M9.0 limb flare

Aaron [Hernandez-Perez](#), [Yang Su](#), [Astrid M. Veronig](#), [Julia K. Thalmann](#), [Peter Gömöry](#), [Bhuwan Joshi](#)

ApJ 2019

<https://arxiv.org/pdf/1902.08436.pdf>

We report a detailed study of the pre-eruption activities that led to the occurrence of an M9.0 flare/CME event on **2012 October 20** in NOAA AR 11598. This includes the study of the preceding confined C2.4 flare that occurred on the same AR ~25 minutes earlier. We observed that the M9.0 flare occurred as a consequence of two distinct triggering events well separated in time. The first triggering episode occurred as early as ~20 minutes before the onset of the M9.0 flare, evidenced by the destabilization and rise of a pre-existing filament to a new position of equilibrium at a higher coronal altitude during the decay phase of the C2.4 flare. This brought the system to a magnetic configuration where the establishment of the second triggering event was favorable. The second triggering episode occurred ~17 minutes later, during the early phase of the M9.0 flare, evidenced by the further rise of the filament and successful ejection. The second trigger is followed by a flare precursor phase, characterized by non-thermal emission and the sequential formation of a hot channel as shown by the SDO/AIA DEM (differential emission measure) maps, the RHESSI X-ray images and spectra. These observations are suggestive of magnetic reconnection and particle acceleration that can explain the precursor phase and can be directly related to the formation of the hot channel. We discuss on the triggering mechanisms, their implications during the early and precursor phases and highlight the importance of early activities and preceding small confined flares to understand the initiation of large eruptive flares.

## SoloHI observations of coronal mass ejections observed by multiple spacecraft★

P. [Hess](#)<sup>1</sup>, R. C. Colaninno<sup>1</sup>, A. Vourlidis<sup>2</sup>, R. A. Howard<sup>2</sup> and G. Stenborg<sup>2</sup>

A&A 679, A149 (2023)

<https://www.aanda.org/articles/aa/pdf/2023/11/aa46907-23.pdf>

Context. The Solar Orbiter Heliospheric Imager (SoloHI) instrument of the Solar Orbiter mission is a next-generation heliospheric imager. New observations from SoloHI demonstrate the improved spatial and temporal resolution compared to previous observations of the heliosphere and corona. At perihelion, the field of view (FoV) of SoloHI covers the transition between the coronagraph (COR2) and heliospheric imager (HI1) Sun-Earth Connection Coronal and Heliospheric Investigation (SECCHI) suite. In this paper, we focus on an active solar period following the first Solar Orbiter science perihelion that resulted in a number of well-observed large coronal mass ejections (CMEs) in SoloHI data in **March and April 2022**. Specifically, we highlight a series of events produced by AR12795 between **28 March and 2 April** and show overlapping observations with SECCHI/COR2 and HI1 and LASCO/C3.

Aims. We compare the performance of the SoloHI instrument against similar observations from 1 au imagers. We describe CME observations, highlighting the unique structural features captured within the SoloHI FoV. These observations demonstrate that SoloHI will provide new insights into CME morphology and evolution from a unique vantage point.

Methods. To provide a direct and relevant comparison, images from all the telescopes we used in the paper are presented in FoVs common to each and with minimal processing applied. The J-maps we used to highlight outflowing features are also presented to show that the CME kinematics can be tracked through the SoloHI FoV, and also to report how the rest of the Heliophysics Systems Observatory (HSO) can be used to support the SoloHI data.

Results. The high-resolution SoloHI images of these eruptions, taken from ~0.3 au, reveal a number of detailed structural CME features, including internal cavities or cores of the CME flux rope(s). They also show the surrounding material and associated sheath region of the compressed upstream solar wind plasma. Many features that could not have been observed by other instruments are highlighted and discussed.

Conclusions. The SoloHI instrument is performing well and has already provided detailed observations of CMEs that can help us understand the details of the internal structure and magnetic field of CMEs. These new observations in combination with synoptic observations from 1 au offer new opportunities for CME propagation from the corona to the heliosphere.

## HIGH-RESOLUTION IMAGING OF CORONAL MASS EJECTIONS FROM SOLOHI

## WISPR Imaging of a Pristine CME

Phillip Hess, Alexis Rouillard, Athanasios Kouloumvakos, Paulett C. Liewer, Jie Zhang, Suman Dhakal, Guillermo Stenborg, Robin C. Colaninno, Russell A. Howard

ApJ 2019

<https://arxiv.org/pdf/1912.02255.pdf>

The Wide-field Imager for Solar Probe (WISPR) on board the Parker Solar Probe (PSP) observed a CME on **2018 November 01**, the first day of the initial PSP encounter. The speed of the CME, approximately 200-300 km s<sup>-1</sup> in the WISPR field of view, is typical of slow, streamer blowout CMEs. This event was also observed by the LASCO coronagraphs. WISPR and LASCO view remarkably similar structures that enable useful cross-comparison between the two data sets as well as stereoscopic imaging of the CME. Analysis is extended to lower heights by linking the white-light observations to EUV data from AIA, which reveal a structure that erupts more than a full day earlier before the CME finally gathers enough velocity to propagate outward. This EUV feature appears as a brightness enhancement in cooler temperatures such as 171 Å, but as a cavity in nominal coronal temperatures such as 193 Å. By comparing this circular, dark feature in 193 Å to the dark, white-light cavity at the center of the eruption in WISPR and LASCO, it can be seen that this is one coherent structure that exists prior to the eruption in the low corona before entering the heliosphere and likely corresponds to the core of the magnetic flux rope. It is also believed that the relative weakness of the event contributed to the clarity of the flux rope in WISPR, as the CME did not experience impulsive forces or strong interaction with external structures that can lead to more complex structural evolution.

## Inflows in the Inner White-light Corona: The Closing-down of Flux after Coronal Mass Ejections

P. Hess and Y.-M. Wang

2017 ApJ 850 6

<http://sci-hub.cc/10.3847/1538-4357/aa921d>

During times of high solar activity, the Solar and Heliospheric Observatory/Large Angle and Spectrometric Coronagraph C2 coronagraph has recorded multitudes of small features moving inward through its 2–6 R<sub>☉</sub> field of view. These outer-coronal inflows, which are concentrated around the heliospheric current sheet, tend to be poorly correlated with individual coronal mass ejection (CME) events. Using running-difference movies constructed from Solar Terrestrial Relations Observatory/COR1 coronagraph images taken during 2008–2014, we have identified large numbers of inward-moving features at heliocentric distances below 2 R<sub>☉</sub>, with the rate increasing with sunspot and CME activity. Most of these inner-coronal inflows are closely associated with CMEs, being observed during and in the days immediately following the eruptions. Here, we describe several examples of the pinching-off of tapered streamer structures in the wake of CMEs. This type of inflow event is characterized by a separation of the flow into incoming and outgoing components connected by a thin spike, which is interpreted as a continually elongating current sheet viewed edge-on; by the prior convergence of narrow rays toward the current sheet; and by a succession of collapsing loops that form a cusp-shaped structure at the base of the current sheet. The re-forming streamer overlies a growing post-eruption arcade that is visible in EUV images. These observations provide support for standard reconnection models for the formation/evolution of flux ropes during solar eruptive events. We suggest that inflow streams that occur over a relatively wide range of position angles result from the pinching-off of loop arcades whose axes are oriented parallel rather than perpendicular to the sky plane. **28 Feb 2010, 2011 March 1–2, 2011 Apr 7–10, 2012 June 2, 2013 February 14–15, 2013 May 23–24, 2013 July 1–2**

## A Study of the Earth-Affecting CMEs of Solar Cycle 24

Phillip Hess, Jie Zhang

[Solar Physics](#) June 2017, 292:80 **File**

Using in situ observations from the Advanced Composition Explorer (ACE), we have identified 70 Earth-affecting interplanetary coronal mass ejections (ICMEs) in Solar Cycle 24. Because of the unprecedented extent of heliospheric observations in Cycle 24 that has been achieved thanks to the Sun Earth Connection Coronal and Heliospheric Investigation (SECCHI) instruments onboard the Solar Terrestrial Relations Observatory (STEREO), we observe these events throughout the heliosphere from the Sun to the Earth, and we can relate these in situ signatures to remote sensing data. This allows us to completely track the event back to the source of the eruption in the low corona. We present a summary of the Earth-affecting CMEs in Solar Cycle 24 and a statistical study of the properties of these events including the source region. We examine the characteristics of CMEs that are more likely to be strongly geoeffective and examine the effect of the flare strength on in situ properties. We find that Earth-affecting CMEs in the first half of Cycle 24 are more likely to come from the northern hemisphere, but after April 2012, this reverses, and these events are more likely to originate in the southern hemisphere, following the observed magnetic asymmetry in the two

hemispheres. We also find that as in past solar cycles, CMEs from the western hemisphere are more likely to reach Earth. We find that Cycle 24 lacks in events driving extreme geomagnetic storms compared to past solar cycles. **Table 1** The catalog of Earth-affecting ICME events from 2007 to 2015.

## Comparing Automatic CME Detections in Multiple LASCO and SECCHI Catalogs

Phillip [Hess](#)<sup>1</sup> and Robin C. Colaninno

2017 ApJ 836 134

<http://iopscience.iop.org/sci-hub.cc/0004-637X/836/1/134/>

With the creation of numerous automatic detection algorithms, a number of different catalogs of coronal mass ejections (CMEs) spanning the entirety of the Solar and Heliospheric Observatory (SOHO) Large Angle Spectrometric Coronagraph (LASCO) mission have been created. Some of these catalogs have been further expanded for use on data from the Solar Terrestrial Earth Observatory (STEREO) Sun Earth Connection Coronal and Heliospheric Investigation (SECCHI) as well. We compare the results from different automatic detection catalogs (Solar Eruption Event Detection System (SEEDS), Computer Aided CME Tracking (CACTus), and Coronal Image Processing (CORIMP)) to ensure the consistency of detections in each. Over the entire span of the LASCO catalogs, the automatic catalogs are well correlated with one another, to a level greater than 0.88. Focusing on just periods of higher activity, these correlations remain above 0.7. We establish the difficulty in comparing detections over the course of LASCO observations due to the change in the instrument image cadence in 2010. Without adjusting catalogs for the cadence, CME detection rates show a large spike in cycle 24, despite a notable drop in other indices of solar activity. The output from SEEDS, using a consistent image cadence, shows that the CME rate has not significantly changed relative to sunspot number in cycle 24. These data, and mass calculations from CORIMP, lead us to conclude that any apparent increase in CME rate is a result of the change in cadence. We study detection characteristics of CMEs, discussing potential physical changes in events between cycles 23 and 24. We establish that, for detected CMEs, physical parameters can also be sensitive to the cadence.

## The 17 January 2005 Complex Solar Radio Event Associated with Interacting Fast Coronal Mass Ejections

A. [Hillar](#), O. Malandraki, K.-L. Klein, P. Preka-Papadema, X. Moussas, C. Bouratzis, E. Mitsakou, P. Tsitsipis and A. Kontogeorgos

Solar Physics, Volume 273, Number 2, 493-509, 2011

<http://arxiv.org/pdf/1101.5759v7.pdf>

On 17 January 2005 two fast coronal mass ejections were recorded in close succession during two distinct episodes of a 3B/X3.8 flare. Both were accompanied by metre-to-kilometre type-III groups tracing energetic electrons that escape into the interplanetary space and by decametre-to-hectometre type-II bursts attributed to CME-driven shock waves. A peculiar type-III burst group was observed below 600 kHz 1.5 hours after the second type-III group. It occurred without any simultaneous activity at higher frequencies, around the time when the two CMEs were expected to interact. We associate this emission with the interaction of the CMEs at heliocentric distances of about 25 R<sub>☉</sub>. <sup>Relative</sup> Relativistic electrons observed by the EPAM experiment onboard ACE near 1 AU revealed successive particle releases that can be associated with the two flare/CME events and the low-frequency type-III burst at the time of CME interaction. We compare the pros and cons of shock acceleration and acceleration in the course of magnetic reconnection for the escaping electron beams revealed by the type-III bursts and for the electrons measured in situ.

## Solar flares with and without SOHO/LASCO coronal mass ejections and type II shocks

[Hillar](#), A.; Petousis, V.; Mitsakou, E.; Vassiliou, C.; Moussas, X.; Polygiannakis, J.; Preka-Papadema, P.; Caroubalos, C.; Alissandrakis, C.; Tsitsipis, P.; Kontogeorgos, A.; Bougeret, J.-L.; Dumas, G.

Advances in Space Research, Volume 38, Issue 5, p. 1007-1010, 2006.

<http://arxiv.org/pdf/1009.3636v1.pdf>

We analyse of a set of radio rich (accompanied by type IV or II bursts) solar flares and their association with SOHO/LASCO Coronal Mass Ejections in the period 1998-2000. The intensity, impulsiveness and energetics of these events are investigated. We find that, on the average, flares associated both with type II's and CMEs are more impulsive and more energetic than flares associated with type II's only (without CME reported), as well as flares accompanied by type IV continua but not type II shocks. From the last two classes, flares with type II bursts (without CMEs reported) are the shortest in duration and the most impulsive.

## Observation of bi-directional jets in a prominence

[Hillier](#), A. ; [Polito](#), V.

Astronomy & Astrophysics, Volume 651, id.A60, 10 pp. 2021

<https://www.aanda.org/articles/aa/pdf/2021/07/aa35774-19.pdf>

Quiescent prominences host a large range of flows, many driven by buoyancy, which lead to velocity shear. The presence of these shear flows could bend and stretch the magnetic field resulting in the formation of current sheets which can lead to magnetic reconnection. Though this has been hypothesised to occur in prominences, with some observations that are suggestive of this process, clear evidence has been lacking. In this paper we present observations performed on June 30, 2015 using the Interface Region Imaging Spectrograph Si IV and Mg II slit-jaw imagers of two

bi-directional jets that occur inside the body of the prominence. Such jets are highly consistent with what would be expected from magnetic reconnection theory. Using this observation, we estimate that the prominence under study has an ambient field strength in the range of 4.5–9.2 G with 'turbulent' field strengths of 1 G. Our results highlight the ability of gravity-driven flows to stretch and fold the magnetic field of the prominence, implying that locally, the quiescent prominence field can be far from a static, force-free magnetic field. ## On Kelvin-Helmholtz and parametric instabilities driven by coronal waves

Andrew Hillier, Adrian Barker, Inigo Arregui, Henrik Latter

MNRAS 2018

<https://arxiv.org/pdf/1810.02773.pdf>

The Kelvin-Helmholtz instability has been proposed as a mechanism to extract energy from magnetohydrodynamic (MHD) kink waves in flux tubes, and to drive dissipation of this wave energy through turbulence. It is therefore a potentially important process in heating the solar corona. However, it is unclear how the instability is influenced by the oscillatory shear flow associated with an MHD wave. We investigate the linear stability of a discontinuous oscillatory shear flow in the presence of a horizontal magnetic field within a Cartesian framework that captures the essential features of MHD oscillations in flux tubes. We derive a Mathieu equation for the Lagrangian displacement of the interface and analyse its properties, identifying two different instabilities: a Kelvin-Helmholtz instability and a parametric instability involving resonance between the oscillatory shear flow and two surface Alfvén waves. The latter occurs when the system is Kelvin-Helmholtz stable, thus favouring modes that vary along the flux tube, and as a consequence provides an important and additional mechanism to extract energy. When applied to flows with the characteristic properties of kink waves in the solar corona, both instabilities can grow, with the parametric instability capable of generating smaller scale disturbances along the magnetic field than possible via the Kelvin-Helmholtz instability. The characteristic time-scale for these instabilities is  $\sim 100$  s, for wavelengths of 200 km. The parametric instability is more likely to occur for smaller density contrasts and larger velocity shears, making its development more likely on coronal loops than on prominence threads.

## Analysis of signal to noise ratio in coronagraph observations of coronal mass ejections

Johannes Hinrichs, Jackie A. Davies, Matthew J. West, Volker Bothmer, Bram Bourgoignie, Chris J. Eyles, Philipp Huke, Piers Jiggins, Bogdan Nicula and James Tappin

J. Space Weather Space Clim. 2021, 11, 11

<https://doi.org/10.1051/swsc/2020070>

<https://www.swsc-journal.org/articles/swsc/pdf/2021/01/swsc200025.pdf>

We establish a baseline signal-to-noise ratio (SNR) requirement for the European Space Agency (ESA)-funded Solar Coronagraph for OPERations (SCOPE) instrument in its field of view of 2.5–30 solar radii based on existing observations by the Solar and Heliospheric Observatory (SOHO). Using automatic detection of coronal mass ejections (CMEs), we analyse the impacts when SNR deviates significantly from our previously established baseline. For our analysis, SNR values are estimated from observations made by the C3 coronagraph on the Solar and Heliospheric Observatory (SOHO) spacecraft for a number of different CMEs. Additionally, we generate a series of artificial coronagraph images, each consisting of a modelled coronal background and a CME, the latter simulated using the graduated cylindrical shell (GCS) model together with the SCRaytrace code available in the Interactive Data Language (IDL) SolarSoft library. Images are created with CME SNR levels between 0.5 and 10 at the outer edge of the field of view (FOV), generated by adding Poisson noise, and velocities between 700 km s<sup>-1</sup> and 2800 km s<sup>-1</sup>. The images are analysed for the detectability of the CME above the noise with the automatic CME detection tool CACTus. We find in the analysed C3 images that CMEs near the outer edge of the field of view are typically 2% of the total brightness and have an SNR between 1 and 4 at their leading edge. An SNR of 4 is defined as the baseline SNR for SCOPE. The automated detection of CMEs in our simulated images by CACTus succeeded well down to SNR = 1 and for CME velocities up to 1400 km s<sup>-1</sup>. At lower SNR and higher velocity of  $\geq 2100$  km s<sup>-1</sup> the detection started to break down. For SCOPE, the results from the two approaches confirm that the initial design goal of SNR = 4 would, if achieved, deliver a comparable performance to established data used in operations today, with a more compact instrument design, and a margin in SNR before existing automatic detection produces significant false positives. 2012-Jan-21, 25-27 Jan 2012, 2012-Jul-23

## Scientific considerations for future spectroscopic measurements from space of activity on the Sun

Review

Gordon D. Holman

JGR 2016

<http://sci-hub.cc/10.1002/2016JA022651>

High-resolution UV and X-ray spectroscopy are important to understanding the origin and evolution of magnetic energy release in the solar atmosphere, as well as the subsequent evolution of heated plasma and accelerated particles. Electromagnetic radiation is observed from plasma heated to temperatures ranging from about 10 kK to above 10 MK, from accelerated electrons emitting photons primarily at X-ray energies, and from ions emitting in  $\gamma$  rays. These observations require space-based instruments sensitive to emissions at wavelengths shorter than the near UV. This article reviews some recent observations with emphasis on solar eruptive events, the models that describe them, and the

measurements they indicate are needed for substantial progress in the future. Specific examples are discussed demonstrating that imaging spectroscopy with a cadence of seconds or better is needed to follow, understand, and predict the evolution of solar activity. Critical to substantial progress is the combination of a judicious choice of UV, EUV, and soft X-ray imaging spectroscopy sensitive to the evolution of this thermal plasma combined with hard X-ray imaging spectroscopy sensitive to suprathermal electrons. The major challenge will be to conceive instruments that, within the bounds of possible technologies and funding, have the flexibility and field of view to obtain spectroscopic observations where and when events occur while providing an optimum balance of dynamic range, spectral resolution and range, and spatial resolution.

## **Direct Spatial Association of an X-Ray Flare with the Eruption of a Solar Quiescent Filament**

Gordon D. **Holman** & Adi Foord

ApJ 804 108 **2015**

[http://hesperia.gsfc.nasa.gov/~kim/Holman\\_Foord\\_2015\\_quiescent\\_filament\\_flare.pdf](http://hesperia.gsfc.nasa.gov/~kim/Holman_Foord_2015_quiescent_filament_flare.pdf)

Solar flares primarily occur in active regions. Hard X-ray flares have been found to occur only in active regions. They are often associated with the eruption of active region filaments and coronal mass ejections (CMEs). CMEs can also be associated with the eruption of quiescent filaments, not located in active regions. Here we report the first identification of a solar X-ray flare outside an active region observed by the Ramaty High Energy Solar Spectroscopic Imager (RHESSI). The X-ray emission was directly associated with the eruption of a long, quiescent filament and fast CME. Images from RHESSI show this flare emission to be located along a section of the western ribbon of the expanding, post-eruption arcade. EUV images from the Solar Dynamics Observatory (SDO) Atmospheric Imaging Assembly (AIA) show no connection between this location and nearby active regions. Therefore the flare emission is found to not be located in or associated with an active region. However, a nearby, small, magnetically strong dipolar region provides a likely explanation for the existence and location of the flare X-ray emission. This emerging dipolar region may have also triggered the filament eruption. **September 29, 2013**

## **RHESSI Detection of X-ray Emission from a Quiet-Sun Filament Eruption**

Gordon **Holman** and Adi Foord

RHESSI Science Nugget No. 250, April **2015**

[http://sprg.ssl.berkeley.edu/~tohban/wiki/index.php/RHESSI\\_Science\\_Nuggets](http://sprg.ssl.berkeley.edu/~tohban/wiki/index.php/RHESSI_Science_Nuggets)

The event described in this Nugget reveals the presence of intense energy release even in the quiet Sun, in the form of an otherwise innocuous-looking quiescent filament. The power of the the CME that resulted, and its interplanetary development, do not have the same kind of associations with a solar flare as in an active-region event. Nevertheless high temperatures and non-thermal effects result, and hard X-ray observations such as those of RHESSI (or more sensitive ones) can diagnose them. **September 29, 2013**

## **Solar eruptive events**

**Review**

Gordon D. **Holman**

Physics Today 65, 4, 56 (**2012**);

<https://sci-hub.tw/10.1063/PT.3.1520>

It's long been known that the Sun plays host to the most energetic explosions in the solar system. But key insights into how they work have only recently become available

## **CME volume calculation from 3D GCS reconstruction**

Central European Astrophysical Bulletin (CEAB)

**2019**

<https://arxiv.org/pdf/1904.11418.pdf>

The mass evolution of a coronal mass ejection (CME) is an important parameter characterizing the drag force acting on a CME as it propagates through interplanetary space. Spacecraft measure in-situ plasma densities of CMEs during crossing events, but for investigating the mass evolution, we also need to know the CME geometry, more specific, its volume. Having derived the CME volume and mass from remote sensing data using 3D reconstructed CME geometry, we can calculate the CME density and compare it with in-situ proton density measurements near Earth. From that we may draw important conclusions on a possible mass increase as the CME interacts with the ambient solar wind in the heliosphere. In this paper we will describe in detail the method for deriving the CME volume using the graduated cylindrical shell (GCS) model (Thernisien et al., 2006,2009, see Figure 1). We show that, assuming self-similar expansion, one can derive the volume of the CME from two GCS parameters and that it furthermore can be expressed as a function of distance.

## **Magnetic Evolution of Mini-Coronal Mass Ejections**

L. **Honarbaksh**, N. Alipour, H. Safari

Solar Phys. Volume 291, **Issue 3**, pp 941-952 **2016**

The present study investigates the relationship between mini-coronal mass ejections (mini-CMEs) and the evolution of their magnetic fluxes. An automatic detection algorithm was used to detect mini-dimmings in 171 Å images taken with the Atmospheric Imaging Assembly (AIA) onboard the Solar Dynamics Observatory (SDO). Using the difference

images for the dimmings, 131 events that satisfied mini-CME signatures were selected. Changes in their magnetic structure using photospheric line-of-sight magnetograms taken with the Heliospheric and Magnetic Imager (HMI) on SDO were investigated. It was found that 27 % of the events had slight changes and 73 % showed considerable changes in magnetic flux. About 18 % of the magnetic structures evolved by cancellation and 38 % by complex flux changes.

### **Quasi-periodic microjets driven by granular advection as observed with high-resolution imaging at He I 10830 Å**

[Zhenxiang Hong](#), [Ya Wang](#), [Haisheng Ji](#)

ApJ *ApJ* **928** 2022

<https://arxiv.org/pdf/2201.12837.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac590c/pdf>

With high-resolution narrowband He I 10830 Å filtergrams from GST, we give an extensive analysis for 4 granular sized microeruptions which appear as the gentle ejection of material in He I 10830 Å band. The analysis was aided with the EUV data from AIA and line-of-sight magnetograms from HMI on board SDO. The microeruptions are situated on magnetic polarity inversion lines (PILs), and their roots are accurately traced down to intergranular lanes. Their durations are different, two microeruptions are repetitive microjets, lasting ~ 50 and 27 minutes respectively, while the other two events are singular, lasting ~ 5 minutes. For the two microjets, they are continuous and recurrent in He I 10830 Å band, and the recurrence is quasi-periodic with the period of ~ 5 minutes. We found that only transient co-spatial EUV brightenings are observed for the longer duration microjets and EUV brightenings are absent for the two singular microeruptions. What is essential to the longer duration microjets is that granules with the concentration of positive magnetic field persistently transport the magnetic field to the PILs, canceling the opposite magnetic flux and making the base of the two microjets and the underlying granules migrate with the speed of ~ 0.25 and 1.0 km/s. The observations support the scenario of magnetic reconnection for the quasi-periodic microjets and further show that the reconnection continuously generates multi-temperature components, especially the cool component with chromospheric temperature. In addition, the ongoing reconnection is modulated by p-mode oscillations inside the Sun. **July 22, 2011**

### **Observation of a reversal of breakout reconnection preceding a jet: evidence of oscillatory magnetic reconnection?**

Junchao [Hong](#), [Jiayan Yang](#), [Huadong Chen](#), [Yi Bi](#), [Bo Yang](#), [Hechao Chen](#)

ApJ **874** 146 2019

<https://arxiv.org/pdf/1903.01201.pdf>

[sci-hub.se/10.3847/1538-4357/ab0c9d](https://sci-hub.se/10.3847/1538-4357/ab0c9d)

Recent studies have revealed that solar jets involving minifilament eruptions may be initiated under the well-known magnetic-breakout mechanism. Before or just at the onset of those jets, there should be a current sheet, where breakout magnetic reconnection takes place, between open fields and the outside of the jet-base arcade carrying minifilament in its core. In this paper we present a jet produced by eruption of two minifilaments lying at the jet base. A current sheet is directly detected near the jet base before the onset of the eruption, suggesting the magnetic-breakout mechanism. However, we further find that the current sheet undergoes a transition. The current sheet first shortens to zero in length, but then lengthens towards an orthogonal direction relative to its initial orientation. The change of the current sheet gives rise to a reversal of the breakout reconnection, as the inflow and outflow regions before the transition become the outflow and inflow regions after the transition, respectively. We therefore propose that this observation provides evidence for the so-called oscillatory reconnection which is defined by a series of reconnection reversals but not yet proved to exist in real plasma environment of the solar atmosphere. **2014 November 16**

### **MINIFILAMENT ERUPTION AS THE SOURCE OF A BLOWOUT JET, C-CLASS FLARE, AND TYPE-III RADIO BURST**

Junchao [Hong](#), Yunchun Jiang, Jiayan Yang, Haidong Li1, and Zhe Xu1

2017 ApJ 835 35

<http://sci-hub.cc/doi/10.3847/1538-4357/835/1/35>

We report a strong minifilament eruption associated with Geostationary Operational Environmental Satellite C1.6 flare and WIND type-III radio burst. The minifilament, which lies at the periphery of active region 12259, is detected by Ha images from the New Vacuum Solar Telescope. The minifilament undergoes a partial and then a full eruption. Simultaneously, two co-spatial jets are successively observed in extreme ultraviolet images from the Solar Dynamic Observatory. The first jet exhibits a typical fan-spine geometry, suggesting that the co-spatial minifilament is possibly embedded in magnetic fields with a fan-spine structure. However, the second jet displays blowout morphology when the entire minifilament erupts upward, leaving behind a hard X-ray emission source in the base. Differential emission measure analyses show that the eruptive region is heated up to about 4 MK during the fan-spine jet, while up to about 7 MK during the blowout jet. In particular, the blowout jet is accompanied by an interplanetary type-III radio burst observed by WIND/WAVES in the frequency range from above 10 to 0.1 MHz. Hence, the minifilament eruption is correlated with the interplanetary type-III radio burst for the first time. These results not only suggest that coronal jets can result from magnetic reconnection initiated by erupting minifilaments with open fields, but also shed light on the potential influence of minifilament eruption on interplanetary space. **2015 January 14,**

## **MINI-FILAMENT ERUPTION AS THE INITIATION OF A JET ALONG CORONAL LOOPS**

Junchao [Hong](#), Yunchun Jiang, Jiayan Yang, Bo Yang<sup>1</sup>, Zhe Xu<sup>1</sup>, and Yongyuan Xiang

2016 ApJ 830 60

Minifilament eruptions (MFEs) and coronal jets are different types of solar small-scale explosive events. We report an MFE observed at the New Vacuum Solar Telescope (NVST). As seen in the NVST H $\alpha$  images, during the rising phase, the minifilament erupts outward orthogonally to its length, accompanied with a flare-like brightening at the bottom. Afterward, dark materials are found to possibly extend along the axis of the expanded filament body. The MFE is analogous to large filament eruptions. However, a simultaneous observation of the Solar Dynamics Observatory shows that a jet is initiated and flows out along nearby coronal loops during the rising phase of the MFE. Meanwhile, small hot loops, which connect the original eruptive site of the minifilament to the footpoints of the coronal loops, are formed successively. A differential emission measure analysis demonstrates that, on the top of the new small loops, a hot cusp structure exists. We conjecture that the magnetic fields of the MFE interact with magnetic fields of the coronal loops. This interaction is interpreted as magnetic reconnection that produces the jet and the small hot loops.

## **Coronal Bright Points Associated with Minifilament Eruptions**

Junchao [Hong](#), Yunchun Jiang, Jiayan Yang, Yi Bi, Haidong Li, Bo Yang<sup>1</sup>, and Dan Yang

2014 ApJ 796 73

Coronal bright points (CBPs) are small-scale, long-lived coronal brightenings that always correspond to photospheric network magnetic features of opposite polarity. In this paper, we subjectively adopt 30 CBPs in a coronal hole to study their eruptive behavior using data from the Atmospheric Imaging Assembly (AIA) and the Helioseismic and Magnetic Imager (HMI) on board the Solar Dynamics Observatory. About one-quarter to one-third of the CBPs in the coronal hole go through one or more minifilament eruption(s) (MFE(s)) throughout their lifetimes. The MFEs occur in temporal association with the brightness maxima of CBPs and possibly result from the convergence and cancellation of underlying magnetic dipoles. Two examples of CBPs with MFEs are analyzed in detail, where minifilaments appear as dark features of a cool channel that divide the CBPs along the neutral lines of the dipoles beneath. The MFEs show the typical rising movements of filaments and mass ejections with brightenings at CBPs, similar to large-scale filament eruptions. Via differential emission measure analysis, it is found that CBPs are heated dramatically by their MFEs and the ejected plasmas in the MFEs have average temperatures close to the pre-eruption BP plasmas and electron densities typically near 10<sup>9</sup> cm<sup>-3</sup>. These new observational results indicate that CBPs are more complex in dynamical evolution and magnetic structure than previously thought.

## **A MICRO CORONAL MASS EJECTION ASSOCIATED BLOWOUT EXTREME-ULTRAVIOLET JET**

Junchao [Hong](#), Yunchun Jiang, Ruisheng Zheng, Jiayan Yang, Yi Bi and Bo Yang

2011 ApJ 738 L20, [File?](#)

The so-called mini coronal mass ejections (CMEs) were recently identified as small-scale eruptive events showing the same on-disk characteristics as large-scale CMEs, and Moore et al. further found that one-third of polar X-ray jets are the so-called blowout jets, in which the jet-base magnetic arch, often carrying a filament, undergoes a miniature version of the blowout eruptions that produce major CMEs. By means of the two viewpoint observations from the Solar Dynamics Observatory (SDO) and the Ahead of Solar Terrestrial Relations Observatory (STEREO A), in this Letter, we present the first observations that a blowout jet from the eruption of an EUV mini-filament channel in the quiet Sun was indeed associated with a real micro-CME. Captured by the on-disk SDO observations, the whole life of the mini-filament channel, from the formation to eruption, was associated with convergences and cancellations of opposite-polarity magnetic flux in the photosphere, and its eruption was accompanied by a small flare-like brightening, a small corona dimming, and posteruptive loops. The near-limb counterpart of the eruption observed by STEREO A, however, showed up as a small EUV jet followed by a white-light jet. These observations not only confirm the previous results that mini-filaments have characteristics common to large-scale ones, but also give clear evidences that blowout jets can result from the eruptions of mini-filaments and are associated with mini-CME.

## **Short, large-amplitude speed enhancements in the near-Sunfast solar wind**

[T S Horbury](#) [L Matteini](#) [D Stansby](#)

MNRoyal Astronomical Society, Volume 478, Issue 2, 1 August 2018, Pages 1980–1986

<https://doi.org/10.1093/mnras/sty953>

[sci-hub.tw/10.1093/mnras/sty953](http://sci-hub.tw/10.1093/mnras/sty953)

We report the presence of intermittent, short discrete enhancements in plasma speed in the near-Sun high-speed solar wind. Lasting tens of seconds to minutes in spacecraft measurements at 0.3 au, speeds inside these enhancements can reach 1000 km s<sup>-1</sup>, corresponding to a kinetic energy up to twice that of the bulk high-speed solar wind. These events, which occur around 5 per cent of the time, are Alfvénic in nature with large magnetic field deflections and are the same temperature as the surrounding plasma, in contrast to the bulk fast wind which has a well-established positive speed–temperature correlation. The origin of these speed enhancements is unclear but they may be signatures of discrete jets associated with transient events in the chromosphere or corona. Such large short velocity changes represent a measurement and analysis challenge for the upcoming Parker Solar Probe and Solar Orbiter missions.

## **Generation of twist on magnetic flux tubes at the base of the solar convection zone**

H. [Hotta](#) and T. Yokoyama

A&A 548, A74 (2012)

Using two-dimensional magnetohydrodynamics calculations, we investigate a twist generation mechanism on a magnetic flux tube at the base of the solar convection zone based on the idea of Choudhuri (2003, Sol. Phys., 215, 31) in which a toroidal magnetic field is wrapped by a surrounding mean poloidal field. During generation of the twist, the flux tube follows four phases. (1) It quickly splits into two parts with vortex motions rolling up the poloidal magnetic field. (2) Owing to the physical mechanism similar to that of the magneto-rotational instability, the rolled-up poloidal field is bent and amplified. (3) The magnetic tension of the disturbed poloidal magnetic field reduces the vorticity, and the lifting force caused by vortical motion decreases. (4) The flux tube gets twisted and begins to rise again without splitting. Investigation of these processes is significant because it shows that a flux tube without any initial twist can rise to the surface in relatively weak poloidal fields.

## Numerous Bidirectionally Propagating Plasma Blobs near the Reconnection Site of a Solar Eruption

<https://arxiv.org/pdf/2404.18092>

<https://www.aanda.org/articles/aa/pdf/2024/07/aa49765-24.pdf>

Current sheet is a common structure involved in solar eruptions. However, it is observed in minority of the events and the physical properties of its fine structures during a solar eruption are rarely investigated. Here, we report an on-disk observation that displays 108 compact, circular or elliptic bright structures, presumably plasma blobs, propagating bidirectionally along a flare current sheet during a period of  $\sim 24$  minutes. From extreme ultraviolet images, we have investigated the temporal variation of the blob number around the flare peak time. The current sheet connects the flare loops and the erupting filament. The width, duration, projected velocity, temperature, and density of these blobs are  $\sim 1.7 \pm 0.5$  Mm,  $\sim 79 \pm 57$  s,  $\sim 191 \pm 81$  km/s,  $\sim 106.4 \pm 0.1$  K, and  $\sim 1010.1 \pm 0.3$  cm $^{-3}$ , respectively. The reconnection site rises with a velocity of  $\leq 69$  km/s. The observational results suggest that plasmoid instability plays an important role in the energy release process of solar eruptions. **November 19, 2022**

## Partial Eruption of Solar Filaments. I. Configuration and Formation of Double-decker Filaments

[Yijun Hou](#), [Chuan Li](#), [Ting Li](#), [Jiangtao Su](#), [Ye Qiu](#), [Shuhong Yang](#), [Liheng Yang](#), + + +

ApJ 959 69 2023 as part of the Focus Issue "Early results from the Chinese Ha Solar Explorer (CHASE)"

<https://arxiv.org/pdf/2311.00456.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ad08bd/pdf>

Partial eruptions of solar filaments are the typical representative of solar eruptive behavior diversity. Here we investigate a typical filament partial eruption event and present integrated evidence for configuration of the pre-eruption filament and its formation. The CHASE H $\alpha$  observations reveal structured Doppler velocity distribution within the pre-eruption filament, where distinct redshift only appeared in the east narrow part of the south filament region and then disappeared after the partial eruption while the north part dominated by blueshift remained. Combining the SDO, ASO-S observations, and NLFFF modeling results, we verify that there were two independent material flow systems within the pre-flare filament, whose magnetic topology is a special double-decker configuration consisting of two magnetic flux ropes (MFRs) with opposite magnetic twist. During the formation of this filament system, continuous magnetic flux cancellation and footpoint motion were observed around its north end. Therefore, we propose a new double-decker formation scenario that the two MFRs composing such double-decker configuration originated from two magnetic systems with different initial connections and opposite magnetic twist. Subsequent magnetic reconnection with surrounding newly-emerging fields resulted in the motion of footpoint of the upper MFR to the region around footpoint of the lower MFR, thus leading to eventual formation of the double-decker configuration consisting of two MFRs with similar footpoints but opposite signs of magnetic twist. These results provide a potential way to determine unambiguously the progenitor configuration of a partial-eruptive filament and reveal a special type of double-decker MFR configuration and a new double-decker formation scenario. **2022 December 30**

## A Type II Radio Burst Driven by a Blowout Jet on the Sun

[Zhenyong Hou](#), [Hui Tian](#), [Wei Su](#), [Maria S. Madjarska](#), [Hechao Chen](#), [Ruisheng Zheng](#), [Xianyong Bai](#), [Yuanyong Deng](#)

ApJ 2023

<https://arxiv.org/pdf/2306.16725.pdf>

Type II radio bursts are often associated with coronal shocks that are typically driven by coronal mass ejections (CMEs) from the Sun. Here, we conduct a case study of a type II radio burst that is associated with a C4.5 class flare and a blowout jet, but without the presence of a CME. The blowout jet is observed near the solar disk center in the extreme-ultraviolet (EUV) passbands with different characteristic temperatures. Its evolution involves an initial phase and an ejection phase with a velocity of 560 km/s. Ahead of the jet front, an EUV wave propagates at a projected velocity of 403 km/s in the initial stage. The moving velocity of the source region of the type II radio burst is estimated to be 641

km/s, which corresponds to the shock velocity against the coronal density gradient. The EUV wave and the type II radio burst are closely related to the ejection of the blowout jet, suggesting that both are likely the manifestation of a coronal shock driven by the ejection of the blowout jet. The type II radio burst likely starts lower than those associated with CMEs. The combination of the velocities of the radio burst and the EUV wave yields a modified shock velocity at 757 km/s. The Alfvén Mach number is in the range of 1.09-1.18, implying that the shock velocity is 10%-20% larger than the local Alfvén velocity. **12 Nov 2022**

### **Coronal microjets in quiet-Sun regions observed with the Extreme Ultraviolet Imager onboard Solar Orbiter**

[Zhenyong Hou](#), [Hui Tian](#), [David Berghmans](#), [Hechao Chen](#), [Luca Teriaca](#), [Udo Schuhle](#), [Yuhang Gao](#), [Yajie Chen](#), [Jiansen He](#), [Linghua Wang](#), [Xianyong Bai](#)

ApJ **2021**

<https://arxiv.org/pdf/2108.08718.pdf>

We report the smallest coronal jets ever observed in the quiet Sun with recent high resolution observations from the High Resolution Telescopes (HRI-EUV and HRI-Ly $\{\alpha\}$ ) of the Extreme Ultraviolet Imager (EUI) onboard Solar Orbiter. In the HRI-EUV (174 Å) images, these microjets usually appear as nearly collimated structures with brightenings at their footpoints. Their average lifetime, projected speed, width, and maximum length are 4.6 min, 62 km s<sup>-1</sup>, 1.0 Mm, and 7.7 Mm, respectively. Inverted-Y shaped structures and moving blobs can be identified in some events. A subset of these events also reveal signatures in the HRI-Ly $\{\alpha\}$  (H I Ly $\{\alpha\}$  at 1216 Å) images and the extreme ultraviolet images taken by the Atmospheric Imaging Assembly onboard the Solar Dynamics Observatory. Our differential emission measure analysis suggests a multi-thermal nature and an average density of  $\sim 1.4 \times 10^9$  cm<sup>-3</sup> for these microjets. Their thermal and kinetic energies were estimated to be  $\sim 3.9 \times 10^{24}$  erg and  $\sim 2.9 \times 10^{23}$  erg, respectively, which are of the same order of the released energy predicted by the nanoflare theory. Most events appear to be located at the edges of network lanes and magnetic flux concentrations, suggesting that these coronal microjets are likely generated by magnetic reconnection between small-scale magnetic loops and the adjacent network field. **2020-05-20-21, 2020-05-30, 2020-10-19, 2020-10-22, 2020-11-19**

### **External reconnection and resultant reconfiguration of overlying magnetic fields during sympathetic eruptions of two filaments**

[Y. J. Hou](#), [T. Li](#), [Z. P. Song](#), [J. Zhang](#)

A&A **2020**

<https://arxiv.org/pdf/2006.06191.pdf>

Sympathetic eruptions of two solar filaments have been studied for several decades, but the detailed physical process through which one erupting filament triggers another is still under debate. Here we investigate a sympathetic event involving successive eruptions of two filaments on **2015 November 15-16**, which presented abundant sympathetic characteristics. The two filaments (F1 and F2) were separated by a narrow region of negative polarity, and F1 firstly erupted, producing a two-ribbon flare. When the outward-spreading ribbon produced by F1 approached stable F2, a weak brightening was observed to the south of F2 and then spread northward, inward approaching F2. Behind this inward-spreading brightening, a dimming region characterized by a plasma density reduction of 30% was extending. NLFFF extrapolations with a time sequence reveal that fields above pre-eruption F1 and F2 constituted a quadrupolar magnetic system with a possible null point. Moreover, the null point kept moving towards F2 and descending within the following hours. We infer that the rising F1 pushed its overlying fields towards the fields above stable F2 and caused successive external reconnection between the overlying fields. From outside to inside (lower and lower in height), the fields above pre-eruption F2 were gradually involved in the reconnection, manifesting as the inward-spreading brightening and extending dimming on the south side of F2. Furthermore, the external reconnection could reconfigure the overlying fields of F2 by transporting magnetic flux from its west part to the east part, which is further verified by the subsequent partial eruption of F2. We propose an integrated evidence chain to demonstrate the critical roles of external magnetic reconnection and the resultant reconfiguration of overlying fields on the sympathetic eruptions of two filaments.

### **Eruption of a multi-flux-rope system in solar active region 12673 leading to the two largest flares in Solar Cycle 24**

[Y. J. Hou](#), [J. Zhang](#), [T. Li](#), [S. H. Yang](#), [X. H. Li](#)

A&A 619, A100 **2018**

<https://arxiv.org/pdf/1808.06795.pdf>

Solar active region (AR) 12673 in 2017 September produced two largest flares in Solar Cycle 24: the X9.3 flare on **September 06** and the X8.2 flare on **September 10**. We attempt to investigate the evolutions of the two great flares and their associated complex magnetic system in detail. Aided by the NLFFF modeling, we identify a double-decker flux rope configuration above the polarity inversion line (PIL) in the AR core region. The north ends of these two flux ropes were rooted in a negative-polarity magnetic patch, which began to move along the PIL and rotate anticlockwise before the X9.3 flare on September 06. The strong shearing motion and rotation contributed to the destabilization of the two magnetic flux ropes, of which the upper one subsequently erupted upward due to the kink-instability. Then another two sets of twisted loop bundles beside these ropes were disturbed and successively erupted within 5 minutes like a chain reaction. Similarly, multiple ejecta components were detected to consecutively erupt during the X8.2 flare occurring in

the same AR on September 10. We examine the evolution of the AR magnetic fields from **September 03 to 06** and find that five dipoles emerged successively at the east of the main sunspot. The interactions between these dipoles took place continuously, accompanied by magnetic flux cancellations and strong shearing motions. In AR 12673, significant flux emergence and successive interactions between the different emerging dipoles resulted in a complex magnetic system, accompanied by the formations of multiple flux ropes and twisted loop bundles. We propose that the eruptions of a multi-flux-rope system resulted in the two largest flares in Solar Cycle 24.

### **Flux rope proxies and fan-spine structures in active region NOAA 11897**

Y. J. **Hou**, T. Li, J. Zhang

A&A 592, A138 **2016**

<http://arxiv.org/pdf/1606.09322v1.pdf>

Employing the high-resolution observations from the Solar Dynamics Observatory (SDO) and the Interface Region Imaging Spectrograph (IRIS), we statistically investigate flux rope proxies in NOAA AR 11897 from **14-Nov-2013 to 19-Nov-2013** and display two fan-spine structures in this AR. For the first time, we detect flux rope proxies of NOAA 11897 for total 30 times in 4 different locations. These flux rope proxies were either tracked in both lower and higher temperature wavelengths or only detected in hot channels. Specially, none of these flux rope proxies was observed to erupt, but just faded away gradually. In addition to these flux rope proxies, we firstly detect a secondary fan-spine structure. It was covered by dome-shaped magnetic fields which belong to a larger fan-spine topology. These new observations imply that considerable amounts of flux ropes can exist in an AR and the complexity of AR magnetic configuration is far beyond our imagination.

### **Partially Erupted Prominence Material as a Diagnostic of Coronal Mass Ejection Trajectory**

**B. A. Hovis-Afflerbach**, **B. J. Thompson**, **E. I. Mason**

Space Weather **Volume 21, Issue 8** August **2023** e2022SW003256

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2022SW003256>

Coronal mass ejections (CMEs) are energetic releases of large-scale magnetic structures from the Sun. CMEs can have impacts on spacecraft and at Earth. This trajectory is typically assumed to be radial, but often the CME moves outward with some spatial offset from the source region where the eruption initially occurred. A CME is frequently accompanied by a prominence eruption, a movement of cool, dense material up into the corona that can be ejected or fall back down. We investigate eruptions in which some portion of the prominence material falls back to the Sun along field lines which have reconfigured in the eruption, rather than draining back to the source or escaping with the CME. Using a method called persistence mapping, 304 Å images from the Solar Dynamics Observatory (SDO), and coronagraph images from the Solar and Heliospheric Observatory, we measure and compare the offsets in latitude of 20 CMEs and their respective prominences with respect to the source region. The 20 events were chosen to sample over the first 10 years of the SDO mission. We find that the offsets are correlated. We find no difference between eruptions offset toward the equator or the poles, suggesting that the offset is a result of local changes in the eruptive field, rather than of the Sun's global magnetic field structure. These findings help us contextualize individual eruptions and highlight changes in the local magnetic field associated with the prominence eruption. **2011-02-24, 2012-04-22, 2019-04-22**

### **The Evolution of Our Understanding of Coronal Mass Ejections**

**Review**

Russell **Howard**, Angelos Vourlidas, and Guillermo Stenborg

Front. Astron. Space Sci. 10: 1264226. **2023**

doi: 10.3389/fspas.2023.1264226

<https://www.frontiersin.org/articles/10.3389/fspas.2023.1264226/full> **File**

The unexpected observation of a sudden expulsion of mass through the solar corona in 1971 opened up a new field of interest in solar and stellar physics. The discovery came from a white-light coronagraph, which creates an artificial eclipse of the Sun, enabling the viewing of the faint glow from the corona. This observation was followed by many more observations and new missions. In the five decades since that discovery, there have been five generations of coronagraphs, each with improved performance, enabling continued understanding of the phenomena, which became known as Coronal Mass Ejection (CME) events. The conceptualization of the CME structure evolved from the elementary 2-dimensional loop to basically two fundamental types: a 3-dimensional magnetic flux rope and a non-magnetic eruption from pseudo-streamers. The former persists to 1 AU and beyond, whereas the latter dissipates by 15 R<sub>☉</sub>. Historically, most of the studies have been devoted to understanding the CME large-scale structure and its associations, but this is changing. With the advent of the fourth and fifth coronagraph generations, more attention is being devoted to their internal structure and initiation mechanisms. In this review, we describe the evolution of CME observations and their associations with other solar and heliospheric phenomena, with one of the

more important correlations being its recognition as a driver of space-weather. We conclude with a brief overview of open questions and present some ideas for future observations.

### **Evolution of CME Mass in the Corona**

Russell A. [Howard](#), Angelos Vourlidas

[Solar Physics](#) April 2018, 293:55

<http://sci-hub.tw/http://link.springer.com/10.1007/s11207-018-1274-9>

The idea that coronal mass ejections (CMEs) pile up mass in their transport through the corona and heliosphere is widely accepted. However, it has not been shown that this is the case. We perform an initial study of the volume electron density of the fronts of 13 three-part CMEs with well-defined frontal boundaries observed with the Solar and Heliospheric Observatory/Large Angle and Spectrometric COronagraph (SOHO/LASCO) white-light coronagraphs. We find that, in all cases, the volume electron density decreases as the CMEs travel through the LASCO-C2 and -C3 fields of view, from  $2.6\text{--}30 R_{\odot}$  to  $2.6\text{--}30 R_{\odot}$ . The density decrease follows closely a power law with an exponent of  $-3$ , which is consistent with a simple radial expansion. This indicates that in this height regime there is no observed pile-up. **05 Oct. 1996, 18 Jan. 1997, 04 Feb. 1997, 09 Mar. 1997, 14 Dec. 1997, 17 May 1999, 30 May 1999, 09 Feb. 2000, 17 Jul. 2000, 23 Jul. 2000, 08 Jan. 2001, 13 Jan. 2001, 20 Feb. 2001**

### **Measuring the magnetic field of coronal mass ejections near the Sun using pulsars,**

[Howard](#), T.A., K. Stovall, Dowell, J., G. Taylor, and S. White,

*Astrophys. J.*, 831 208, 2016.

<http://sci-hub.cc/10.3847/0004-637X/831/2/208>

The utility of Faraday rotation to measure the magnetic field of the solar corona and large-scale transients within is a small, yet growing field in solar physics. This is largely because it has been recognized as a potentially valuable frontier in space weather studies, because the ability to measure the intrinsic magnetic field within coronal mass ejections (CMEs) when they are close to the Sun is of great interest for understanding a key element of space weather. Such measurements have been attempted over the last few decades using radio signals from artificial sources (i.e., spacecraft on the far side of the Sun), but studies involving natural radio sources are scarce in the literature. We report on a preliminary study involving an attempt to detect the Faraday rotation of a CME that passed in front of a pulsar (PSR B0950+08) in 2015 August. We combine radio measurements with those from a broadband visible light coronagraph, to estimate the upper limit of the magnetic field of the CME when it was in the corona. We find agreement between different approaches for obtaining its density, and values that are consistent with those predicted from prior studies of CME density close to the Sun. **2015-08-21**

### **Overview of the remote sensing observations from PSP solar encounter 10 with perihelion at 13.3 R<sub>sun</sub>**

The closest perihelion pass of Parker Solar Probe (PSP), so far, occurred between **16 and 26 of November 2021** and reached  $\sim 13.29 R_{\text{sun}}$  from Sun center. This pass resulted in very unique observations of the solar corona by the Wide-field Instrument for Solar Probe (WISPR). WISPR observed at least ten CMEs, some of which were so close that the structures appear distorted. All of the CMEs appeared to have a magnetic flux rope (MFR) structure and most were oriented such that the view was along the axis orientation, revealing very complex interiors. Two CMEs had a small MFR develop in the interior, with a bright circular boundary surrounding a very dark interior. Trailing the larger CMEs were substantial outflows of small blobs and flux-rope like structures within striated ribbons, lasting for many hours. When the heliophysics plasma sheet (HPS) was inclined, as it was during the days around perihelion on November 21, 2021, the outflow was over a very wide latitude range. One CME was overtaken by a faster one, with a resultant compression of the rear of the leading CME and an unusual expansion in the trailing CME. The small Thomson Surface creates brightness variations of structures as they pass through the field of view. In addition to this dynamic activity, a brightness band from excess dust along the orbit of asteroid/comet 3200 Phaethon is also seen for several days. **16, 19, 20-21, 22-23, 24-26 Nov 2021**

<http://iopscience.iop.org/sci-hub.cc/0004-637X/834/1/86/> **File**

When a coronal mass ejection (CME) appears in a coronagraph it often exhibits three parts. This "classic" three-part configuration consists of a bright leading edge, a dark circular- or teardrop-shaped cavity, and a bright core within the cavity. It is generally accepted that these are manifestations of coronal plasma pileup, the driving magnetic flux rope, and the associated eruptive filament, respectively. The latter has become accepted by the community since coronagraph

CMEs have been commonly associated with eruptive filaments for over 40 years. In this second part of our series challenging views on CMEs, we present the case that the inner core of the three-part coronagraph CME may not be, and in the most common cases is not, a filament. We present our case in the form of four exhibits showing that most of the CMEs in a broad survey are not associated with an eruptive filament at the Sun, and that the cores of those CMEs that are filament-associated do not geometrically resemble or consist of material from the associated filament. We conclude with a discussion on the possible causes of the bright CME core and what happens to the filament material postlaunch. We discuss how the CME core could arise spontaneously from the eruption of a flux rope from the Sun, or could be the result of a mathematical caustic produced by the geometric projection of a twisted flux rope. **2010.12.14, 2011.05.01, 2011.10.25, 2011.11.02, 2012.01.27, 2012.01.31, 2012.03.24, 2012.04.14, 2012.04.28, 2012.06.27, 2012.07.26, 2012.08.20, 2012.10.22, 2012.11.18**

### **I. THE CASE FOR BLAST WAVES**

T. A. **Howard**<sup>1</sup> and V. J. Pizzo

**2016** ApJ 824 92

<http://sci-hub.cc/doi/10.3847/0004-637X/824/2/92> **File**

Since the closure of the "solar flare myth" debate in the mid-1990s, a specific narrative of the nature of coronal mass ejections (CMEs) has been widely accepted by the solar physics community. This narrative describes structured magnetic flux ropes at the CME core that drive the surrounding field plasma away from the Sun. This narrative replaced the "traditional" view that CMEs were blast waves driven by solar flares. While the flux rope CME narrative is supported by a vast quantity of measurements made over five decades, it does not adequately describe every observation of what have been termed CME-related phenomena. In this paper we present evidence that some large-scale coronal eruptions, particularly those associated with EIT waves, exhibit characteristics that are more consistent with a blast wave originating from a localized region (such as a flare site) rather than a large-scale structure driven by an intrinsic flux rope. We present detailed examples of CMEs that are suspected blast waves and flux ropes, and show that of our small sample of 22 EIT-wave-related CMEs, 91% involve a blast wave as at least part of the eruption, and 50% are probably blast waves exclusively. We conclude with a description of possible signatures to look for in determining the difference between the two types of CMEs and with a discussion on modeling efforts to explore this possibility.

## **Regarding the detectability and measurement of coronal mass ejections Review**

Timothy A. **Howard**

J. Space Weather Space Clim., 5, A22 (2015) **File**

<http://www.swsc-journal.org/articles/swsc/pdf/2015/01/swsc140065.pdf>

In this review I discuss the problems associated with the detection and measurement of coronal mass ejections (CMEs). CMEs are important phenomena both scientifically, as they play a crucial role in the evolution of the solar corona, and technologically, as their impact with the Earth leads to severe space weather activity in the form of magnetic storms. I focus on the observation of CMEs using visible white light imagers (coronagraphs and heliospheric imagers), as they may be regarded as the binding agents between different datasets and different models that are used to reconstruct them. Our ability to accurately measure CMEs observed by these imagers is hampered by many factors, from instrumental to geometrical to physical. Following a brief review of the history of CME observation and measurement, I explore the impediments to our ability to measure them and describe possible means for which we may be able to mitigate those impediments. I conclude with a discussion of the claim that we have reached the limit of the information that we can extract from the current generation of white light imagers, and discuss possible ways forward regarding future instrument capabilities. **27 February 2000, 12 December 2008, 2013/05/03**

## **Measuring an Eruptive Prominence at Large Distances from the Sun. II. Approaching 1 AU**

T. A. **Howard**

**2015** ApJ 806 176

The physical properties of eruptive prominences are unknown at large distances from the Sun. They are rarely, if ever, measured by in situ spacecraft and until recently our ability to measure them beyond the fields of view of solar imagers has been severely limited. The data quality of heliospheric imaging has reached a point where some quantitative measurements of prominences are now possible. I present the first such measurements of a bright prominence continually out to distances of around 1 AU from the Sun. This work follows on from the preparatory work presented in an accompanying paper, which showed that the brightness of a prominence can be safely assumed to arise entirely from Thomson scattering in the STEREO/HI fields of view. Measurements of distance, speed, and mass are provided along with those from its accompanying coronal mass ejection (CME) to demonstrate their geometric, kinematic, and mass relationships. I find that the prominence travels with a slower speed than that of the CME, but its location relative to the CME structure does not conform to the expected location for basic geometric expansion. Further, the mass of the prominence was found to decrease by around an order of magnitude while that of the CME increased by an order of magnitude across the same distance.

## Measuring an Eruptive Prominence at Large Distances from the Sun. I. Ionization and Early Evolution

T. A. **Howard**

2015 ApJ 806 175

Measurements of H $\alpha$  emission within an eruptive solar prominence are presented, using white light polarization properties as a proxy for the presence of H $\alpha$  in the STEREO COR1 and COR2 coronagraphs. The transition from H $\alpha$  emission to Thomson scattering radiance serves as an indicator of the ionization of the prominence, and I discuss the physical implications regarding the behavior of the neutrals and ions, and also for the measurement of coronal mass ejection properties using the Thomson scattering assumption. I find that the prominence has a high concentration of neutrals at around two solar radii that gradually exhibit ionization characteristics as it moves away from the Sun. The prominence reaches complete ionization, or at least a state where the Thomson-scattered brightness dominates, by the time it reaches around seven solar radii. This is consistent with predictions inferred from direct H $\alpha$  measurements made from earlier studies in the 1980s and with the predicted ionization rate of neutral hydrogen near solar maximum. These results pave the way for an accompanying paper that reports on measurements of the prominence at large distances from the Sun using the assumptions verified here.

## The Formation and Launch of a Coronal Mass Ejection Flux Rope: A Narrative Based on Observations

T. A. **Howard** and C. E. DeForest

2014 ApJ 796 33, **File**

We present a data-driven narrative of the launch and early evolution of the magnetic structure that gave rise to the coronal mass ejection (CME) on **2008 December 12**. The structure formed on December 7 and launched early on December 12. We interpret this structure as a flux rope based on prelaunch morphology, postlaunch magnetic measurements, and the lack of large-scale magnetic reconnection signatures at launch. We ascribe three separate onset mechanisms to the complete disconnection of the flux rope from the Sun. It took 19 hr for the flux rope to be fully removed from the Sun, by which time the segment that first disconnected was around 40 R $\odot$  away. This implies that the original flux rope was stretched or broken; we provide evidence for a possible bisection. A transient dark arcade was observed on the Sun that was later obscured by a bright arcade, which we interpret as the strapping field stretching and magnetically reconnecting as it disconnected from the coronal field. We identify three separate structures in coronagraph images to be manifestations of the same original flux rope, and we describe the implications for CME interpretation. We cite the rotation in the central flux rope vector of the magnetic clouds observed in situ by ACE/Wind and STEREO-B as evidence of the kink instability of the eastern segment of the flux rope. Finally, we discuss possible alternative narratives, including multiple prelaunch magnetic structures and the nonflux rope scenario. Our results support the view that, in at least some CMEs, flux rope formation occurs before launch.

## Stealth Coronal Mass Ejections: A Perspective

Timothy A. **Howard**, Richard A. Harrison

Solar Physics, July 2013, Volume 285, Issue 1-2, pp 269-280

“Stealth CME” has become a commonly used term in recent studies of solar activity. It refers to a coronal mass ejection (CME) with no apparent solar surface association, and therefore has no easily identifiable signature to locate the region on the Sun from which the CME erupted. We review the literature and express caution in categorising CMEs in this way. CMEs were discovered some 40 years ago and there have been numerous statistical studies of associations with phenomena in the solar atmosphere which clearly identify a range of associations, from bright flares and large prominence eruptions to small flares, and even a lack of flares or any identifiable surface activity at all. In this sense the stealth CME concept is not new. One major question relates to whether the range of associations reveal different CME classes, i.e. different CME launch processes, or are indicative of a spectrum of coronal responses to one common process. We favour the latter and stress that this spectrum must be considered in the description of the CME launch, meaning that the physics of a so-called stealth CME must not be fundamentally different from a CME associated with major surface events. On the other hand we also stress that the use of a stealth CME category implies that all surface activity could indeed be detected using modern instrumentation. We argue that this may not be the case, and that even in the SDO era of full-Sun, high resolution imaging, we are restricted by instrument sensitivity and bandwidth issues. Thus, having reviewed the case for stealth CMEs as a distinct category, we stress the need to keep the concept in perspective.

## WHITE-LIGHT OBSERVATIONS OF SOLAR WIND TRANSIENTS AND COMPARISON WITH AUXILIARY DATA SETS

T. A. [Howard](#)<sup>1</sup>, C. E. DeForest<sup>1</sup>, and A. A. Reinard

2012 ApJ 754 102

This paper presents results utilizing a new data processing pipeline for STEREO/SECCHI. The pipeline is used to identify and track 24 large- and small-scale solar wind transients from the Sun out to 1 AU. This comparison was performed during a few weeks around the minimum at the end of Solar Cycle 23 and the start of Cycle 24 (2008 December to 2009 January). We use coronagraph data to identify features near the Sun, track them through HI-2A, and identify their signatures with in situ data at the Earth and STEREO-B. We provide measurements and preliminary analysis of the in situ signatures of these features near 1 AU. Along with the demonstration of the utility of heliospheric imagers for tracking even small-scale structures, we identify and discuss an important limitation in using geometric triangulation for determining three-dimensional properties.

## INNER HELIOSPHERIC FLUX ROPE EVOLUTION VIA IMAGING OF CORONAL MASS EJECTIONS

T. A. [Howard](#) and C. E. DeForest

2012 ApJ 746 64, [File](#)

Understanding the evolution of flux ropes in coronal mass ejections (CMEs) is of importance both to the scientific and technological communities. Scientifically their presence is critical to models describing CME launch and they likely play a role in CME evolution. Technologically they are the major contributor to severe geomagnetic storms. Using a new processing technique on the STEREO/SECCHI heliospheric imaging data, we have tracked a magnetic flux rope observed by the Wind spacecraft in **December 2008** to its origins observed by coronagraphs. We thereby establish that the cavity in the classic three-part coronagraph CME is the feature that becomes the magnetic cloud. This implies that the bright material ahead of the cavity is piled-up coronal or solar wind material. We track the evolution of the cavity en-route and find that its structure transforms from concave inward (curving away from the Sun) to concave outward (toward the Sun) around 0.065 AU from the Sun. The pileup was tracked and its leading edge remained concave inward throughout its journey. Two other CMEs in **January 2009** are also inspected and a similar cavity is observed in each, suggesting that they too each contained a flux rope. The results presented here are the first direct observation, through continuous tracking, associating a particular flux rope observed in situ with the same flux rope before ejection from the corona. We speculate that detailed heliospheric imagery of CMEs may lead to a means by which flux ropes can be identified remotely in the heliosphere.

## "Coronal Mass Ejections: An Introduction", [Boook](#) [File](#)

T. [Howard](#).

Series: Astrophysics and Space Science Library, Vol. 376, 2011

The [book](#) brings the reader up to date on the status quo of CME study: the history of their observation; techniques for their detection; their space weather impact; and theories describing their onset, evolution and eventual fate. It also provides an exhaustive list of historical and topical references from experts in the field past and present.

## Application of a new phenomenological coronal mass ejection model to space weather forecasting,

[Howard](#), T. A., and S. J. Tappin

Space Weather, 8, S07004, doi:10.1029/2009SW000531 (2010).

Recent work by the authors has produced a new phenomenological model for coronal mass ejections (CMEs). This model, called the Tappin-Howard (TH) Model, takes advantage of the breakdown of geometrical linearity when CMEs are observed by white-light imagers at large distances from the Sun. The model extracts 3-D structure and kinematic information on the CME using heliospheric image data. This can estimate arrival times of the CME at 1 AU and impact likelihood with the Earth. Hence the model can be used for space weather forecasting. We present a preliminary evaluation of this potential with three mock trial forecasts performed using the TH Model. These are already-studied events from 2003, 2004 and 2007 but we performed the trials assuming that they were observed for the first time. The earliest prediction was made 17 hours before impact and predicted arrival times reached differences within one hour for at least one forecast for all three events. The most accurate predicted arrival time was 15 min from the actual, and all three events reach accuracies of the order of 30 min. Arrival speeds were predicted to be very similar to the bulk plasma speed within the CME near 1 AU for each event, with the largest difference around 300 km/s and the least 40 km/s. The

model showed great potential and we aspire to fully validate it for integration with existing tools for space weather forecasting.

### **Three-Dimensional Reconstruction of Two Solar Coronal Mass Ejections Using the STEREO Spacecraft**

Timothy A. Howard · S. James Tappin

Solar Phys, 252: 373–383, 2008, DOI 10.1007/s11207-008-9262-0, File

Previous attempts to produce three-dimensional (3-D) reconstructions of coronal mass ejections (CMEs) have required either modeling efforts or comparisons with secondary associated eruptions near the solar surface. This is because coronagraphs are only able to produce sky-plane-projected images of CMEs and it has hence been impossible to overcome projection effects by using coronagraphs alone. The SECCHI suite aboard the twin STEREO spacecraft allows us to provide the means for 3-D reconstruction of CMEs directly from coronagraph measurements alone for the first time. We present these measurements from two CMEs observed in November 2007. By identifying common features observed simultaneously with the LASCO coronagraphs aboard SOHO and the COR coronagraphs aboard STEREO we have triangulated the source region of both CMEs. We present the geometrical analysis required for this triangulation and identify the location of the CME in solar-meridional, ecliptic, and Carrington coordinates. None of the two events were associated with an easily detectable solar surface eruption, so this triangulation technique is the only means by which the source location of these CMEs could be identified. We present evidence that both CMEs originated from the same magnetic structure on the Sun, but from a different magnetic field configuration. Our results reveal some insight into the evolution of the high corona magnetic field, including its behavior over time scales of a few days and its reconfiguration after a major eruption.

### **Interplanetary coronal mass ejections that are undetected by solar coronagraphs, Howard, T. A., and G. M. Simnett**

J. Geophys. Res., 113, A08102, 2008

<http://dx.doi.org/10.1029/2007JA012920>

From February 2003 to September 2005 the Solar Mass Ejection Imager on the Coriolis spacecraft detected 207 interplanetary coronal mass ejections (ICME) in the inner heliosphere. We have examined the data from the Large Angle Spectroscopic Coronagraph (LASCO) on the SOHO spacecraft for evidence of coronal transient activity that might have been the solar progenitor of the Solar Mass Ejection Imager (SMEI) events, taking into account the projected speed of the SMEI event and its position angle in the plane of the sky. We found a significant number of SMEI events where there is either only a weak or unlikely coronal mass ejection (CME) detected by LASCO or no event at all. A discussion of the effects of projection across large distances on the ICME measurements is made, along with a new technique called the Cube-Fit procedure that was designed to model the ICME trajectory more accurately than simple linear fits to elongation-time plots. Of the 207 SMEI events, 189 occurred during periods of full LASCO data coverage. Of these, 32 or 17% were found to have a weak or unlikely LASCO counterpart, and 14 or 7% had no apparent LASCO transient association. Using solar X-ray, EUV and H $\alpha$  data we investigated three main physical possibilities for ICME occurrence with no LASCO counterpart: (1) Corotating interaction regions (CIRs), (2) erupting magnetic structures (EMS), and (3) flare blast waves. We find that only one event may possibly be a CIR and that flare blast waves can be ruled out. *The most likely phenomenon is investigated and discussed, that of EMS. Here, the transient erupts in the same manner as a typical CME, except that they do not have sufficient mass to be detected by LASCO. As the structure moves outward, it accumulates and concentrates solar wind material until it is bright enough to be detected by SMEI.*

### **Kinematic properties of solar coronal mass ejections: Correction for projection effects in spacecraft coronagraph measurements,**

Howard, T. A., D. Nandy, and A. C. Koepke,

J. Geophys. Res., 113, A01104, 2008, File

<http://solar.physics.montana.edu/~nandi/papers/nandy07c.pdf>

By identifying solar surface source regions of CMEs using X-ray and H $\alpha$  flare and disappearing filament data, and through considerations of CME trajectories in three-dimensional (3-D) geometry, we have devised a methodology to correct for the projection effect. We outline this method here.

We conclude that while using the plane-of-sky measurements may be suitable for studies of general trends in a large sample of events, correcting for projection effects is mandatory for those investigations which rely on a numerically precise determination of the properties of individual CMEs.

### **A Historical Perspective on Coronal Mass Ejections.**

R.A. Howard

In: (2006). Solar Eruptions and Energetic Particles. doi:10.1029/165gm03

[sci-hub.tw/10.1029/165GM03](http://sci-hub.tw/10.1029/165GM03)

The concept of mass leaving the Sun was thought possible over 100 years ago from the observations of prominence material that was seen to be moving outward at speeds in excess of the escape velocity. While the direct observation was elusive, the coupling between solar activity and geomagnetic storms became quite apparent. In the 1940's the concept of corpuscular radiation from the sun was proposed and then in the 1950's used to explain the discontinuity in a comet tail. Parker's theory in 1957 predicted a continuous outflow from the sun that was then observed by in-situ spacecraft less than 10 years later. The first optical observations of a transient event showing mass moving through the solar corona in 1971 were accompanied by excitement, fascination and speculation. Two questions at that time were: What causes the CME eruption? What is their significance? These questions and others are still with us. In this paper, the coronal mass ejection is viewed in its historical context.

### **Excitation of Quasiperiodic Fast-propagating Waves in the Early Stage of the Solar Eruption**

Jialiing Hu<sup>1,2,3</sup>, Jing Ye<sup>1,3,4</sup>, Yuhao Chen<sup>1,2,3</sup>, Zhixing Mei<sup>1,3</sup>, Zehao Tang<sup>1,2,3</sup>, and Jun Lin

2024 ApJ 962 42

<https://iopscience.iop.org/article/10.3847/1538-4357/ad1993/pdf>

We propose a mechanism for the excitation of large-scale quasiperiodic fast-propagating magnetoacoustic (QFP) waves observed on both sides of the coronal mass ejection. Through a series of numerical experiments, we successfully simulated the quasi-static evolution of the equilibrium locations of the magnetic flux rope in response to the change of the background magnetic field, as well as the consequent loss of the equilibrium that eventually gives rise to the eruption. During the eruption, we identified QFP waves propagating radially outward of the flux rope, and tracing their origin reveals that they result from the disturbance within the flux rope. Acting as an imperfect waveguide, the flux rope allows the internal disturbance to escape to the outside successively via its surface, invoking the observed QFP waves. Furthermore, we synthesized the images of QFP waves on the basis of the data given by our simulations and found consistency with observations. This indicates that the leakage of the disturbance outside the flux rope could be a reasonable mechanism for QFP waves. **2012 May 7**

### **Spectroscopic and Imaging Observations of Spatially Extended Magnetic Reconnection in the Splitting of a Solar Filament Structure**

Huidong Hu<sup>1</sup>, Ying D. Liu<sup>1,2</sup>, Lakshmi Pradeep Chitta<sup>3</sup>, Hardi Peter<sup>3</sup>, and Mingde Ding<sup>4,5</sup>

2022 ApJL 940 L12

<https://iopscience.iop.org/article/10.3847/2041-8213/ac9dfd/pdf>

<https://arxiv.org/pdf/2211.10216>

On the Sun, Doppler shifts of bidirectional outflows from the magnetic-reconnection site have been found only in confined regions through spectroscopic observations. Without spatially resolved spectroscopic observations across an extended region, the distribution of reconnection and its outflows in the solar atmosphere cannot be made clear. Magnetic reconnection is thought to cause the splitting of filament structures, but unambiguous evidence has been elusive. Here we report spectroscopic and imaging analysis of a magnetic-reconnection event on the Sun, using high-resolution data from the Interface Region Imaging Spectrograph and the Solar Dynamics Observatory. Our findings reveal that the reconnection region extends to an unprecedented length of no less than 14,000 km. The reconnection splits a filament structure into two branches, and the upper branch erupts eventually. Doppler shifts indicate clear bidirectional outflows of  $\sim 100 \text{ km s}^{-1}$ , which decelerate beyond the reconnection site. Differential-emission-measure analysis reveals that in the reconnection region the temperature reaches over 10 MK and the thermal energy is much larger than the kinetic energy. This Letter provides definite spectroscopic evidence for the splitting of a solar filament by magnetic reconnection in an extended region. **2017 July 13-14**

### **Validation and interpretation of three-dimensional configuration of a magnetic cloud flux rope**

Qiang Hu, Chunming Zhu, Wen He, Jiong Qiu, Lan K. Jian, Avijeet Prasad

ApJ 2022

<https://arxiv.org/pdf/2204.03457>

One "strong" magnetic cloud (MC) with the magnetic field magnitude reaching  $\sim 40 \text{ nT}$  at 1 au during **2012 June 16-17** is examined in association with a pre-existing magnetic flux rope (MFR) identified on the Sun. The MC is characterized by a quasi-three dimensional (3D) flux rope model based on in situ measurements from the Wind spacecraft. The magnetic flux contents and other parameters are quantified. In addition, a correlative study with the corresponding measurements of the same structure crossed by the Venus Express (VEX) spacecraft at a heliocentric distance 0.7 au and with an angular separation  $\sim 6^\circ$  in longitude is performed to validate the MC modeling results. The spatial variation between the Wind and VEX magnetic field measurements is attributed to the 3D configuration of the structure as featured by a knotted bundle of flux. The comparison of the magnetic flux contents between the MC and the source region on the Sun indicates that the 3D reconnection process accompanying an M1.9 flare may correspond to the magnetic reconnection between the field lines of the pre-existing MFR rooted in the opposite polarity footpoints. Such a process reduces the amount of the axial magnetic flux in the erupted flux rope, by approximately 50%, in this case.

## The Grad-Shafranov Reconstruction of Toroidal Magnetic Flux Ropes: First Applications

Qiang Hu, [M. G. Linton](#), [B. E. Wood](#), [P. Riley](#), [T. Nieves-Chinchilla](#)

Solar Phys. 2017

<https://arxiv.org/pdf/1707.09454.pdf>

This article completes and extends a recent study of the Grad-Shafranov (GS) reconstruction in toroidal geometry, as applied to a two and a half dimensional configurations in space plasmas with rotational symmetry. A further application to the benchmark study of an analytic solution to the toroidal GS equation with added noise shows deviations in the reconstructed geometry of the flux rope configuration, characterized by the orientation of the rotation axis, the major radius, and the impact parameter. On the other hand, the physical properties of the flux rope, including the axial field strength, and the toroidal and poloidal magnetic flux, agree between the numerical and exact GS solutions. We also present a real event study of a magnetic cloud flux rope from *in situ* spacecraft measurements. The devised procedures for toroidal GS reconstruction are successfully executed. Various geometrical and physical parameters are obtained with associated uncertainty estimates. The overall configuration of the flux rope from the GS reconstruction is compared with the corresponding morphological reconstruction based on white-light images. The results show overall consistency, but also discrepancy in that the inclination angle of the flux rope central axis with respect to the ecliptic plane differs by about 20-30 degrees in the plane of the sky. We also compare the results with the original straight-cylinder GS reconstruction and discuss our findings. **06-07-Jun-2008**

## Multi-spacecraft Observations of the Coronal and Interplanetary Evolution of a Solar Eruption Associated with Two Active Regions

Huidong Hu, Ying D. Liu, Rui Wang, Xiaowei Zhao, Bei Zhu, Zhongwei Yang

ApJ 840 76 2017

<https://arxiv.org/pdf/1704.05496.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/aa6d54/pdf>

We investigate the coronal and interplanetary evolution of a coronal mass ejection (CME) launched on **2010 September 4** from a source region linking two active regions (ARs) 11101 and 11103, using extreme ultraviolet imaging, magnetogram, white-light and *in situ* observations from SDO, STEREO, SOHO, VEX and Wind. A potential-field source-surface model is employed to examine the configuration of the coronal magnetic field surrounding the source region. The graduated cylindrical shell model and a triangulation method are applied to determine the kinematics of the CME in the corona and interplanetary space. From the remote sensing and *in situ* observations we obtain some key results: (1) the CME was deflected in both the eastward and southward directions in the low corona by the magnetic pressure from the two ARs and possibly interacted with another ejection, which caused that the CME arrived at VEX that was longitudinally distant from the source region; (2) although VEX was closer to the Sun, the observed and derived CME arrival times at VEX are not earlier than those at Wind, which suggests the importance of determining both the frontal shape and propagation direction of the CME in interplanetary space; (3) the ICME was compressed in the radial direction while the longitudinal transverse size was extended.

## Sun-to-Earth Characteristics of the 2012 July 12 Coronal Mass Ejection and Associated Geo-effectiveness

Huidong Hu, Ying D. Liu, Rui Wang, [Christian Möstl](#), [Zhongwei Yang](#)

ApJ 829 97 2016

<http://arxiv.org/pdf/1607.06287v1.pdf> File

We analyze multi-spacecraft observations associated with the 2012 July 12 Coronal Mass Ejection (CME), covering the source region on the Sun from SDO, stereoscopic imaging observations from STEREO, magnetic field characteristics at MESSENGER, and type II radio burst and *in situ* measurements from Wind. A triangulation method based on STEREO stereoscopic observations is employed to determine the kinematics of the CME, and the outcome is compared with the result derived from the type II radio burst with a solar wind electron density model. A Grad-Shafranov technique is applied to Wind *in situ* data to reconstruct the flux-rope structure and compare it with the observation of the solar source region, which helps understand the geo-effectiveness associated with the CME structure. Conclusions are as follows: (1) the CME undergoes an impulsive acceleration, a rapid deceleration before reaching MESSENGER, and then a gradual deceleration out to 1 AU, which should be noticed in CME kinematics models; (2) the type II radio burst was probably produced from a high-density interaction region between the CME-driven shock and a nearby streamer or from the shock flank with lower heights, which implies uncertainties in the determination of CME kinematics using solely type II radio bursts; (3) the flux-rope orientation and chirality deduced from *in situ* reconstruction at Wind agree with those obtained from solar source observations; (4) the prolonged southward magnetic field near the Earth is mainly from the axial component of the largely southward inclined flux rope, which indicates the importance of predicting both the flux-rope orientation and magnetic field components in geomagnetic activity forecasting.

## Structures of Interplanetary Magnetic Flux Ropes and Comparison with Their Solar Sources

[https://dl.dropboxusercontent.com/u/96898685/ms\\_fr\\_v4.pdf](https://dl.dropboxusercontent.com/u/96898685/ms_fr_v4.pdf)  
<http://arxiv.org/pdf/1408.1470v1.pdf>

During the process of magnetic flux rope ejection, magnetic reconnection is essential to release the flux rope. The question remains: how does the magnetic reconnection change the flux rope structure? In this work, we continue with the original study by Qiu et al. (2007) by using a larger sample of flare-CME-ICME events to compare properties of ICME/MC flux ropes measured at 1 AU and properties of associated solar progenitors including flares, filaments, and CMEs. In particular, the magnetic field-line twist distribution within interplanetary magnetic flux ropes is systematically derived and examined. Our analysis shows that, similar to what was found before, for most of these events, the amount of twisted flux per AU in MCs is comparable with the total reconnection flux on the Sun, and the sign of the MC helicity is consistent with the sign of helicity of the solar source region judged from the geometry of postflare loops. Remarkably, we find that about one half of the 18 magnetic flux ropes, most of them being associated with erupting filaments, have a nearly uniform and relatively low twist distribution from the axis to the edge, and the majority of the other flux ropes exhibit very high twist near the axis, of up to  $\geq 5$  turns per AU, which decreases toward the edge. The flux ropes are therefore not linear force free. We also conduct detailed case studies showing the contrast of two events with distinct twist distribution in MCs as well as different flare and dimming characteristics in solar source regions, and discuss how reconnection geometry reflected in flare morphology may be related to the structure of the flux rope formed on the Sun. 03/08/2008, 05/28/2010, 08/04/2010, 03/30/2011, 06/05/2011, 08/05/2011, 09/09/2011, 09/17/2011, **2011 September 13-17**, 10/24/2011

### **Science Operation and Data Analysis Center of the Advanced Space-Based Solar Observatory (ASO-S) Mission.**

**Huang, Y.**, Li, Y., Liu, S. et al.

Sol Phys 299, 135 (2024).

<https://doi.org/10.1007/s11207-024-02368-x>

A reliable data analysis center plays a crucial role in the successful execution of a space mission. The Science Operation and Data analysis Center (SODC) of Advanced Space-based Solar Observatory (ASO-S) is a bridge between the science team of ASO-S and data users (Huang et al. 2019). ASO-S plays a crucial role in understanding the solar eruptions (such as flares and coronal mass ejections) and the magnetism behind them. In this article, we outline the current status of ASO-S, as well as its data products and analysis software. These resources aid in the enhanced understanding of solar magnetism and its associated energetic eruptions.

### **Formation and Dynamics in an Observed Preeruptive Filament**

The formation of filaments/prominences is still a debated topic. Many different processes have been proposed: levitation, injection of cool plasma, merging filaments, and cooling plasma in hot loops. We take the opportunity to make a multiwavelength analysis of the formation of an active-region filament, combining several UV and EUV observations including the new Ne VII 465 Å filtergrams provided by the Solar Upper Transition Region Imager on board the Space Advanced Technology satellite. The filament is mainly observed at the limb for 3 hr. It is progressively formed through a series of stages, including emergence and cooling of hot loops, reconnection between small filaments, material transfer in a large filament channel, and reconnection between filaments and emerged hot loops. From the observations at 465 Å, we find that the new-formed filaments show bright structures as in 304 Å, while the long-lived stable filaments display dark morphology as in 211 Å. This suggests that the plasma around 0.5 MK would be an essential component of new-formed filaments and the material temperature in filaments would be variable during their evolution. The filament formed by the recombination of two filaments and an emerged hot loop finally erupts. After reconnection, the final filament shows a highly twisted structure of both bright and dark strands, which is surrounded by several weak and dispersive looplike structures. This eruptive filament has a complex multichannel topology and covers a wide range of temperatures. **2022 September 23**

### **Statistical Study of Ejections in Coronal Hole Regions As Possible Sources of Solar Wind Switchbacks and Small-scale Magnetic Flux Ropes**

Nengyi **Huang**<sup>1,2</sup>, Sophia D'Anna<sup>1</sup>, and Haimin Wang<sup>1,2</sup>

**2023** ApJL 946 L17

<https://iopscience.iop.org/article/10.3847/2041-8213/acc0f1/pdf>

The omnipresence of transient fluctuations in the solar wind, such as switchbacks (SBs) and small-scale magnetic flux ropes (SMFRs), have been well observed by the in situ observation of Parker Solar Probe (PSP), yet their sources are not clear. Possible candidates fall into two categories: solar origin and in situ generation in the solar wind. Among the solar-origin scenarios, the small-scale activities (such as ejections and eruptions) in coronal hole (CH) regions, where solar wind originates, are suggested as candidates. Using full-disk extreme ultraviolet images from Atmospheric Imaging Assembly on board the Solar Dynamic Observatory, we identify small-scale ejections in CH regions during PSP Encounters 5, 7, and 8, and study their statistical properties. These ejections belong to two categories: standard jets and blowout jets. With 27,832 ejections identified in 24 days (about 2/3 of them are blowout jets), we updated the expected frequency for PSP to detect their counterparts in the heliospace. The ejections we identified are comparable to

the frequency of PSP-detected SMFRs, but they are insufficient to serve as the only producer of SBs or SB patches. Certain smaller events missed by this study, such as jetlets, may fill the gap. **2020-01-23, 2020-06-09-10, 2021-04-29**

## **The Kinematic Evolution of Erupting Structures in Confined Solar Flares**

Z. W. [Huang](#)<sup>1,2</sup>, X. Cheng<sup>1,2,3</sup>, and M. D. Ding<sup>1,2</sup>

**2020** ApJL 904 L2

<https://doi.org/10.3847/2041-8213/abc5b0>

In this Letter, we study the kinematic properties of ascending hot blobs associated with confined flares. Taking advantage of high-cadence extreme-ultraviolet images provided by the Atmospheric Imaging Assembly on board the Solar Dynamics Observatory, we find that for the 26 events selected here, the hot blobs are first impulsively accelerated outward, but then quickly slow down to motionlessness. Their velocity evolution is basically synchronous with the temporal variation of the Geostationary Operational Environmental Satellite soft X-ray flux of the associated flares, except that the velocity peak precedes the soft X-ray peak by minutes. Moreover, the duration of the acceleration phase of the erupting blobs is moderately correlated with that of the flare rise phase. For nine of the 26 cases, the erupting blobs even appear minutes prior to the onset of the associated flares. Our results show that a fraction of confined flares also involve the eruption of a magnetic flux rope, which sometimes is formed and heated prior to the flare onset. We suggest that the initiation and development of these confined flares are similar to that of eruptive ones, and the main difference may lie in the background field constraint, which is stronger for the former than for the latter.

## **Heating at the remote footpoints as a brake on jet flows along loops in the solar atmosphere**

[Zhenghua Huang](#), [Qingmin Zhang](#), [Lidong Xia](#), [Bo Li](#), [Zhao Wu](#), [Hui Fu](#)

ApJ **2020**

<https://arxiv.org/pdf/2007.04132.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ab96bd/pdf>

We report on observations of a solar jet propagating along coronal loops taken by the Solar Dynamics Observatory (SDO), the Interface Region Imaging Spectrograph (IRIS) and 1-m New Vacuum Solar Telescope (NVST). The ejecta of the jet consist of multi-thermal components and propagate with a speed greater than 100 km/s. Brightenings are found in the remote footpoints of the coronal loops having compact and round-shape in the H $\alpha$  images. The emission peak of the remote brightening in the Atmospheric Imaging Assembly (AIA) 94 Å passband lags 60 s behind that in the jet base. The brightenings in the remote footpoints are believed to be consequences of heating by nonthermal electrons, MHD waves and/or conduction front generated by the magnetic reconnection processes of the jet. The heating in the remote footpoints leads to extension of the brightening along the loops toward the jet base, which is believed to be the chromospheric evaporation. This apparently acts as a brake on the ejecta, leading to a deceleration in the range from 1.5 to 3 km s<sup>-2</sup> with an error of  $\sim 1.0$  km s<sup>-2</sup> when the chromospheric evaporation and the ejecta meet at locations near the loop apexes. The dynamics of this jet allows a unique opportunity to diagnose the chromospheric evaporation from the remote footpoints, from which we deduce a velocity in the range of 330–880 km/s. **4 May 2015**

## **Formation and Eruption of a Mini-sigmoid Originating in Coronal Hole**

Z. W. [Huang](#), [X. Cheng](#), [Y. N. Su](#), [T. Liu](#), [M. D. Ding](#)

**2020**

<https://arxiv.org/pdf/1912.10404.pdf>

In this paper, we study in detail the evolution of a mini-sigmoid originating in a cross-equatorial coronal hole, where the magnetic field is mostly open and seriously distinct from the closed background field above active-region sigmoids. The source region first appeared as a bipole, which subsequently experienced a rapid emergence followed by a long-term decay. Correspondingly, the coronal structure initially appeared as arc-like loops, then gradually sheared and transformed into continuously sigmoidal loops, mainly owing to flux cancellation near the polarity inversion line. The temperature of J-shaped and sigmoidal loops is estimated to be about  $2.0 \times 10^6$  K, greater than that of the background coronal hole. Using the flux-rope insertion method, we further reconstruct the nonlinear force-free fields that well reproduces the transformation of the potential field into a sigmoidal field. The fact that the sheared and sigmoidal loops are mainly concentrated at around the high-Q region implies that the reconnection most likely takes place there to form the sigmoidal field and heat the plasma. Moreover, the twist of sigmoidal field lines is estimated to be around 0.8, less than the values derived for the sigmoids from active regions. However, the sigmoidal flux may quickly enter an unstable regime at the very low corona ( $< 10$  Mm) due to the open background field. The results suggest that the mini-sigmoid, at least the one in our study, has the same formation and eruption process as the large-scale one, but is significantly influenced by the overlying flux. **2017 January 28-31**

## **Localized Microwave and EUV Bright Structures in an Eruptive Prominence**

Jing [Huang](#)<sup>1</sup>, Baolin Tan<sup>1</sup>, Satoshi Masuda<sup>2</sup>, Xin Cheng<sup>3</sup>, Susanta Kumar Bisoi<sup>1</sup>, and Victor Melnikov<sup>1</sup>

**2019** ApJ 874 176

<https://doi.org/10.3847/1538-4357/ab0e80>

We study a solar eruptive prominence with flare/coronal mass ejection (CME) event by microwave and extreme ultraviolet (EUV) observations. Its evolution can be divided into three phases: slow rise, fast expansion, and ejection. In the slow-rise phase, the prominence continuously twists for more than one hour with a patch of bright emission appearing around the top. When the north leg interacts with the local small-size loops, the fast expansion is initiated and the flare takes place there. The prominence grows rapidly, and a series of localized brightenings appear in the whole

prominence structure. Then the ejection occurs, followed by a CME. In microwave images, the brightness temperature ( $T_b$ ) at 17 and 34 GHz can be divided into three components. The strongest emission with  $T_b$  at 25,000–300,000 K is related to the bright flare region near the north foot. The medium  $T_b$  (10,000–20,000 K) outlines a series of small-scale bright enhancements scattering in the prominence, which are superposed on a weak background with  $T_b$  at 5000–10,000 K. These localized bright structures, first appearing at the top and then scattering in the entire prominence structure, are cospatial with EUV bright threads, fibers, or spots in both high- and low-temperature passbands. They display significant temporal variations on the scale of 3–5 s in the microwave observations. Thus, the plasma inside the prominence is spatially structured and changes with time in both density and temperature. This behavior could be interpreted in the frame of the small-scale and short-term process of energy releases in the twisted magnetic structure.

### **Magnetic braids in eruptions of a spiral structure in the solar atmosphere**

Zhenghua [Huang](#), [Lidong Xia](#), [Chris J. Nelson](#), [Jiajia Liu](#), [Thomas Wiegelmann](#), [Hui Tian](#), [James A. Klimchuk](#), [Yao Chen](#), [Bo Li](#)

ApJ **854** 80 **2018**

<https://arxiv.org/pdf/1801.05967.pdf>

<http://sci-hub.tw/http://iopscience.iop.org/0004-637X/854/2/80/>

We report on high-resolution imaging and spectral observations of eruptions of a spiral structure in the transition region, which were taken with the Interface Region Imaging Spectrometer (IRIS), the Atmospheric Imaging Assembly (AIA) and the Helioseismic and Magnetic Imager (HMI). The eruption coincided with the appearance of two series of jets, with velocities comparable to the Alfvén speeds in their footpoints. Several pieces of evidence of magnetic braiding in the eruption are revealed, including localized bright knots, multiple well-separated jet threads, transition region explosive events and the fact that all these three are falling into the same locations within the eruptive structures.

Through analysis of the extrapolated three-dimensional magnetic field in the region, we found that the eruptive spiral structure corresponded well to locations of twisted magnetic flux tubes with varying curl values along their lengths. The eruption occurred where strong parallel currents, high squashing factors, and large twist numbers were obtained. The electron number density of the eruptive structure is found to be  $\sim 3 \times 10^{12} \text{ cm}^{-3}$ , indicating that significant amount of mass could be pumped into the corona by the jets. Following the eruption, the extrapolations revealed a set of seemingly relaxed loops, which were visible in the AIA 94 Å channel indicating temperatures of around 6.3 MK. With these observations, we suggest that magnetic braiding could be part of the mechanisms explaining the formation of solar eruption and the mass and energy supplement to the corona. **2014 June 11**

### **Explosive events on subarcsecond scale in IRIS observations: a case study**

Zhenghua [Huang](#), Maria S. Madjarska, Lidong Xia, J. G. Doyle, Klaus Galsgaard, Hui Fu

ApJ **797** 88 **2014**

<http://star.arm.ac.uk/preprints/2014/659.pdf>

We present study of a typical explosive event (EE) at subarcsecond scale witnessed by strong non-Gaussian profiles with blue- and red-shifted emission of up to 150 km/s seen in the transition-region Si iv 1402.8 Å, and the chromospheric Mg ii k 2796.4 Å and C ii 1334.5 Å observed by the Interface Region Imaging Spectrograph (IRIS) at unprecedented spatial and spectral resolution. For the first time an EE is found to be associated with very small-scale ( $\sim 120$  km wide) plasma ejection followed by retraction in the chromosphere. These small-scale jets originate from a compact bright-point-like structure of  $\sim 1.5''$  size as seen in the IRIS 1330 Å images. SDO/AIA and SDO/HMI co-observations show that the EE lies in the footpoint of a complex loop-like brightening system. The EE is detected in the higher temperature channels of AIA 171 Å, 193 Å, and 131 Å suggesting that it reaches a higher temperature of  $\log T = 5.36 \pm 0.06$  (K). Brightenings observed in the AIA channels with durations  $90 \sim 120$  s are probably caused by the plasma ejections seen in the chromosphere. The wings of the C ii line behave in a similar manner to the Si iv's, indicating close formation temperatures, while the Mg ii k wings show additional Doppler-shifted emission. Magnetic convergence or emergence followed by cancellation at a rate of  $5 \sim 10^{14} \text{ Mx/s}$  is associated with the EE region. The combined changes of the locations and the flux of different magnetic patches suggest that magnetic reconnection must have taken place. Our results challenge several theories put forward in the past to explain non-Gaussian line profiles, i.e., EEs. Our case study on its own, however, cannot reject these theories, thus further in-depth studies on the phenomena producing EEs are required. **2013 October 4**

### **H $\alpha$ spectroscopy and multi-wavelength imaging of a solar flare caused by filament eruption**

Z. [Huang](#), M. S. Madjarska, K. Koleva, J. G. Doyle, P. Duchlev, M. Dechev, and K. Reardon

E-print, May 2014; A&A

<http://star.arm.ac.uk/preprints/2014/652.pdf>

We study a sequence of eruptive events including filament eruption, a GOES C4.3 flare and a coronal mass ejection. We aim to identify the possible trigger(s) and precursor(s) of the filament destabilisation; investigate flare kernel characteristics; flare ribbons/kernels formation and evolution; study the interrelation of the filament-eruption/flare/coronal-mass-ejection phenomena as part of the integral active-region magnetic field configuration; determine H  $\alpha$  line profile evolution during the eruptive phenomena. Multi-instrument observations are analysed including H  $\alpha$  line profiles, speckle images at H  $\alpha$   $-0.8$  Å and H  $\alpha$   $+0.8$  Å from IBIS at DST/NSO, EUV images and magnetograms from the SDO, coronagraph images from STEREO and the X-ray flux observations from FERMI and GOES. We establish that the filament destabilisation and eruption are the main trigger for the flaring activity. A

surge-like event with a circular ribbon in one of the filament footpoints is determined as the possible trigger of the filament destabilisation. Plasma draining in this footpoint is identified as the precursor for the filament eruption. A magnetic flux emergence prior to the filament destabilisation followed by a high rate of flux cancellation of  $1.34 \times 10^{16} \text{ Mx s}^{-1}$  is found during the flare activity. The flare X-ray lightcurves reveal three phases that are found to be associated with three different ribbons occurring consecutively. A kernel from each ribbon is selected and analysed. The kernel lightcurves and  $H \alpha$  line profiles reveal that the emission increase in the line centre is stronger than that in the line wings. A delay of around 5-6 mins is found between the increase in the line centre and the occurrence of red asymmetry. Only red asymmetry is observed in the ribbons during the impulsive phases. Blue asymmetry is only associated with the dynamic filament. **11 Nov 2010**

## INITIATION AND EARLY DEVELOPMENT OF THE 2008 APRIL 26 CORONAL MASS EJECTION

J. [Huang](#)<sup>1,2</sup>, P. D´emoulin<sup>2</sup>, M. Pick<sup>2</sup>, F. Auch`ere<sup>3</sup>, Y. H. Yan<sup>1</sup>, and A. Bouteille<sup>2</sup>

*Astrophysical Journal*, 729:107 (10pp), **2011**, [File](#)

We present a detailed study of a coronal mass ejection (CME) with high temporal cadence observations in radio and extreme-ultraviolet (EUV). The radio observations combine imaging of the low corona with radio spectra in the outer corona and interplanetary space. The EUV observations combine the three points of view of the *STEREO* and *SOHO* spacecraft. The beginning of the CME initiation phase is characterized by emissions that are signatures of the reconnection of the outer part of the erupting configuration with surrounding magnetic fields. Later on, a main source of emission is located in the core of the active region. It is an indirect signature of the magnetic reconnection occurring behind the erupting flux rope. Energetic particles are also injected in the flux rope and the corresponding radio sources are detected. Other radio sources, located in front of the EUV bright front, trace the interaction of the flux rope with the surrounding fields. Hence, the observed radio sources enable us to detect the main physical steps of the CME launch. We find that imaging radio emissions in the metric range permits us to trace the extent and orientation of the flux rope which is later detected in interplanetary space. Moreover, combining the radio images at various frequencies with fast EUV imaging permits us to characterize in space and time the processes involved in the CME launch.

## Chapter 9 - High-Energy Solar Physics

**Review**

H.S. [Hudson](#) and A.L. MacKinnon

In: *The Sun as a Guide to Stellar Physics* **Book**

Eds. Oddbjørn Engvold, Jean-Claude Vial, and Andrew Skumanich

Elsevier, November **2018**

<https://www.sciencedirect.com/book/9780128143346/the-sun-as-a-guide-to-stellar-physics>

This chapter deals generally with the high-energy astrophysics of the Sun, specifically with solar flares and coronal mass ejections (CMEs), but it also touches on the whole range of nonthermality or departures from Maxwellian distributions in solar plasmas. Radio, x-ray, and  $\gamma$ -ray observations provide primary remote-sensing observations of these departures, but such signatures can be hidden by brighter thermal emissions that may not be as fundamental in physics events. The solar paradigm for flare/CME development appears to match many of the new stellar observations of similar phenomena, but the limitations of observational sensitivity mean that we have few direct observations of the expected hard x-rays and none at all of the  $\gamma$ -rays that could confirm this.

## Momentum Distribution in Solar Flare Processes

H. S. [Hudson](#), L. Fletcher, G. H. Fisher, W. P. Abbett and A. Russell

*Solar Physics*, Volume 277, Number 1, 77-88, **2012**

We discuss the consequences of momentum conservation in processes related to solar flares and coronal mass ejections (CMEs), in particular describing the relative importance of vertical impulses that could contribute to the excitation of seismic waves (“sunquakes”). The initial impulse associated with the primary flare energy transport in the impulsive phase contains sufficient momentum, as do the impulses associated with the acceleration of the evaporation flow (the chromospheric shock) or the CME itself. We note that the deceleration of the evaporative flow, as coronal closed fields arrest it, will tend to produce an opposite impulse, reducing the energy coupling into the interior. The actual mechanism of the coupling remains unclear at present.

<https://sci-hub.tw/https://iopscience.iop.org/article/10.3847/1538-4357/ab974d>

<https://arxiv.org/pdf/2010.04042.pdf>

High-resolution observations of dynamic phenomena give insight into properties and processes that govern the low solar atmosphere. We present the analysis of jet-like phenomena emanating from a penumbral foot-point in active region (AR) 12192 using imaging and spectral observations from the Interface Region Imaging Spectrograph (IRIS) and the Atmospheric Imaging Assembly (AIA) on board the Solar Dynamics Observatory. These jets are associated with line-of-sight (LoS) Doppler speeds of  $\pm 10$ –22 km s<sup>-1</sup> and bright fronts which seem to move across the Plane-of-Sky (PoS) at speeds of 23–130 km s<sup>-1</sup>. Such speeds are considerably higher than the expected sound speed in the chromosphere. The jets have signatures which are visible both in the cool and hot channels of IRIS and AIA. Each jet lasts on average 15 minutes and occur 5–7 times over a period of 2 hours. Possible mechanisms to explain this phenomenon are suggested, the most likely of which involve p-mode or Alfv n wave shock trains impinging on the transition region (TR) and corona as a result of steepening photospheric wavefronts or gravity waves. **Oct. 25, 2014**

### Automated Detection of Solar Eruptions

Neal **Hurlburt**

Journal of Space Weather and Space Climate, 5, A39 2015 **Open Access**

<http://arxiv.org/pdf/1504.03395v1.pdf>

Observation of the solar atmosphere reveals a wide range of motions, from small scale jets and spicules to global-scale coronal mass ejections. Identifying and characterizing these motions are essential to advancing our understanding the drivers of space weather. Both automated and visual identifications are currently used in identifying CMEs. To date, eruptions near the solar surface (which may be precursors to CMEs) have been identified primarily by visual inspection. Here we report on EruptionPatrol (EP): a software module that is designed to automatically identify eruptions from data collected by SDO/AIA. We describe the method underlying the module and compare its results to previous identifications found in the Heliophysics Event Knowledgebase. EP identifies eruptions events that are consistent with those found by human annotations, but in a significantly more consistent and quantitative manner. Eruptions are found to be distributed within 15Mm of the solar surface. They possess peak speeds ranging from 4 to 100 km/sec and display a power-law probability distribution over that range. These characteristics are consistent with previous observations of prominences. **2010-Aug-01**

### Cross-field Diffusion Effects on Particle Transport in a Solar Coronal Flux Rope

Solar energetic particles associated with solar flares and coronal mass ejections (CMEs) are key agents of space weather phenomena, posing severe threats to spacecraft and astronauts. Recent observations by Parker Solar Probe indicate that the magnetic flux ropes of a CME can trap energetic particles and act as barriers, preventing other particles from crossing. In this Letter, we introduce the novel COCONUT+PARADISE model to investigate the confinement of energetic particles within a flux rope and the effects of cross-field diffusion (CFD) on particle transport in the solar corona, particularly in the presence of a CME. Using the global magnetohydrodynamic coronal model COolfluid COroNal Unstructured (COCONUT), we generate background configurations containing a CME modeled as a Titov–D moulin flux rope (TDFR). We then utilize the particle transport code PArticle Radiation Asset Directed at Interplanetary Space Exploration (PARADISE) to inject monoenergetic 100 keV protons inside one of the TDFR legs near its footpoint and evolve the particles through the COCONUT backgrounds. To study CFD, we employ two different approaches regarding the perpendicular proton mean free path (MFP): a constant MFP and a Larmor radius-dependent MFP. We contrast these results with those obtained without CFD. While particles remain fully trapped within the TDFR without CFD, we find that even relatively small perpendicular MFP values allow particles on the outer layers to escape. In contrast, the initially interior trapped particles stay largely confined. Finally, we highlight how our model and this Letter's results are relevant for future research on particle acceleration and transport in an extended domain encompassing both the corona and inner heliosphere.

## **Automated detection of coronal mass ejections in three-dimensions using multi-viewpoint observations**

J. [Hutton](#) and H. Morgan

A&A 599, A68 (2017)

<http://www.aanda.org/articles/aa/pdf/2017/03/aa29516-16.pdf>

A new, automated method of detecting coronal mass ejections (CMEs) in three dimensions for the LASCO C2 and STEREO COR2 coronagraphs is presented. By triangulating isolated CME signal from the three coronagraphs over a sliding window of five hours, the most likely region through which CMEs pass at  $5 R_{\odot}$  is identified. The centre and size of the region gives the most likely direction of propagation and approximate angular extent. The Automated CME Triangulation (ACT) method is tested extensively using a series of synthetic CME images created using a wireframe flux rope density model, and on a sample of real coronagraph data; including halo CMEs. The accuracy of the angular difference ( $\sigma$ ) between the detection and true input of the synthetic CMEs is  $\sigma = 7.14^{\circ}$ , and remains acceptable for a broad range of CME positions relative to the observer, the relative separation of the three observers and even through the loss of one coronagraph. For real data, the method gives results that compare well with the distribution of low coronal sources and results from another instrument and technique made further from the Sun. The true three dimension (3D)-corrected kinematics and mass/density are discussed. The results of the new method will be incorporated into the CORIMP database in the near future, enabling improved space weather diagnostics and forecasting. **14th January, 2009, 27th January, 2012, 1st September, 2012, 2013-07-26, 26th October, 2013**

## **ERUPTING FILAMENTS WITH LARGE ENCLOSING FLUX TUBES AS SOURCES OF HIGH-MASS THREE-PART CMEs, AND ERUPTING FILAMENTS IN THE ABSENCE OF ENCLOSING FLUX TUBES AS SOURCES OF LOW-MASS UNSTRUCTURED CMEs**

Joe [Hutton](#) and Huw Morgan

2015 ApJ 813 35

The 3-part appearance of many coronal mass ejections (CMEs) arising from erupting filaments emerges from a large magnetic flux tube structure, consistent with the form of the erupting filament system. Other CMEs arising from erupting filaments lack a clear 3-part structure and reasons for this have not been researched in detail. This paper aims to further establish the link between CME structure and the structure of the erupting filament system and to investigate whether CMEs which lack a 3-part structure have different eruption characteristics. A survey is made of **221 near-limb filament eruptions observed from 2013 May 03 to 2014 June 30** by Extreme UltraViolet (EUV) imagers and coronagraphs. Ninety-two filament eruptions are associated with 3-part structured CMEs, 41 eruptions are associated with unstructured CMEs. The remaining 88 are categorized as failed eruptions. For 34% of the 3-part CMEs, processing applied to EUV images reveals the erupting front edge is a pre-existing loop structure surrounding the filament, which subsequently erupts with the filament to form the leading bright front edge of the CME. This connection is confirmed by a flux-rope density model. Furthermore, the unstructured CMEs have a narrower distribution of mass compared to structured CMEs, with total mass comparable to the mass of 3-part CME cores. This study supports the interpretation of 3-part CME leading fronts as the outer boundaries of a large pre-existing flux tube. Unstructured (non 3-part) CMEs are a different family to structured CMEs, arising from the eruption of filaments which are compact flux tubes in the absence of a large system of enclosing closed field.

## **Comparison Between Radio Loud and Radio Quiet Fast CMEs: A Reason for Radio Quietness**

[M. Syed Ibrahim](#), [E. Ebenezer](#) & [A. Shanmugaraju](#)

[Solar Physics](#) volume 298, Article number: 59 (2023)

<https://doi.org/10.1007/s11207-023-02151-4>

It is well known that fast CMEs are mostly associated with magnetohydrodynamic (MHD) shocks in the solar corona, forming type-II radio bursts. However, the absence of type-II radio bursts is not uncommon. Herein, we aim to analyze the differences between the radio loud (RL) and radio quiet (RQ) fast Coronal Mass Ejections (CMEs) (speed  $\geq 900 \text{ km s}^{-1}$ ) during Solar Cycle 24 (2008 – 2021). From the 309 fast CMEs, we could identify 143 events with a known source origin on the visible disk (Earth view). We identified the associated flares/CMEs for 143 events using running-difference images from (i) Solar Dynamic Observatory/Atmospheric Imaging Assembly (SDO/AIA) and (ii) Large Angle Spectrometric Coronagraph (LASCO) observations. Among these 143 events, RQ and RL groups have 70 and 73 events, respectively. CALLISTO and Wind/WAVES observations are used to identify these RL and RQ sets. We analyzed the possibilities of streamer-CME and CME-CME interaction. In this study, we report the important differences between RL and RQ CMEs and the underlying reasons for the radio quietness of fast CMEs. In the LASCO field of view, the majority of RL CMEs (almost 90%) interacted with streamers and/or pre-CMEs, whereas only 25% of RQ CMEs did the same, and there was no pre-CME interaction. The observational evidence led to the conclusion that substantial density perturbation/interaction increases the probability of production of type-II radio emissions by the shock of RL CMEs.

## **Investigation of two coronal mass ejections from circular ribbon source region: Origin, Sun-Earth propagation and Geo-effectiveness**

Research in Astronomy and Astrophysics

2021

<https://arxiv.org/pdf/2110.06547.pdf>

In this article, we compare the properties of two coronal mass ejections (CMEs) that show similar source region characteristics but different evolutionary behavior in the later phases. We discuss the two events in terms of their near-Sun characteristics, interplanetary evolution, and geo-effectiveness. We carefully analyzed the initiation and propagation parameters of these events to establish the precise CME-ICME connection and their near-Earth consequences. The First event was associated with poor geo-magnetic storm disturbance index (Dst  $\approx$ -20 nT) while the second event is associated with intense geomagnetic storm of DST  $\approx$ -119 nT. The configuration of the sunspots in the active regions and their evolution are observed by Helioseismic and Magnetic Imager (HMI). For source region imaging, we rely on data obtained from Atmospheric Imaging Assembly (AIA) on board Solar Dynamics Observatory (SDO) and H $\alpha$  filtergrams from Solar Tower Telescope at Aryabhata Research Institute of Observational Sciences (ARIES). For both the CMEs, flux rope eruptions from the source region triggered flares of similar intensities ( $\approx$ M1). At the solar source region of the eruptions, we observed circular ribbon flare (CRF) for both the cases, suggesting fan-spine magnetic configuration in the active region corona. **2013 May 02, 2014 February 16**

## **Interplanetary Coronal Mass Ejections During Solar Cycles 23 and 24: Sun–Earth Propagation Characteristics and Consequences at the Near-Earth Region**

M. Syed **Ibrahim**, Bhuwan Joshi, K.-S. Cho, R.-S. Kim, Y.-J. Moon

[Solar Physics](#) May 2019, 294:54 **File**

[sci-hub.se/10.1007/s11207-019-1443-5](http://sci-hub.se/10.1007/s11207-019-1443-5)

In this article, we present a statistical study probing the relation between interplanetary coronal mass ejections (ICMEs) observed at 1 AU and their corresponding coronal mass ejections at the near-Sun region. The work encompasses the ICME activity that occurred during Solar Cycles 23 and 24 (1996 – 2017) while presenting an overall picture of ICME events during the complete Solar Cycle 24 for the first time. The importance of this study further lies in comparing two subsets of ICMEs, i.e. magnetic clouds (MCs) and ejecta (EJ), to explore how the observed structures of ICMEs at 1 AU could be associated with the properties of CMEs during their launch at the Sun. We find that, although Solar Cycle 24 saw a significant reduction in the number of ICME events compared to the previous cycle, the fraction of MCs was much higher during Cycle 24 than Cycle 23 (60% versus 41%). In general, the ICME transit-time decreases with the increase in the CME initial speed, although a broad range of transit times were observed for a given CME speed. We also find that the high-speed ICMEs ( $\geq$ 500 kms $^{-1}$ ) form a distinct group in terms of the deficit in their transit times when compared with low-speed events ( $\leq$ 500 kms $^{-1}$ ), which means that high-speed ICMEs acquire a much higher internal energy from the source active regions during the initiation process that effectively overcomes the aerodynamic drag force while they transit in the interplanetary medium. The CME propagation from the Sun to the near-Earth environment shows both an overall positive and negative acceleration (i.e. deceleration), although the acceleration is limited to only low-speed CMEs that are launched with a speed comparable with or less than the mean solar wind speed ( $\approx$ 400–450 kms $^{-1}$ ). Within a given cycle, the similarities of MC and EJ profiles with respect to the CME–ICME speed relation as well as interplanetary acceleration support the hypothesis that all CMEs have a flux rope structure and that the trajectory of the CMEs essentially determines the observed ICME structure at 1 AU. **13 December 2006, 22 June 2015**

## **Properties and relationship between solar eruptive flares and Coronal Mass Ejections during rising phase of Solar Cycles 23 and 24**

M.Syed **Ibrahim**, [A.Shanmugaraju](#), [Y.-J.Moon](#), [B.Vrsnak](#), [S.Umapathy](#)

[Advances in Space Research](#) Volume 61, Issue 1, 1 January 2018, Pages 540-551

[https://ac.els-cdn.com/S027311771730666X/1-s2.0-S027311771730666X-main.pdf?\\_tid=4faa2d64-de43-11e7-8054-00000aab0f01&acdnat=1512976814\\_f6b3fddde3a016b209ccb968996e7adf](https://ac.els-cdn.com/S027311771730666X/1-s2.0-S027311771730666X-main.pdf?_tid=4faa2d64-de43-11e7-8054-00000aab0f01&acdnat=1512976814_f6b3fddde3a016b209ccb968996e7adf)

Statistical relationship between major flares and the associated CMEs during rising phases of Solar Cycles 23 and 24 are studied. Totally more than 6000 and 10,000 CMEs were observed by SOHO/LASCO (Solar and Heliospheric Observatory/Large Angle Spectrometric Coronagraph) during 23rd [May 1996–June 2002] and 24th [December 2008–December 2014] solar cycles, respectively. In particular, we studied the relationship between properties of flares and CMEs using the limb events (longitude 70–85°) to avoid projection effects of CMEs and partial occultation of flares that occurred near 90°. After selecting a sample of limb flares, we used certain spatial and temporal constraints to find the flare-CME pairs. Using these constraints, we compiled 129 events in Solar Cycle 23 and 92 events in Solar Cycle 24. We compared the flare-CME relationship in the two solar cycles and no significant differences are found between the two cycles. We only found out that the CME mean width was slightly larger and the CME mean acceleration was slightly higher in cycle 24, and that there was somewhat a better relation between flare flux and CME deceleration in cycle 24 than in cycle 23.

## **Propagation of Coronal Mass Ejections Observed During the Rising Phase of Solar Cycle 24**

M. Syed **Ibrahim**, P. K. Manoharan, A. Shanmugaraju

[Solar Physics](#) September 2017, 292:133 **File**

In this study, we investigate the interplanetary consequences and travel time details of 58 coronal mass ejections (CMEs) in the Sun–Earth distance. The CMEs considered are halo and partial halo events of width  $>120^\circ$ . These CMEs occurred during 2009 – 2013, in the ascending phase of the Solar Cycle 24. Moreover, they are Earth-directed events that originated close to the centre of the solar disk (within about  $\pm 30^\circ$  from the Sun’s centre) and propagated approximately along the Sun–Earth line. For each CME, the onset time and the initial speed have been

estimated from the white-light images observed by the LASCO coronagraphs onboard the SOHO space mission. These CMEs cover an initial speed range of  $\sim 260\text{--}2700\text{ km s}^{-1}$ . For these CMEs, the associated interplanetary shocks (IP shocks) and interplanetary CMEs (ICMEs) at the near-Earth environment have been identified from *in-situ* solar wind measurements available at the OMNI data base. Most of these events have been associated with moderate to intense IP shocks. However, these events have caused only weak to moderate geomagnetic storms in the Earth's magnetosphere. The relationship of the travel time with the initial speed of the CME has been compared with the observations made in the previous Cycle 23, during 1996–2004. In the present study, for a given initial speed of the CME, the travel time and the speed at 1 AU suggest that the CME was most likely not much affected by the drag caused by the slow-speed dominated heliosphere. Additionally, the weak geomagnetic storms and moderate IP shocks associated with the current set of Earth-directed CMEs indicate magnetically weak CME events of Cycle 24. The magnetic energy that is available to propagate CME and cause geomagnetic storm could be significantly low. **15 March 2013.**

**Table 1** Observational parameters of 58 CME events (eight interacting CMEs are marked with asterisk symbols).

## A New Solar Imaging System for Observing High-Speed Eruptions: Solar Dynamics Doppler Imager (SDDI)

Kiyoshi [Ichimoto](#), Takako T. Ishii, Kenichi Otsuji, [Goichi Kimura](#)...

Sol Phys (2017) 292: 63. doi:10.1007/s11207-017-1082-7

A new solar imaging system was installed at Hida Observatory to observe the dynamics of flares and filament eruptions. The system (Solar Dynamics Doppler Imager; SDDI) takes full-disk solar images with a field of view of  $2520\text{ arcsec} \times 2520\text{ arcsec}$  at multiple wavelengths around the  $\text{H}\alpha$  line at  $6562\text{ \AA}$ . Regular operation was started in May 2016, in which images at 73 wavelength positions spanning from  $\text{H}\alpha - 9\text{ \AA}$  to  $\text{H}\alpha + 9\text{ \AA}$  are obtained every 15 seconds. The large dynamic range of the line-of-sight velocity measurements ( $\pm 400\text{ km s}^{-1}$ ) allows us to determine the real motions of erupting filaments in 3D space. It is expected that SDDI provides unprecedented datasets to study the relation between the kinematics of filament eruptions and coronal mass ejections (CME), and to contribute to the real-time prediction of the occurrence of CMEs that cause a significant impact on the space environment of the Earth.

## Analysis of a long-duration AR throughout five solar rotations: Magnetic properties and ejective events

Francisco A. [Iglesias](#), [Hebe Cremades](#), [Luciano A. Merenda](#), [Cristina H. Mandrini](#), [Fernando M. Lopez](#), [Marcelo C. Lopez Fuentes](#), [Ignacio Ugarte-Urra](#)

Advances in Space Research **2019**

<https://arxiv.org/pdf/1911.01265.pdf>

Coronal mass ejections (CMEs), which are among the most magnificent solar eruptions, are a major driver of space weather and can thus affect diverse human technologies. Different processes have been proposed to explain the initiation and release of CMEs from solar active regions (ARs), without reaching consensus on which is the predominant scenario, and thus rendering impossible to accurately predict when a CME is going to erupt from a given AR. To investigate AR magnetic properties that favor CMEs production, we employ multi-spacecraft data to analyze a long duration AR (NOAA 11089, 11100, 11106, 11112 and 11121) throughout its complete lifetime, spanning five Carrington rotations from **July to November 2010**. We use data from the Solar Dynamics Observatory to study the evolution of the AR magnetic properties during the five near-side passages, and a proxy to follow the magnetic flux changes when no magnetograms are available, i.e. during far-side transits. We characterized the angular widths, speeds and masses of 108 CMEs that we associated to the AR, when examining a 124-day period. Such an ejectivity tracking was possible thanks to the multiviewpoint images provided by the STEREO and SOHO in a quasi-quadrate configuration. We also inspected the X-ray flares registered by the GOES satellite and found 162 to be associated to the AR under study. Given the substantial number of ejections studied, we use a statistical approach instead of a single-event analysis. We found three well defined periods of very high CMEs activity and two periods with no mass ejections that are preceded or accompanied by characteristic changes in the AR magnetic flux, free magnetic energy and/or presence of electric currents. Our large sample of CMEs and long term study of a single AR, provide further evidence relating AR magnetic activity to CME and Flare production. **19-23 July 2010, 2-28 Aug 2010, 30 Aug-4 Sep 2010, 5-17 Sep 2010, 8-16 Oct 2010, 17-23 Oct 2010, 28 Oct-6 Nov 2010, 10-15 Nov 2010, 17 Nov 2010**

**Table 1:** Identification numbers (ID), dates (in dd/mm format) and times of 108 white-light ejective events (CMEs), originating from the AR under study.

## A Three-dimensional Magnetohydrodynamic Simulation of the Formation of Solar Chromospheric Jets with Twisted Magnetic Field Lines

H. [Iijima](#)<sup>1</sup> and T. Yokoyama

2017 ApJ 848 38

This paper presents a three-dimensional simulation of chromospheric jets with twisted magnetic field lines. Detailed treatments of the photospheric radiative transfer and the equations of state allow us to model realistic thermal convection near the solar surface, which excites various MHD waves and produces chromospheric jets in the simulation. A tall chromospheric jet with a maximum height of 10–11 Mm and lifetime of 8–10 minutes is formed

above a strong magnetic field concentration. The magnetic field lines are strongly entangled in the chromosphere, which helps the chromospheric jet to be driven by the Lorentz force. The jet exhibits oscillatory motion as a natural consequence of its generation mechanism. We also find that the produced chromospheric jet forms a cluster with a diameter of several Mm with finer strands. These results imply a close relationship between the simulated jet and solar spicules.

### **Effect of coronal temperature on the scale of solar chromospheric jets**

H. [Iijima](#), T. Yokoyama

ApJL 812 L30 2015

<http://arxiv.org/pdf/1509.06677v1.pdf>

We investigate the effect of coronal temperature on the formation process of solar chromospheric jets using two-dimensional magnetohydrodynamic simulations of the region from the upper convection zone to the lower corona. We develop a new radiative magnetohydrodynamic code for the dynamic modeling of the solar atmosphere, employing a LTE equation of state, optically thick radiative loss in the photosphere, optically thin radiative loss in the chromosphere and the corona, and thermal conduction along the magnetic field lines. Many chromospheric jets are produced in the simulations by shock waves passing through the transition region. We find that these jets are projected farther outward when the coronal temperature is lower (similar to that in coronal holes) and shorter when the coronal temperature is higher (similar to that in active regions). When the coronal temperature is high, the deceleration of the chromospheric jets is consistent with the model in which deceleration is determined by the periodic chromospheric shock waves. However, when the coronal temperature is low, the gravitational deceleration becomes more important and the chromospheric jets approach ballistic motion.

### **Simple Model for Temporal Variations of H $\alpha$ Spectrum by an Eruptive Filament from a Superflare on a Solar-type Star**

[Kai Ikuta](#), [Kazunari Shibata](#)

ApJ 2024

<https://arxiv.org/pdf/2401.04279.pdf>

Flares are intense explosions on the solar and stellar surfaces, and solar flares are sometimes accompanied by filament or prominence eruptions. Recently, a large filament eruption associated with a superflare on a solar-type star EK Dra was discovered for the first time. The absorption of the H $\alpha$  spectrum initially exhibited a blueshift with the velocity of 510 (km s<sup>-1</sup>), and decelerated in time probably due to gravity. Stellar coronal mass ejections (CMEs) were thought to occur, although the filament eruption did not exceed the escape velocity under the surface gravity. To investigate how such filament eruption occur and whether CMEs are associated with the filament eruption or not, we perform one-dimensional hydrodynamic simulation of the flow along an expanding magnetic loop emulating a filament eruption under adiabatic and unsteady conditions. The loop configuration and expanding velocity normal to the loop are specified in the configuration parameters, and we calculate the line-of-sight velocity of the filament eruption using the velocities along and normal to the loop. We found that (i) the temporal variations of the H $\alpha$  spectrum for EK Dra can be explained by falling filament eruption in the loop with longer time and larger spatial scales than that of the Sun, and (ii) the stellar CMEs are also thought to be associated with the filament eruption from the superflare on EK Dra, because the rarefied loop unobserved in the H $\alpha$  spectrum needs to expand faster than the escape velocity, whereas the observed filament eruption does not exceed the escape velocity.

### **Energy release from a stream of infalling prominence debris on 2011 September 7-8**

Andrew R. [Inglis](#), [Holly R. Gilbert](#), [Leon Ofman](#)

ApJ 2017

<https://arxiv.org/pdf/1708.01555.pdf>

In recent years high-resolution and high-cadence EUV imaging has revealed a new phenomenon, impacting prominence debris, where prominence material from failed or partial eruptions can impact the lower atmosphere and release energy. We report a clear example of energy release and EUV brightening due to infalling prominence debris that occurred on **2011 September 7-8**. The initial eruption of prominence material was associated with an X1.8-class flare from AR11283, occurring at 22:30 UT on 2011 September 7. Subsequently, a semi-continuous stream of this material was observed to return to the solar surface with a velocity  $v > 150$  km/s, impacting a region remote from the original active region between 00:20 - 00:40 UT on 2011 September 8. Using SDO/AIA, the differential emission measure of the plasma was estimated throughout this brightening event. We found that the radiated energy of the impacted plasma was  $L \sim 10^{27}$  ergs, while the thermal energy peaked at  $\sim 10^{28}$  ergs. From this we were able to determine the mass content of the debris to be in the range  $2 \times 10^{14} < m < 2 \times 10^{15}$  g. Given typical prominence masses, the likely debris mass is towards the lower end of this range. This clear example of a prominence debris event shows that significant energy release takes place during these events, and that such impacts may be used as a novel diagnostic tool for investigating prominence material properties.

### **Analysis of UV and EUV emission from impacts on the Sun after 2011 June 7 eruptive flare**

Davina [Innes](#), Philipp Heinrich, Bernd Inhester, Li-Jia Guo

A&A 2016

<http://arxiv.org/pdf/1603.06379v1.pdf>

On **2011 June 7** debris from a large filament eruption fell back to the Sun causing bright ultraviolet (UV) and extreme ultraviolet (EUV) splashes across the surface. These impacts may give clues on the process of stellar accretion. The aim is to investigate how the impact emission is influenced by structures in the falling ejecta and at the solar surface. We determine the UV and EUV light curves of a sample of impacts. The ballistic impact velocity is estimated from the ejection and landing times and, where possible, compared with the velocity derived by tracking the downflows in SDO/AIA and STEREO/EUVI images. Estimates of the column density before impact are made from the darkness of the falling plasma in the 193 Å channel. The impact velocities were between 230 and 450 km/s. All impacts produced bright EUV emission at the impact site but bright UV was only observed when the impacting fragments reached the chromosphere. There was no clear relation between EUV intensity and kinetic energy. Low UV to EUV intensity ratios ( $I\{UV\}/I\{EUV\}$ ) were seen (i) from impacts of low column-density fragments, (ii) when splashes, produced by some impacts, prevented subsequent fragments from reaching the chromosphere, and (iii) from an impact in an active region. The earliest impacts with the lowest velocity ( $\sim 250$  km/s) had the highest  $I\{UV\}/I\{EUV\}$ . The  $I\{UV\}/I\{EUV\}$  decreases with impact velocity, magnetic field at the impact site, and EUV ionising flux. Many of the infalling fragments dissipate above the chromosphere either due to ionisation and trapping in magnetic structures, or to them encountering a splash from an earlier impact. If the same happens in accreting stars then the reduced X-ray compared to optical emission that has been observed is more likely due to absorption by the trailing stream than locally at the impact site.

## **Observations of solar X-ray and EUV jets and their related phenomena** Review

Davina **Innes**, Radoslav Bucik, Li-Jia Guo, Nariaka Nitte

Astronomische Nachrichten **2016**

<http://arxiv.org/pdf/1603.03258v1.pdf>

Solar jets are fast-moving, elongated brightenings related to ejections seen in both images and spectra on all scales from barely visible chromospheric jets to coronal jets extending up to a few solar radii. The largest, most powerful jets are the source of type III radio bursts, energetic electrons and ions with greatly enhanced 3He and heavy element abundances. The frequent coronal jets from polar and equatorial coronal holes may contribute to the solar wind. The primary acceleration mechanism for all jets is believed to be release of magnetic stress via reconnection; however the energy buildup depends on the jets' source environment. In this review, we discuss how certain features of X-ray and EUV jets, such as their repetition rate and association with radio emission, depends on their underlying photospheric field configurations (active regions, polar and equatorial coronal holes, and quiet Sun). **3 Aug 2010, 2012 July 02, 2014 May 16**

## **Observations of Supra-arcade Fans: Instabilities at the Head of Reconnection Jets**

D. E. **Innes**<sup>1,2</sup>, L.-J. Guo<sup>1,2</sup>, A. Bhattacharjee<sup>2,3,4</sup>, Y.-M. Huang<sup>2,3,4</sup>, and D. Schmit

**2014 ApJ 796 27.**

Supra-arcade fans are bright, irregular regions of emission that develop during eruptive flares above flare arcades. The underlying flare arcades are thought to be a consequence of magnetic reconnection along a current sheet in the corona. At the same time, theory predicts plasma jets from the reconnection sites which are extremely difficult to observe directly because of their low densities. It has been suggested that the dark supra-arcade downflows (SADs) seen falling through supra-arcade fans may be low-density jet plasma. The head of a low-density jet directed toward higher-density plasma would be Rayleigh-Taylor unstable, and lead to the development of rapidly growing low- and high-density fingers along the interface. Using Solar Dynamics Observatory/Atmospheric Imaging Assembly 131 Å images, we show details of SADs seen from three different orientations with respect to the flare arcade and current sheet, and highlight features that have been previously unexplained, such as the splitting of SADs at their heads, but are a natural consequence of instabilities above the arcade. Comparison with three-dimensional magnetohydrodynamic simulations suggests that SADs are the result of secondary instabilities of the Rayleigh-Taylor type in the exhaust of reconnection jets.

## **Quiet Sun Explosive Events: Jets, Splashes, and Eruptions**

D. E. **Innes**, L. Teriaca

Solar Physics, February **2013**, Volume 282, Issue 2, pp 453-469

Explosive events appear as broad non-Gaussian wings in the line profiles of small transition-region phenomena. Images from the Solar Dynamics Observatory (SDO) give a first view of the plasma dynamics at the sites of explosive events seen simultaneously in O vi spectra of a region of quiet Sun, taken with the ultraviolet spectrometer Solar Ultraviolet Measurements of Emitted Radiation (SUMER) onboard the Solar and Heliospheric Observatory (SOHO). Distinct event bursts were seen either at the junction of supergranular network cells or near emerging flux. Three are described in the context of their surrounding transition region (304 Å) and coronal (171 Å) activity. One showed plasma ejections from an isolated pair of sites, with a time lag of 50 seconds between events. At the site where the later explosive event was seen, the extreme ultraviolet (EUV) images show a hot core surrounded by a small, expanding ring of chromospheric emission, which we interpret as a "splash." The second explosive-event burst was related to flux cancellation, inferred from Helioseismic and Magnetic Imager (HMI) magnetograms, and a coronal dimming surrounded by a ring of bright EUV emission with explosive events at positions where the spectrometer slit crossed the bright ring. The third series of events occurred at the base of a slow, small coronal mass ejection (**mini-CME**). All events studied here imply jet-like

flows probably triggered by magnetic reconnection at supergranular junctions. Events come from sites close to the footpoints of jets seen in Atmospheric Imaging Assembly (AIA) images, and possibly from the landing site of high-velocity flows. They are not caused by rapid rotation in spicules.

### **Break up of returning plasma after the 7 June 2011 filament eruption by Rayleigh-Taylor instabilities\***

D. E. [Innes](#)<sup>1</sup>, R. H. Cameron<sup>1</sup>, L. Fletcher<sup>2</sup>, B. Inhester<sup>1</sup> and S. K. Solanki<sup>1</sup>  
A&A 540, L10 (2012)

Context. A prominence eruption on **7 June 2011** produced spectacular curtains of plasma falling through the lower corona. At the solar surface they created an incredible display of extreme ultraviolet brightenings.

Aims. To identify and analyze some of the local instabilities which produce structure in the falling plasma.

Methods. The structures were investigated using SDO/AIA 171 Å and 193 Å images in which the falling plasma appeared dark against the bright coronal emission.

Results. Several instances of the Rayleigh-Taylor instability were investigated. In two cases the Alfvén velocity associated with the dense plasma could be estimated from the separation of the Rayleigh-Taylor fingers. A second type of feature, which has the appearance of self-similar branching horns was discussed.

### **Quiet Sun mini-coronal mass ejections activated by supergranular flows\_**

D. E. [Innes](#)<sup>1</sup>, A. Genetelli<sup>1,2</sup>, R. Attie<sup>1</sup>, and H. E. Potts<sup>3</sup>

A&A 495, 319–323 (2009); DOI: [10.1051/0004-6361:200811011](https://doi.org/10.1051/0004-6361/200811011); **File**

Context. The atmosphere of the quiet Sun is controlled by photospheric flows sweeping up concentrations of mixed polarity magnetic field. Along supergranule boundaries and junctions, there is a strong correlation between magnetic flux and bright chromospheric and transition region emission.

Aims. The aim is to investigate the relationship between photospheric flows and small flare-like brightenings seen in Extreme Ultraviolet images.

Methods. We describe observations of small eruptions seen in quiet Sun images taken with the Extreme UltraViolet Imager (EUVI) on STEREO. The photospheric flows during the eruption build-up phase are investigated by tracking granules in high resolution MDI continuum images.

Results. Eruptions with characteristics of small coronal mass ejections (CMEs) occur at the junctions of supergranular cells. The eruptions produce brightening at the onset site, dark cloud or small filament ejections, and faint waves moving with plane-of-sky speeds up to 100 km s<sup>-1</sup>. In the two examples studied, they appear to be activated by converging and rotating supergranular flows, twisting small concentrations of opposite polarity magnetic field. An estimate of the occurrence rate is about 1400 events per day over the whole Sun. One third of these events seem to be associated with waves. Typically, the waves last for about 30 min and travel a distance of 80 Mm, so at any one time they cover 1/50th of the lower corona.

### **Quiet Sun Mini-CMEs Observed in STEREO**

[Innes](#), D.1; Genetelli, A.2; Attie, R.1; Potts, H.

ESPM Freiburg 2008, **Presentation**

Mini-CMEs are eruptions of cool chromospheric material into the corona seen up to 50 Mm from the source. They are usually accompanied by flare-like brightenings at the onset site. The velocities are typically 20-30 km/s, but may be 5 times faster at onset.

STEREO 171 A observations of a region around a small equatorial coronal hole when it was crossing the disk center are studied over a period of 24 hours. Many events are seen. Events are generally characterized by dark clouds in the 171 images and strong brightening in the chromosphere. Selected events will be discussed with emphasis on the underlying photospheric magnetic field and photospheric flows.

### **Detection of a High-velocity Prominence Eruption Leading to a CME Associated with a Superflare on the RS CVn-type Star V1355 Orionis**

Shun [Inoue](#)<sup>1</sup>, Hiroyuki Maehara<sup>2</sup>, Yuta Notsu<sup>3,4,5</sup>, Kosuke Namekata<sup>6</sup>, Satoshi Honda<sup>7</sup>, Keiichi Namizaki<sup>8</sup>, Daisaku Nogami<sup>8,9</sup>, and Kazunari Shibata<sup>10,11</sup>

2023 ApJ 948 9

<https://iopscience.iop.org/article/10.3847/1538-4357/acb7e8/pdf>

Stellar coronal mass ejections (CMEs) have recently received much attention for their impacts on exoplanets and stellar evolution. Detecting prominence eruptions, the initial phase of CMEs, as the blueshifted excess component of Balmer lines is a technique to capture stellar CMEs. However, most of prominence eruptions identified thus far have been slow and less than the surface escape velocity. Therefore, whether these eruptions were developing into CMEs remained unknown. In this study, we conducted simultaneous optical photometric observations with Transiting Exoplanet Survey Satellite and optical spectroscopic observations with the 3.8 m Seimei Telescope for the RS CVn-type star V1355 Orionis that frequently produces large-scale superflares. We detected a superflare releasing  $7.0 \times 10^{35}$  erg. In the early stage of this flare, a blueshifted excess component of H $\alpha$  extending its velocity up to 760–1690 km s<sup>-1</sup> was observed and thought to originate from prominence eruptions. The velocity greatly exceeds the escape velocity (i.e.,  $\sim 350$  km s<sup>-1</sup>), which provides important evidence that stellar prominence eruptions can develop into CMEs. Furthermore, we found that the prominence is very massive ( $9.5 \times 10^{18}$  g < M <  $1.4 \times 10^{21}$  g). These data will clarify whether such

events follow existing theories and scaling laws on solar flares and CMEs even when the energy scale far exceeds solar cases.

## **An Evolution and Eruption of the Coronal Magnetic Field through a Data-Driven MHD Simulation**

[Satoshi Inoue](#), [Keiji Hayashi](#), [Takahiro Miyoshi](#)

ApJ 946 46 2023

<https://arxiv.org/pdf/2210.07492>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac9eaa/pdf>

We present a newly developed data-driven magnetohydrodynamics (MHD) simulation code under a zero-beta approximation based on a method proposed by Hayashi et al. 2018 and 2019. Although many data-driven MHD simulations have been developed and conducted, there are not many studies on how accurately those simulations can reproduce the phenomena observed in the solar corona. In this study, we investigated the performance of our data-driven simulation quantitatively using ground-truth data. The ground-truth data was produced by an MHD simulation in which the magnetic field is twisted by the sunspot motions. A magnetic flux rope (MFR) is created by the cancellation of the magnetic flux at the polarity inversion line due to the converging flow on the sunspot, which eventually leads the eruption of the MFR. We attempted to reproduce these dynamics using the data-driven MHD simulation. The coronal magnetic fields are driven by the electric fields, which are obtained from a time-series of the photospheric magnetic field that is extracted from the ground-truth data, on the surface. As a result, the data-driven simulation could capture the subsequent MHD processes, the twisted coronal magnetic field and formation of the MFR, and also its eruption. We report these results and compare with the ground-truth data, and discuss how to improve the accuracy and optimize numerical method.

## **Onset mechanism of solar eruptions**

[Satoshi Inoue](#) [Yumi BambacKanya Kusanob](#)

[Journal of Atmospheric and Solar-Terrestrial Physics Volume 180](#), November 2018, Pages 3-8  
[sci-hub.tw/10.1016/j.jastp.2017.08.035](http://sci-hub.tw/10.1016/j.jastp.2017.08.035)

Solar eruptions are the most energetic phenomena observed in the [solar system](#) observed as flares, [coronal mass ejections](#)(CMEs) and filament/prominence eruption. The helically twisted flux tube is widely thought to be the source and driver of solar eruptions and to carry the plasma into the [interplanetary space](#). Those may eventually reach the [magnetosphere](#) and cause strong disturbances of the [geomagnetic field](#). Therefore, the understanding of the onset of solar eruptions is important not only in the framework of solar physics but also for the space weather forecast. In this paper, we report on new insight into the onset mechanism of solar eruptions recently obtained from our new studies. We perform the studies in terms of the observational approach with state-of-the-art solar physics satellites and the numerical one with the latest super computer system. We specified two types of small magnetic perturbations of the photospheric [magnetic field](#). These can enhance the magnetic reconnection in the pre-existing non-potential magnetic field, which produces a large flux tube and then drives the eruption. We further confirmed that this reconnection is a key process for the eruption in our latest data-constrained simulation. We report our latest results and our interpretation of the onset mechanism of solar eruptions. **2006 December 13, 2011 Feb 13-15**

## **Magnetohydrodynamic Modeling of a Solar Eruption Associated with X9.3 Flare Observed in Active Region 12673**

[Satoshi Inoue](#), [Daikou Shiota](#), [Yumi Bamba](#), [Sung-Hong Park](#)

ApJ 867 83 2018

<https://arxiv.org/pdf/1809.02309.pdf>

[sci-hub.tw/10.3847/1538-4357/aae079](http://sci-hub.tw/10.3847/1538-4357/aae079)

On **2017 September 6**, the solar active region 12673 produced an X9.3 flare, regarded to be the largest to have occurred in solar cycle 24. In this work we have performed a magnetohydrodynamic (MHD) simulation in order to reveal the three-dimensional (3D) dynamics of the magnetic fields associated with the X9.3 solar flare. We first performed an extrapolation of the 3D magnetic field based on the observed photospheric magnetic field prior to the flare and then used this as the initial condition for the MHD simulation, which revealed a dramatic eruption. In particular, we found that a large coherent flux rope composed of highly twisted magnetic field lines formed during the eruption. A series of small flux ropes were found to lie along a magnetic polarity inversion line prior to the flare. Reconnection occurring between each flux rope during the early stages of the eruption formed the large, highly twisted flux rope. Furthermore, we observed a writhing motion of the erupting flux rope. Understanding these dynamics is important in the drive to increase the accuracy of space weather forecasting. We report on the detailed dynamics of the 3D eruptive flux rope and discuss the possible mechanisms of the writhing motion.

## **Formation and dynamics of a solar eruptive flux tube**

[Satoshi Inoue](#), [Kanya Kusano](#), [Jörg Büchner](#) & [Jan Skála](#)

Nature Communications volume 9, Article number: 174(2018)

<https://www.nature.com/articles/s41467-017-02616-8.pdf>

Solar eruptions are well-known drivers of extreme space weather, which can greatly disturb the Earth's magnetosphere and ionosphere. The triggering process and initial dynamics of these eruptions are still an area of intense study. Here we perform a magnetohydrodynamic simulation taking into account the observed photospheric magnetic field to reveal the dynamics of a solar eruption in a real magnetic environment. In our simulation, we confirmed that tether-cutting reconnection occurring locally above the polarity inversion line creates a twisted flux tube, which is lifted into a toroidal unstable area where it loses equilibrium, destroying the force-free state, and driving the eruption. Consequently, a more highly twisted flux tube is built up during this initial phase, which can be further accelerated even when it returns to a stable area. We suggest that a nonlinear positive feedback process between the flux tube evolution and reconnection is the key to ensure this extra acceleration. **2011 February 13**

## **Magnetohydrodynamics modeling of coronal magnetic field and solar eruptions based on the photospheric magnetic field**

**Review**

Satoshi **Inoue**

Progress in Earth and Planetary Science **2016** 3:19

<http://progearthplanetsci.springeropen.com/articles/10.1186/s40645-016-0084-7>

E-print, 4 July **2016**

In this paper, we summarize current progress on using the observed magnetic fields for magnetohydrodynamics (MHD) modeling of the coronal magnetic field and of solar eruptions, including solar flares and coronal mass ejections (CMEs). Unfortunately, even with the existing state-of-the-art solar physics satellites, only the photospheric magnetic field can be measured. We first review the 3D extrapolation of the coronal magnetic fields from measurements of the photospheric field. Specifically, we focus on the nonlinear force-free field (NLFFF) approximation extrapolated from the three components of the photospheric magnetic field. On the other hand, because in the force-free approximation the NLFFF is reconstructed for equilibrium states, the onset and dynamics of solar flares and CMEs cannot be obtained from these calculations. Recently, MHD simulations using the NLFFF as an initial condition have been proposed for understanding these dynamics in a more realistic scenario. These results have begun to reveal complex dynamics, some of which have not been inferred from previous simulations of hypothetical situations, and they have also successfully reproduced some observed phenomena. Although MHD simulations play a vital role in explaining a number of observed phenomena, there still remains much to be understood. Herein, we review the results obtained by state-of-the-art MHD modeling combined with the NLFFF. **13 February 2011, 15 February 2011, 11 September 2011, 29 March 2014**

## **Magnetohydrodynamic Simulation of the X2.2 Solar Flare on 2011 February 15: II. Dynamics Connecting the Solar Flare and the Coronal Mass Ejection**

S. **Inoue**, K. Hayashi, [T. Magara](#), [G. S. Choe](#), [Y. D. Park](#)

ApJ **2015**

<http://arxiv.org/pdf/1501.07663v2.pdf>

We clarify a relationship of the dynamics of a solar flare and a growing Coronal Mass Ejection (CME) by investigating the dynamics of magnetic fields during the X2.2-class flare taking place in the solar active region 11158 on **2011 February 15**, based on simulation results obtained from Inoue et al. 2014. We found that the strongly twisted lines formed through the tether-cutting reconnection in the twisted lines of a nonlinear force-free field (NLFFF) can break the force balance within the magnetic field, resulting in their launch from the solar surface. We further discover that a large-scale flux tube is formed during the eruption as a result of the tether-cutting reconnection between the eruptive strongly twisted lines and these ambient weakly twisted lines. Then the newly formed large flux tube exceeds the critical height of the torus instability. The tether-cutting reconnection thus plays an important role in the triggering a CME. Furthermore, we found that the tangential fields at the solar surface illustrate different phases in the formation of the flux tube and its ascending phase over the threshold of the torus instability. We will discuss about these dynamics in detail.

## **FRiED: A NOVEL THREE-DIMENSIONAL MODEL OF CORONAL MASS EJECTIONS**

A. **Isavnin**

**2016** ApJ 833 267

<http://sci-hub.cc/10.3847/1538-4357/833/2/267>

<https://arxiv.org/pdf/1703.01659.pdf>

We present a novel three-dimensional (3D) model of coronal mass ejections (CMEs) that unifies all key evolutionary aspects of CMEs and encapsulates their 3D magnetic field configuration. This fully analytic model is capable of reproducing the global geometrical shape of a CME with all major deformations taken into account, i.e., deflection, rotation, expansion, "pancaking," front flattening, and rotational skew. Encapsulation of 3D magnetic structure allows the model to reproduce in-situ measurements of magnetic field for trajectories of spacecraft-CME encounters of any degree of complexity. As such, the model can be used single-handedly for the consistent analysis of both remote and in-situ observations of CMEs at any heliocentric distance. We demonstrate the latter by successfully applying the model for the analysis of two CMEs. **2010 December 12, 2011 October 1**

## **Three-Dimensional Evolution of Flux-Rope CMEs and Its Relation to the Local Orientation of the Heliospheric Current Sheet**

A. [Isavnin](#), A. Vourlidas, E. K. J. Kilpua

Solar Phys., **2014**, **File**

Flux ropes ejected from the Sun may change their geometrical orientation during their evolution, which directly affects their geoeffectiveness. Therefore, it is crucial to understand how solar flux ropes evolve in the heliosphere to improve our space-weather forecasting tools. We present a follow-up study of the concepts described by Isavnin, Vourlidas, and Kilpua (Solar Phys. 284, 203, 2013). We analyze 14 coronal mass ejections (CMEs), with clear flux-rope signatures, observed during the decay of Solar Cycle 23 and rise of Solar Cycle 24. First, we estimate initial orientations of the flux ropes at the origin using extreme-ultraviolet observations of post-eruption arcades and/or eruptive prominences. Then we reconstruct multi-viewpoint coronagraph observations of the CMEs from  $\approx 2$  to  $30 R_{\odot}$  with a three-dimensional geometric representation of a flux rope to determine their geometrical parameters. Finally, we propagate the flux ropes from  $\approx 30 R_{\odot}$  to 1 AU through MHD-simulated background solar wind while using in-situ measurements at 1 AU of the associated magnetic cloud as a constraint for the propagation technique. This methodology allows us to estimate the flux-rope orientation all the way from the Sun to 1 AU. We find that while the flux-rope deflection occurs predominantly below  $30 R_{\odot}$ , a significant amount of deflection and rotation happens between  $30 R_{\odot}$  and 1 AU. We compare the flux-rope orientation to the local orientation of the heliospheric current sheet (HCS). We find that slow flux ropes tend to align with the streams of slow solar wind in the inner heliosphere. During the solar-cycle minimum the slow solar-wind channel as well as the HCS usually occupy the area in the vicinity of the solar equatorial plane, which in the past led researchers to the hypothesis that flux ropes align with the HCS. Our results show that exceptions from this rule are explained by interaction with the Parker-spiraled background magnetic field, which dominates over the magnetic interaction with the HCS in the inner heliosphere at least during solar-minimum conditions.

## **Three-Dimensional Evolution of Erupted Flux Ropes from the Sun ( $2-20 R_{\odot}$ ) to 1 AU**

A. [Isavnin](#), A. Vourlidas, E. K. J. Kilpua

Solar Physics

May **2013**, ApJ, Volume 284, Issue 1, pp 203-215; **File**

Studying the evolution of magnetic clouds entrained in coronal mass ejections using in-situ data is a difficult task, since only a limited number of observational points is available at large heliocentric distances. Remote sensing observations can, however, provide important information for events close to the Sun. In this work we estimate the flux rope orientation first in the close vicinity of the Sun ( $2-20 R_{\odot}$ ) using forward modeling of STEREO/SECCHI and SOHO/LASCO coronagraph images of coronal mass ejections and then in situ using Grad-Shafranov reconstruction of the magnetic cloud. Thus, we are able to measure changes in the orientation of the erupted flux ropes as they propagate from the Sun to 1 AU. We present both techniques and use them to study 15 magnetic clouds observed during the minimum following Solar Cycle 23 and the rise of Solar Cycle 24. This is the first multievent study to compare the three-dimensional parameters of CMEs from imaging and in-situ reconstructions. The results of our analysis confirm earlier studies showing that the flux ropes tend to deflect towards the solar equatorial plane. We also find evidence of rotation on their travel from the Sun to 1 AU. In contrast to past studies, our method allows one to deduce the evolution of the three-dimensional orientation of individual flux ropes rather than on a statistical basis.

## **A THREE-DIMENSIONAL LINE-TIED MAGNETIC FIELD MODEL FOR SOLAR ERUPTIONS**

Philip A. [Isenberg](#) and Terry G. Forbes

The Astrophysical Journal, 670:1453Y1466, **2007**

We introduce a three-dimensional analytical model of a coronal flux rope with its ends embedded in the solar surface. The model allows the flux rope to move in the corona while maintaining line-tied conditions at the solar surface. These conditions ensure that the normal component of the coronal magnetic field at the surface remains fixed during an eruption and that no magnetic energy enters the corona through the surface to drive the eruption. The model is based on the magnetic configuration of Titov&De moulin, where a toroidal flux rope is held in equilibrium by an overlying magnetic arcade. We investigate the stability of this configuration to specific perturbations and show that it is subject to the torus instability when the flux rope length exceeds a critical value. A force analysis of the configuration shows that flux ropes are most likely to erupt in a localized region near the apex, while the regions near the surface remain relatively undisturbed. Thus, the flux rope will tend to form an aneurysm-like structure once it erupts. Our analysis also suggests how the flux rope rotation seen in some eruptions and simulations may be related to the observed orientation of the overlying arcade field. This model exhibits the potential for catastrophic loss of equilibrium as a possible trigger for eruptions, but further study is required to prove this property.

## **Suzaku detection of enigmatic geocoronal solar wind charge exchange event associated with coronal mass ejection**

[Daiki Ishi](#), [Kumi Ishikawa](#), [Masaki Numazawa](#), [Yoshizumi Miyoshi](#), [Naoki Terada](#), [Kazuhiisa Mitsuda](#), [Takaya Ohashi](#), [Yuichiro Ezoe](#)

PASJ

**2019**

<https://arxiv.org/pdf/1902.07652.pdf>

Suzaku detected an enhancement of soft X-ray background associated with solar eruptions on **2013 April 14-15**. The solar eruptions were accompanied by an M6.5 solar flare and a coronal mass ejection with magnetic flux ropes. The enhanced soft X-ray background showed a slight variation in half a day and then a clear one in a few hours. The former spectrum was composed of oxygen emission lines, while the later one was characterized by a series of emission lines from highly ionized carbon to silicon. The soft X-ray enhancement originated from geocoronal solar wind charge exchange. However, there appeared to be no significant time correlation with the solar wind proton flux measured by the ACE and WIND satellites. From other solar wind signatures, we considered that an interplanetary shock associated with the coronal mass ejection and a turbulent sheath immediately behind the shock compressed the ambient solar wind ions and then resulted in the soft X-ray enhancement. Furthermore, the enriched emission lines were presumed to be due to an unusual set of ion abundances and ionization states within the coronal mass ejection. We found a better time correlation with the solar wind alpha flux rather than the solar wind proton flux. Our results suggest that the solar wind proton flux is not always a good indicator of geocoronal solar wind charge exchange, especially associated with coronal mass ejections. Instead, the solar wind alpha flux should be investigated when such a soft X-ray enhancement is detected in astronomical observations.

### **Double arc instability in the solar corona**

N. **Ishiguro**, K. Kusano

ApJ **843** 101 **2017**

<https://arxiv.org/pdf/1706.06112.pdf>

<http://sci-hub.cc/10.3847/1538-4357/aa799b>

The stability of the magnetic field in the solar corona is important for understanding the causes of solar eruptions. Although various scenarios have been suggested to date, the tether-cutting reconnection scenario proposed by Moore et al.(2001) is one of the widely accepted models to explain the onset process of solar eruptions. Although the tether-cutting reconnection scenario proposed that sigmoidal field formed by the internal reconnection is the magnetic field in pre-eruptive state, the stability of the sigmoidal field has not yet been investigated quantitatively. In this paper, in order to elucidate the stability problem of pre-eruptive state, we developed a simple numerical analysis, in which the sigmoidal field is modeled by a double arc electric current loop and its stability is analyzed. As a result, we found that the double arc loop is more easily destabilized than the axisymmetric torus, and it becomes unstable even if the external field does not decay with altitude, which is in contrast to the axisymmetric torus instability. This suggests that the tether-cutting reconnection may well work as the onset mechanism of solar eruptions, and if so the critical condition for eruption under certain geometry may be determined by a new type of instability rather than the torus instability. Based on them, we propose a new type of instability called double arc instability (DAI). We discuss the critical conditions for DAI and derive a new parameter  $\kappa$  defined as the product of the magnetic twist and the normalized flux of tether-cutting reconnection.

### **Particle Acceleration and Heating in Regions of Magnetic Flux Emergence**

Heinz **Isliker**, [Vasilis Archontis](#), [Loukas Vlahos](#)

ApJ **2019**

<https://arxiv.org/pdf/1907.04296.pdf>

The interaction between emerging and pre-existing magnetic fields in the solar atmosphere can trigger several dynamic phenomena, such as eruptions and jets. A key element during this interaction is the formation of large scale current sheets and, eventually, their fragmentation that leads to the creation of a strongly turbulent environment. In this paper, we study the kinetic aspects of the interaction (reconnection) between emerging and ambient magnetic fields. We show that the statistical properties of the spontaneously fragmented and fractal electric fields are responsible for the efficient heating and acceleration of charged particles, which form a power law tail at high energies on sub-second time scales. A fraction of the energized particles escapes from the acceleration volume, with a super-hot component with temperature close to 150MK, and with a power law high energy tail with index between -2 and -3. We estimate the transport coefficients in energy space from the dynamics of the charged particles inside the fragmented and fractal electric fields, and the solution of a fractional transport equation, as appropriate for a strongly turbulent plasma, agrees with the test particle simulations. We also show that the acceleration mechanism is not related to Fermi acceleration, and the Fokker Planck equation is inconsistent and not adequate as a transport model. Finally, we address the problem of correlations between spatial transport and transport in energy space. Our results confirm the observations reported for high energy particles (hard X-rays, type III bursts and solar energetic particles) during the emission of solar jets.

### **Spectral and Polarization Properties of Photospheric Emission from Stratified Jets**

Hirota **Ito**<sup>1</sup>, Shigehiro Nagataki<sup>1</sup>, Jin Matsumoto<sup>1</sup>, Shiu-Hang Lee<sup>1</sup>, Alexey Tolstov<sup>1</sup>, Jirong Mao<sup>1</sup>, Maria Dainotti<sup>1</sup>, and Akira Mizuta

**2014** ApJ 789 159

We explore the spectral and polarization properties of photospheric emissions from stratified jets in which multiple components, separated by sharp velocity shear regions, are distributed in lateral directions. Propagation of thermal photons injected at a high optical depth region are calculated until they escape from the photosphere. It is found that the presence of the lateral structure within the jet leads to the nonthermal feature of the spectra and significant polarization signal in the resulting emission. The deviation from thermal spectra, as well as the polarization degree, tends to be enhanced as the velocity gradient in the shear region increases. In particular, we show that emissions from multicomponent jet can reproduce the typical observed spectra of gamma-ray bursts irrespective of the position of the

observer when a velocity shear region is closely spaced in various lateral ( $\theta$ ) positions. The degree of polarization associated with the emission is significant (>few percent) at a wide range of observer angles and can be higher than 30%.

## **SOLAR RADIO TYPE-I NOISE STORM MODULATED BY CORONAL MASS EJECTIONS**

K. [Iwai](#)<sup>1</sup>, Y. Miyoshi<sup>2</sup>, S. Masuda<sup>2</sup>, M. Shimojo<sup>3</sup>, D. Shiota<sup>4</sup>, S. Inoue<sup>5</sup>, F. Tsuchiya<sup>1</sup>, A. Morioka<sup>1</sup> and H. Misawa

**2012 ApJ 744 167, File**

The first coordinated observations of an active region using ground-based radio telescopes and the Solar Terrestrial Relations Observatory (STEREO) satellites from different heliocentric longitudes were performed to study solar radio type-I noise storms. A type-I noise storm was observed between 100 and 300 MHz during a period from **2010 February 6 to 7**. During this period the two STEREO satellites were located approximately  $65^\circ$  (ahead) and  $-70^\circ$  (behind) from the Sun-Earth line, which is well suited to observe the earthward propagating coronal mass ejections (CMEs). The radio flux of the type-I noise storm was enhanced after the preceding CME and began to decrease before the subsequent CME. This time variation of the type-I noise storm was directly related to the change of the particle acceleration processes around its source region. Potential-field source-surface extrapolation from the Solar and Heliospheric Observatory/Michelson Doppler Imager (SOHO/MDI) magnetograms suggested that there was a multipolar magnetic system around the active region from which the CMEs occurred around the magnetic neutral line of the system. From our observational results, we suggest that the type-I noise storm was activated at a side-lobe reconnection region that was formed after eruption of the preceding CME. This magnetic structure was deformed by a loop expansion that led to the subsequent CME, which then suppressed the radio burst emission.

## **Automatic analysis of double coronal mass ejections from coronagraph images**

Matthew [Jacobs](#), Lin-Ching Chang, Antti Pulkkinen,

Space Weather Volume 13, Issue 11 November **2015** Pages 761–777

Coronal mass ejections (CMEs) can have major impacts on man-made technology and humans, both in space and on Earth. These impacts have created a high interest in the study of CMEs in an effort to detect and track events and forecast the CME arrival time to provide time for proper mitigation. A robust automatic real-time CME processing pipeline is greatly desired to avoid laborious and subjective manual processing. Automatic methods have been proposed to segment CMEs from coronagraph images and estimate CME parameters such as their heliocentric location and velocity. However, existing methods suffered from several shortcomings such as the use of hard thresholding and an inability to handle two or more CMEs occurring within the same coronagraph image. Double-CME analysis is a necessity for forecasting the many CME events that occur within short time frames. Robust forecasts for all CME events are required to fully understand space weather impacts. This paper presents a new method to segment CME masses and pattern recognition approaches to differentiate two CMEs in a single coronagraph image. The proposed method is validated on a data set of 30 halo CMEs, with results showing comparable ability in transient arrival time prediction accuracy and the new ability to automatically predict the arrival time of a double-CME event. The proposed method is the first automatic method to successfully calculate CME parameters from double-CME events, making this automatic method applicable to a wider range of CME events. **1999-07-06, 2002-05-22, 2005-09-09, 2011-11-09**

## **A Numerical Study of the Response of the Coronal Magnetic Field to Flux Emergence**

C. [Jacobs](#), S. Poedts

Solar Physics, October **2012**, Volume 280, Issue 2, pp 389-405

Large-scale solar eruptions, known as coronal mass ejections (CMEs), are regarded as the main drivers of space weather. The exact trigger mechanism of these violent events is still not completely clear; however, the solar magnetic field indisputably plays a crucial role in the onset of CMEs. The strength and morphology of the solar magnetic field are expected to have a decisive effect on CME properties, such as size and speed. This study aims to investigate the evolution of a magnetic configuration when driven by the emergence of new magnetic flux in order to get a better insight into the onset of CMEs and their magnetic structure. The three-dimensional, time-dependent equations for ideal magnetohydrodynamics are numerically solved on a spherical mesh. New flux emergence in a bipolar active region causes destabilisation of the initial stationary structure, finally resulting in an eruption. The initial magnetic topology is suitable for the 'breakout' CME scenario to work. Although no magnetic flux rope structure is present in the initial condition, highly twisted magnetic field lines are formed during the evolution of the system as a result of internal reconnection due to the interaction of the active region magnetic field with the ambient field. The magnetic energy built up in the system and the final speed of the CME depend on the strength of the overlying magnetic field, the flux emergence rate, and the total amount of emerged flux. The interaction with the global coronal field makes the eruption a large-scale event, involving distant parts of the solar surface.

## Models for coronal mass ejections

Carla **Jacobs**, b and Stefaan Poedtsa

Journal of Atmospheric and Solar-Terrestrial Physics, Volume 73, Issue 10, **2011**, Pages 1148-1155, **File**  
Coronal mass ejections (CMEs) play a key role in space weather. The mathematical modelling of these violent solar phenomena can contribute to a better understanding of their origin and evolution and as such improve space weather predictions. We **review** the state-of-the-art in CME simulations, including a brief overview of current models for the background solar wind as it has been shown that the background solar wind affects the onset and initial evolution of CMEs quite substantially. We mainly focus on the attempt to retrieve the initiation and propagation of CMEs in the framework of computational magnetofluid dynamics (CMFD). Advanced numerical techniques and large computer resources are indispensable when attempting to reconstruct an event from Sun to Earth. Especially the simulations developed in dedicated event studies yield very realistic results, comparable with the observations. However, there are still a lot of free parameters in these models and ad hoc source terms are often added to the equations, mimicking the physics that is not really understood yet in detail.

Research highlights

► New insights in the origin and dynamics of coronal mass ejections. ► New developments in the numerical modelling of CMEs. ► State-of-the-art solar wind models. ► New pieces of the space weather puzzle.

## The Internal Structure of Coronal Mass Ejections: Are all Regular Magnetic Clouds Flux Ropes?

C. **Jacobs**, I. I. Roussev, N. Lugaz, and S. Poedts

ApJL, 695, L171-L175, **2009**; **File** doi: [10.1088/0004-637X/695/2/L171](https://doi.org/10.1088/0004-637X/695/2/L171)

In this Letter, we investigate the internal structure of a coronal mass ejection (CME) and its dynamics by invoking a realistic initiation mechanism in a quadrupolar magnetic setting. The study comprises a compressible three-dimensional magnetohydrodynamics simulation. We use an idealized model of the solar corona, into which we superimpose a quadrupolar magnetic source region. By applying shearing motions resembling flux emergence at the solar boundary, the initial equilibrium field is energized and it eventually erupts, yielding a fast CME. The simulated CME shows the typical characteristics of a magnetic cloud (MC) as it propagates away from the Sun and interacts with a bimodal solar wind. However, no distinct flux rope structure is present in the associated interplanetary ejection. In our model, a series of reconnection events between the eruptive magnetic field and the ambient field results in the creation of significant writhe in the CME's magnetic field, yielding the observed rotation of the magnetic field vector, characteristic of an MC. We demonstrate that the magnetic field lines of the CME may suffer discontinuous changes in their mapping on the solar surface, with footpoints subject to meandering over the course of the eruption due to magnetic reconnection. We argue that CMEs with internal magnetic structure such as that described here should also be considered while attempting to explain in situ observations of regular MCs at L1 and elsewhere in the heliosphere.

## Numerical Modeling of the Initiation of Coronal Mass Ejections

**Jacobs**, C.1; Lugaz, N.2; Poedts, S.1; Roussev, I.2

Freiburg ESP Meeting **2008**, **Poster 3.3-24** (<http://espm.kis.uni-freiburg.de/index.php?id=408>)

Coronal Mass Ejections (CMEs) are large expulsions of solar material that involve large disturbances in the structure of the solar corona and in the solar wind. There is general consensus that stressed magnetic field structures are present in the CME source region at the time of eruption. The different theoretical models with regard to CME initiation all have in common the existence of magnetic flux ropes, either present in the solar atmosphere before the CME lift-off, or created during the eruption. Some of the models, like the magnetic 'breakout', presume a specific magnetic topology of the preeruption coronal field. In this research, the initiation of CMEs is studied in the framework of computational ideal magnetohydrodynamics (MHD). A multipolar flux system is energized through photospheric motions of the magnetic foot points. We investigate the interplanetary propagation and magnetic field structure of CMEs originating from regions with different magnetic topology.

## Comparison between 2.5D and 3D simulations of coronal mass ejections:

C. **Jacobs**, B. van der Holst and S. Poedts

A&A 470 (2007) 359-365

<http://www.aanda.org/10.1051/0004-6361:20077305>

we conclude that the 2.5D simulations of the CME evolution are a good first approach and resemble well the 3D result, provided that the appropriate initiation parameters are chosen.

## Solar Mass Ejection Imager 3-D reconstruction of the 27–28 May 2003 coronal mass ejection sequence,

**Jackson**, B. V., M. M. Bisi, P. P. Hick, A. Buffington, J. M. Clover, and W. Sun, *J. Geophys. Res.*, 113, A00A15, doi:10.1029/2008JA013224, (2008).

<http://www.agu.org/pubs/crossref/2008/2008JA013224.shtml>

The Solar Mass Ejection Imager (SMEI) has recorded the inner-heliospheric response in white-light Thomson scattering for many hundreds of interplanetary coronal mass ejections (ICMEs). Some of these have been observed by the Solar and Heliospheric Observatory (SOHO) Large-Angle Spectroscopic Coronagraph (LASCO) instruments and also in situ by near-Earth spacecraft. This article presents a low-resolution three-dimensional (3-D) reconstruction of the 27–28 May 2003 halo CME event sequence observed by LASCO and later using SMEI observations; this sequence was also observed by all in situ monitors near Earth. The reconstruction derives its perspective views from outward flowing solar wind. Analysis results reveal the shape, extent, and mass of this ICME sequence as it reaches the vicinity of Earth. The extended shape has considerable detail that is compared with LASCO images and masses for this event. The 3-D reconstructed density, derived from the remote-sensed Thomson scattered brightness, is also compared with the Advanced Composition Explorer (ACE) and Wind spacecraft in situ plasma measurements. These agree well in peak and integrated total value for this ICME event sequence when an appropriately enhanced (~20%) electron number density is assumed to account for elements heavier than hydrogen in the ionized plasma.

## Estimating early coronal mass ejection propagation direction with DIRECD during the severe May 8 and follow-up June 8, 2024 events

<https://arxiv.org/pdf/2410.18549>

<https://www.aanda.org/articles/aa/pdf/2024/12/aa52324-24.pdf>

On **May 8, 2024**, solar active region 13664 produced an X-class flare, several M-class flares, and multiple Earth-directed Coronal Mass Ejections (CMEs). The initial CME caused coronal dimmings, characterized by localized reductions in extreme-ultraviolet (EUV) emissions, indicating mass loss and expansion during the eruption. After one solar rotation, on **June 8, 2024**, the same region produced another M-class flare followed by coronal dimmings observed by the SDO and STEREO spacecraft. We analyzed early CME evolution and direction from coronal dimming expansion at the end of the impulsive phase using the DIRECD (Dimming Inferred Estimation of CME Direction) method. To validate the 3D CME cone, we compared CME properties from the low corona with white-light coronagraph data. The May 8 CME expanded radially, with a 7.7 deg inclination, 70 deg angular width, and 0.81 R<sub>sun</sub> cone height, while the June 8 CME had a 15.7 deg inclination, 81 deg width, and 0.89 R<sub>sun</sub> height. Our study shows that tracking low coronal signatures, like coronal dimming expansion, can estimate CME direction early, providing crucial lead time for space weather forecasts.

## Coronal dimmings as indicators of early CME propagation direction

**Shantanu Jain**, **Tatiana Podladchikova**, **Galina Chikunova**, **Karin Dissauer**, **Astrid M. Veronig**

*A&A* 683, A15 2023

<https://arxiv.org/pdf/2311.13942.pdf>

<https://www.aanda.org/articles/aa/pdf/2024/03/aa47927-23.pdf>

*Context.* Coronal mass ejections (CMEs) are large-scale eruptions of plasma and magnetic field from the Sun that can cause severe disturbances in space weather. Earth-directed CMEs are responsible for the disruption of technological systems and damaging power grids. However, the early evolution of CMEs, especially Earth-directed ones, is poorly tracked using traditional coronagraphs along the Sun-Earth line.

*Aims.* The most distinct phenomena associated with CMEs in the low corona are coronal dimmings, which are localized regions of reduced emission in the extreme-ultraviolet (EUV) and soft X-rays formed due to mass loss and expansion during a CME. We present a new approach to estimating the early CME propagation direction based on the expansion of coronal dimmings.

*Methods.* We developed the Dimming Inferred Estimate of CME Direction (DIRECD) method. First, we performed simulations of CMEs in 3D using a geometric CME cone model and varying parameters such as width, height, source location, and deflection from the radial direction to study their influence on the CME projection onto the solar sphere. Second, we estimated the dominant direction of the dimming extent based on the evolution of the dimming area. Third, using the derived dominant direction of the dimming evolution on the solar sphere, we solved an inverse problem to reconstruct an ensemble of CME cones at different heights, widths, and deflections from the radial propagation. Finally, we searched for which CME parameter combinations the CME orthogonal projections onto the solar sphere would match the geometry of the dimming at the end of its impulsive phase best; we did so to derive the CME direction in 3D. We tested our approach on two case studies on 1 October, 2011 and 6 September, 2011. We also validated our results with 3D tie-pointing of the CME bubble in an EUV low corona and with 3D reconstructions by graduated cylindrical shell modeling (GCS) of white-light CMEs higher up in the corona.

*Results.* Using DIRECD, we found that the CME on **1 October, 2011** expanded dominantly toward the south-east, while the CME on **6 September, 2011** was inclined toward the north-west. This is in agreement with the CME direction estimates from previous studies using multi-viewpoint coronagraphic observations.

*Conclusions.* Our study demonstrates that coronal dimming information can be used to estimate the CME's direction early in its evolution. This allows us to provide information on the CME direction before it is observed in the coronagraph's field of view, which is of practical importance for space weather forecasting and the mitigation of potential adverse impacts on Earth.

## **Evolution of the critical torus instability height and CME likelihood in solar active regions**

[Alexander W. James](#), [David R. Williams](#), [Jennifer O'Kane](#)

A&A 665, A37 2022

<https://arxiv.org/pdf/2206.10639.pdf>

<https://www.aanda.org/articles/aa/pdf/2022/09/aa42910-21.pdf>

*Aims.* Working towards improved space weather predictions, we aim to quantify how the critical height at which the torus instability drives coronal mass ejections (CMEs) varies over time in a sample of solar active regions. *Methods.* We model the coronal magnetic fields of 42 active regions and quantify the critical height at their central polarity inversion lines throughout their observed lifetimes. We then compare these heights to the changing magnetic flux at the photospheric boundary and identify CMEs in these regions. *Results.* In our sample, the rates of CMEs per unit time are twice as high during phases when magnetic flux is increasing than when it is decreasing, and during those phases of increasing flux, the rate of CMEs is 63% higher when the critical height is rising than when it is falling. Furthermore, we support and extend the results of previous studies by demonstrating that the critical height in active regions is generally proportional to the separation of their magnetic polarities through time. When the separation of magnetic polarities in an active region increases, for example during the continuous emergence and expansion of a magnetic bipole, the critical height also tends to increase. Conversely, when the polarity separation decreases, for example due to the emergence of a new, compact bipole at the central inversion line of an existing active region or into a quiet Sun environment, the critical height tends to decrease. **2010-08-29**

## **A new trigger mechanism for coronal mass ejections: the role of confined flares and photospheric motions in the formation of hot flux ropes**

[Alexander W James](#), [Lucie M Green](#), [Lidia van Driel-Gesztelyi](#), [Gherardo Valori](#)

A&A 644, A137 2020

<https://arxiv.org/pdf/2010.11204.pdf>

<https://doi.org/10.1051/0004-6361/202038781>

*Context:* Many previous studies have shown that the magnetic precursor of a coronal mass ejection (CME) takes the form of a magnetic flux rope, and a subset of them have become known as 'hot flux ropes' due to their emission signatures in  $\sim 10$  MK plasma. *Aims:* We seek to identify the processes by which these hot flux ropes form, with a view of developing our understanding of CMEs and thereby improving space weather forecasts. *Methods:* Extreme-ultraviolet observations were used to identify five pre-eruptive hot flux ropes in the solar corona and study how they evolved. Confined flares were observed in the hours and days before each flux rope erupted, and these were used as indicators of episodic bursts of magnetic reconnection by which each flux rope formed. The evolution of the photospheric magnetic field was observed during each formation period to identify the process(es) that enabled magnetic reconnection to occur in the  $\beta < 1$  corona and form the flux ropes. *Results:* The confined flares were found to be homologous events and suggest flux rope formation times that range from 18 hours to 5 days. Throughout these periods, fragments of photospheric magnetic flux were observed to orbit around each other in sunspots where the flux ropes had a footpoint. Active regions with right-handed (left-handed) twisted magnetic flux exhibited clockwise (anticlockwise) orbiting motions, and right-handed (left-handed) flux ropes formed. *Conclusions:* We infer that the orbital motions of photospheric magnetic flux fragments about each other bring magnetic flux tubes together in the corona, enabling component reconnection that forms a magnetic flux rope above a flaring arcade. This represents a novel trigger mechanism for solar eruptions and should be considered when predicting solar magnetic activity. **13 Mar 2012, 13 Jun 2012, 14 Jun 2012, 08 Oct 2012, 14 Jul 2017**

## **An Observationally-Constrained Model of a Flux Rope that Formed in the Solar Corona**

Alexander W. [James](#), [Gherardo Valori](#), [Lucie M. Green](#), [Yang Liu](#), [Mark C. M. Cheung](#), [Yang Guo](#), [Lidia van Driel-Gesztelyi](#)

ApJL 855 L16 2018

<https://arxiv.org/pdf/1802.07965.pdf>

<http://sci-hub.tw/http://iopscience.iop.org/2041-8205/855/2/L16/>

Coronal mass ejections (CMEs) are large-scale eruptions of plasma from the coronae of stars. Understanding the plasma processes involved in CME initiation has applications to space weather forecasting and laboratory plasma experiments. James et al. (Sol. Phys. 292, 71, 2017) used EUV observations to conclude that a magnetic flux rope formed in the solar corona above NOAA Active Region 11504 before it erupted on **14 June 2012** (SOL2012-06-14). In this work, we use data from the Solar Dynamics Observatory to model the coronal magnetic field of the active region one hour prior to eruption using a nonlinear force-free field extrapolation, and find a flux rope reaching a maximum height of 150 Mm

above the photosphere. Estimations of the average twist of the strongly asymmetric extrapolated flux rope are between 1.35 and 1.88 turns, depending on the choice of axis, although the erupting structure was not observed to kink. The decay index near the apex of the axis of the extrapolated flux rope is comparable to typical critical values required for the onset of the torus instability, so we suggest that the torus instability drove the eruption.

### **On-disc Observations of Flux Rope Formation Prior to its Eruption**

A. W. **James**, L. M. Green, E. Palmerio, G. Valori, H. A. S. Reid, D. Baker, D. H. Brooks, L. van Driel-Gesztelyi, E. K. J. Kilpua

Solar Phys. 292:71 2017

<https://arxiv.org/pdf/1703.10837.pdf>

Coronal mass ejections (CMEs) are one of the primary manifestations of solar activity and can drive severe space weather effects. Therefore, it is vital to work towards being able to predict their occurrence. However, many aspects of CME formation and eruption remain unclear, including whether magnetic flux ropes are present before the onset of eruption and the key mechanisms that cause CMEs to occur. In this work, the pre-eruptive coronal configuration of an active region that produced an interplanetary CME with a clear magnetic flux rope structure at 1 AU is studied. A forward-S sigmoid appears in extreme-ultraviolet (EUV) data two hours before the onset of the eruption (SOL2012-06-14), which is interpreted as a signature of a right-handed flux rope that formed prior to the eruption. Flare ribbons and EUV dimmings are used to infer the locations of the flux rope footpoints. These locations, together with observations of the global magnetic flux distribution, indicate that an interaction between newly emerged magnetic flux and pre-existing sunspot field in the days prior to the eruption may have enabled the coronal flux rope to form via tether-cutting-like reconnection. Composition analysis suggests that the flux rope had a coronal plasma composition, supporting our interpretation that the flux rope formed via magnetic reconnection in the corona. Once formed, the flux rope remained stable for 2 hours before erupting as a CME.

### **Two Distinct Types of CME-flare Relationships Based on SOHO and STEREO Observations**

Soojoeng **Jang**<sup>1</sup>, Yong-Jae Moon<sup>1</sup>, Rok-Soon Kim<sup>2,3</sup>, Sujin Kim<sup>2,3</sup>, and Jae-Ok Lee<sup>2</sup>

2017 ApJ 845 169

<http://iopscience.iop.org/sci-hub.cc/0004-637X/845/2/169/>

In this paper, we present two distinct types of coronal mass ejection (CME)-flare relationships according to their observing time differences using 107 events from 2010 to 2013. The observing time difference,  $\Delta T$ , is defined as flare peak time minus CME first appearance time at Solar Terrestrial Relations Observatory (STEREO) COR1 field of view. There are 41 events for group A ( $\Delta T < 0$ ) and 66 events for group B ( $\Delta T \geq 0$ ). We compare CME 3D parameters (speed and kinetic energy) based on multi-spacecraft data (Solar and Heliospheric Observatory (SOHO) and STEREO A and B) and their associated flare properties (peak flux, fluence, and duration). Our main results are as follows. First, there are better relationships between CME and flare parameters for group B than that of group A. In particular, CME 3D kinetic energy for group B is well correlated with flare fluence with the correlation coefficient of 0.67, which is much stronger than that ( $cc = 0.31$ ) of group A. Second, the events belonging to group A have short flare durations of less than 1 hr (mean = 21 minutes), while the events for group B have longer durations up to 4 hr (mean = 81 minutes). Third, the mean value of height at peak speed for group B is 4.05 Rs, which is noticeably higher than that of group A (1.89 Rs). This is well correlated with the CME acceleration duration ( $cc = 0.75$ ). A higher height at peak speed and a longer acceleration duration of CME for group B could be explained by the fact that magnetic reconnections for group B continuously occur for a longer time than those for group A. **2011 September 7**

### **Coronal Dynamic Activities in the Declining Phase of a Solar Cycle**

Minhwan **Jang**, T. N. Woods, Sunhak Hong, G. S. Choe

2016

<https://arxiv.org/pdf/1610.02944v1.pdf>

It has been known that some solar activity indicators show a double-peak feature in their evolution through a solar cycle, which is not conspicuous in sunspot number. In this letter, we investigate the high solar dynamic activity in the declining phase of the sunspot cycle by examining the evolution of polar and low latitude coronal hole areas and the statistics of splitting and merging events of coronal holes and coronal mass ejections detected by SOHO/LASCO C3 in solar cycle 23. Although the total coronal hole area is at its maximum near the sunspot minimum, in which polar coronal holes prevail, it shows a comparable second maximum in the declining phase of the cycle, in which low latitude coronal holes are dominant. The events of coronal hole splitting or merging, which are attributed to surface motions of magnetic fluxes, are also mostly populated in the declining phase of the cycle. The far-reaching C3 coronal mass ejections are also over-populated in the declining phase of the cycle. From these results we suggest that solar dynamic activities due to the horizontal motions of magnetic fluxes extend far in the declining phase of the sunspot cycle.

**Хорошее Введение.**

### **COMPARISON BETWEEN 2D AND 3D PARAMETERS OF 306 FRONT-SIDE HALO CMEs FROM 2009 TO 2013**

Soojeong **Jang**<sup>1,2</sup>, Y.-J. Moon<sup>1</sup>, R.-S. Kim<sup>2,3</sup>, Harim Lee<sup>1</sup>, and K.-S. Cho

2016 ApJ 821 95 DOI: 10.3847/0004-637X/821/2/95

We investigate 306 LASCO front-side halo (partial and full) CMEs from 2009 to 2013, which are well-observed by both the Solar and Heliospheric Observatory (SOHO) and the Solar TERrestrial RELations Observatory (STEREO). These CMEs have two-dimensional (2D) parameters, such as speed, angular width, and propagation direction, from a single spacecraft (SOHO), as well as three-dimensional (3D) parameters from a multi-spacecraft (STEREO). These 2D CME parameters, which are based on plane-of-sky observations, are taken from the SOHO LASCO CME catalog and the NGDC flare catalog. We have determined their 3D CME parameters using the Stereoscopic CME analysis tool (StereoCAT) provided by the Community Coordinated Modeling Center at NASA. We compare 2D and 3D CME parameters, making this the most comprehensive statistical study on CME 3D parameters. As a result, we find that 2D speeds underestimate the 3D speed by about 20%. The 3D width ranges from  $30^\circ$  to  $158^\circ$ , values which are much smaller than the 2D widths with a mean value of  $225^\circ$ . We also find that the ratio between the 2D and 3D widths decreases with central meridian distance. The 3D propagation directions are similar to the flare locations, with a mean absolute difference of about  $13^\circ$ . The width-speed relationship in 3D is much stronger than that in 2D.

## **A multiple spacecraft detection of the 2 April 2022 M-class flare and filament eruption during the first close Solar Orbiter perihelion**

[M. Janvier](#), [S. Mzerguat](#), [P. R. Young](#), [É. Buchlin](#), <sup>+++</sup>

A&A 677, A130 2023

<https://arxiv.org/pdf/2307.02396.pdf>

<https://www.aanda.org/articles/aa/pdf/2023/09/aa46321-23.pdf>

Context. The Solar Orbiter mission completed its first remote-sensing observation windows in the spring of 2022. On 2 April 2022, an M-class flare followed by a filament eruption was seen both by the instruments on board the mission and from several observatories in Earth's orbit, providing an unprecedented view of a flaring region with a large range of observations.

Aims. We aim to understand the nature of the flaring and filament eruption events via the analysis of the available dataset. The complexity of the observed features is compared with the predictions given by the standard flare model in 3D.

Methods. In this paper, we use the observations from a multi-view dataset, which includes extreme ultraviolet (EUV) imaging to spectroscopy and magnetic field measurements. These data come from the Interface Region Imaging Spectrograph, the Solar Dynamics Observatory, Hinode, as well as several instruments on Solar Orbiter.

Results. The large temporal coverage of the region allows us to analyse the whole sequence of the filament eruption starting with its pre-eruptive state. Information given by spectropolarimetry from SDO/HMI and Solar Orbiter PHI/HRT shows that a parasitic polarity emerging underneath the filament is responsible for bringing the flux rope to an unstable state. As the flux rope erupts, Hinode EIS captures blue-shifted emission in the transition region and coronal lines in the northern leg of the flux rope prior to the flare peak. This may be revealing the unwinding of one of the flux rope legs. At the same time, Solar Orbiter SPICE captures the whole region, complementing the Doppler diagnostics of the filament eruption. Analyses of the formation and evolution of a complex set of flare ribbons and loops, of the hard and soft X-ray emissions with STIX, show that the parasitic emerging bipole plays an important role in the evolution of the flaring region.

Conclusions. The extensive dataset covering this M-class flare event demonstrates how important multiple viewpoints and varied observations are in order to understand the complexity of flaring regions. While the analysed data are overall consistent with the standard flare model, the present particular magnetic configuration shows that surrounding magnetic activity such as nearby emergence needs to be taken into account to fully understand the processes at work. This filament eruption is the first to be covered from different angles by spectroscopic instruments, and provides an unprecedented diagnostic of the multi-thermal structures present before and during the flare. This complete dataset of an eruptive event showcases the capabilities of coordinated observations with the Solar Orbiter mission.

## **From coronal observations to MHD simulations, the building blocks for 3D models of solar flares**

**Review**

Miho [Janvier](#), Guillaume Aulanier, Pascal Demoulin

Solar Phys. 2015, File

<http://arxiv.org/pdf/1505.05299v1.pdf>

Solar flares are energetic events taking place in the Sun's atmosphere, and their effects can greatly impact the environment of the surrounding planets. In particular, eruptive flares, as opposed to confined flares, launch coronal mass ejections into the interplanetary medium, and as such, are one of the main drivers of space weather. After briefly reviewing the main characteristics of solar flares, we summarize the processes that can account for the build up and release of energy during their evolution. In particular, we focus on the development of recent 3D numerical simulations that explain many of the observed flare features. These simulations can also provide predictions of the dynamical evolution of coronal and photospheric magnetic field. Here we present a few observational examples that, together with numerical modelling, point to the underlying physical mechanisms of the eruptions. **18 March 1999**, **27 Feb 2000**, **2 March 2000**, **19 October 2001**, **16/11/2002**, **17=07=2004**, **20 January 2005**, **12 February 2007**, **18 August 2010**, **15 February 2011**, **09/05/2011**, **e 22 October 2011**, **15/01/2012**, **14 October 2012**, **11/03/2014**

Eruptive solar flares, associated with coronal mass ejections (CMEs), are important energetic events taking place in the solar corona. The intense magnetic energy release originates from magnetic reconnection, which is also responsible for newly formed magnetic structures that are ejected as CMEs. Solar coronal observations reveal typical 3D magnetic structures during eruptive flares: flux ropes (twisted magnetic field lines structures), ultimately ejected in the interplanetary medium, and hot and dense flare loops. Magnetic reconnection takes place in regions of drastic changes in the magnetic connectivity: these are separatrices, defining different domains of connectivity, or quasi-separatrix layers (QSLs), which generalize in 3D the regions of strong connectivity gradients.

With an MHD numerical simulation recreating the evolution of a flux rope expansion during an eruptive flare [Ref. 1], we propose a 3D-extended, more complete version of the standard model for eruptive flares. We present below new understandings offered by this model.

Our 3D standard model, built from a 3D MHD simulation, extends our understanding of the observational characteristics, as well as the underlying physical mechanisms of eruptive flares. Its main characteristics are outlined in the cartoon of Figure 1. This model shows that both flare loops and flux rope are constructed by 3D reconnection, in the thin coronal current layer that maps as J-shaped current/flare ribbons onto the photosphere. Field lines entering this region reconnect successively, leading to a slipping motion, as recently seen in coronal observations. This change of connectivity allows shear transfer from dynamically evolving pre- to post-reconnected field lines, and is often observed as a strong-to-weak shear transfer in flare loops observations. The flux rope, on the other hand, is constantly growing as reconnected twisted field lines construct its outer shell. From its ejection in the interplanetary medium, a flux rope can be detected as a magnetic cloud by in situ instruments away from the Sun. **2011-05-09, 2011-02-15, 2012-12-07, See Aulanier, G.**

## Are There Different Populations of Flux Ropes in the Solar Wind?

M. **Janvier**, P. Demoulin, S. Dasso

E-print, Feb 2014

<http://arxiv.org/pdf/1401.6812v1.pdf>

Flux ropes are twisted magnetic structures, which can be detected by in situ measurements in the solar wind. However, different properties of detected flux ropes suggest different types of flux-rope population. As such, are there different populations of flux ropes? The answer is positive, and is the result of the analysis of four lists of flux ropes, including magnetic clouds (MCs), observed at 1 AU. The in situ data for the four lists have been fitted with the same cylindrical force-free field model, which provides an estimation of the local flux-rope parameters such as its radius and orientation. Since the flux-rope distributions have a large dynamic range, we go beyond a simple histogram analysis by developing a partition technique that uniformly distributes the statistical fluctuations over the radius range. By doing so, we find that small flux ropes with radius  $R < 0.1$  AU have a steep power-law distribution in contrast to the larger flux ropes (identified as MCs), which have a Gaussian-like distribution. Next, from four CME catalogs, we estimate the expected flux-rope frequency per year at 1 AU. We find that the predicted numbers are similar to the frequencies of MCs observed in situ. However, we also find that small flux ropes are at least ten times too abundant to correspond to CMEs, even to narrow ones. Investigating the different possible scenarios for the origin of those small flux ropes, we conclude that these twisted structures can be formed by blowout jets in the low corona or in coronal streamers.

## Slingshot prominences: coronal structure, mass loss and spin down

M. **Jardine**, [A. Collier Cameron](#), [J.-F. Donati](#), [G.A.J. Hussain](#)

MNRAS **2019**

<https://arxiv.org/pdf/1911.04339.pdf>

The structure of a star's coronal magnetic field is a fundamental property that governs the high-energy emission from the hot coronal gas and the loss of mass and angular momentum in the stellar wind. It is, however, extremely difficult to measure. We report a new method to trace this structure in rapidly-rotating young convective stars, using the cool gas trapped on coronal field lines as markers. This gas forms "slingshot prominences" which appear as transient absorption features in H- $\alpha$ . By using different methods of extrapolating this field from the surface measurements, we determine locations for prominence support and produce synthetic H- $\alpha$  stacked spectra. The absorption features produced with a potential field extrapolation match well those observed, while those from a non-potential field do not. In systems where the rotation and magnetic axes are well aligned, up to 50% of the prominence mass may transit the star and so produces an observable feature. This fraction may fall as low as 2% in very highly inclined systems. Ejected prominences carry away mass and angular momentum at rates that vary by two orders of magnitude, but which may approach those carried by the stellar wind.

## Stellar mass ejections

**Review**

It has been known for some time now that rapidly-rotating solar-like stars possess the stellar equivalent of solar prominences. These may be three orders of magnitude more massive than their solar counterparts, and their ejection from the star may form a significant contribution to the loss of angular momentum and mass in the stellar wind. In addition, their number and distribution provide valuable clues as to the structure of the stellar corona and hence to the nature of magnetic activity in other stars.

## **Parametric study of the kinematic evolution of coronal mass ejection shock waves and their relation to flaring activity**

<https://www.aanda.org/articles/aa/pdf/2023/04/aa45480-22.pdf>

Coronal and interplanetary shock waves produced by coronal mass ejections (CMEs) are major drivers of space-weather phenomena, inducing major changes in the heliospheric radiation environment and directly perturbing the near-Earth environment, including its magnetosphere. A better understanding of how these shock waves evolve from the corona to the interplanetary medium can therefore contribute to improving nowcasting and forecasting of space weather. Early warnings from these shock waves can come from radio measurements as well as coronagraphic observations that can be exploited to characterise the dynamical evolution of these structures. Our aim is to analyse the geometrical and kinematic properties of 32 CME shock waves derived from multi-point white-light and ultraviolet imagery taken by the Solar Dynamics Observatory (SDO), Solar and Heliospheric Observatory (SoHO), and Solar-Terrestrial Relations Observatory (STEREO) to improve our understanding of how shock waves evolve in 3D during the eruption of a CME. We use our catalogue to search for relations between the shock wave's kinematic properties and the flaring activity associated with the underlying genesis of the CME piston. Past studies have shown that shock waves observed from multiple vantage points can be aptly reproduced geometrically by simple ellipsoids. The catalogue of reconstructed shock waves provides the time-dependent evolution of these ellipsoidal parameters. From these parameters, we deduced the lateral and radial expansion speeds of the shocks evolving over time. We compared these kinematic properties with those obtained from a single viewpoint by SoHO in order to evaluate projection effects. Finally, we examined the relationships between the shock wave and the associated flare when the latter was observed on the disc by considering the measurements of soft and hard X-rays. **23 July 2012**

Solar Phys (2018) 293:33

<http://sci-hub.tw/10.1007/s11207-018-1251-3>

We determine an optimal width and shape of the narrow-band filter centered around the HeI D3 line for prominence and coronal mass ejection (CME) observations with the ASPIICS (Association of Spacecraft for Polarimetric and Imaging Investigation of the Corona of the Sun) coronagraph onboard the PROBA-3 (Project for On-board Autonomy) satellite, to be launched in 2020. We analyze HeI D3 line intensities for three representative non-LTE prominence models at temperatures 8, 30 and 100 kK computed by the radiative transfer code and the prominence visible-light (VL) emission due to Thomson scattering on the prominence electrons. We compute various useful relations at prominence line-of-sight (LOS) velocities of 0, 100, and 300 km s<sup>-1</sup> for 20-Å wide flat filter and three Gaussian filters with full width at half maximum (FWHM) equal to 5, 10, and 20 Å to show the relative brightness contribution of the HeI D3 line and the prominence VL to the visibility in a given narrow-band filter. We also discuss possible signal contamination by NaI D1 and D2 lines which otherwise may be useful to detect comets. Results mainly show: i) an optimal narrow-band filter should be flat or somewhere between flat and Gaussian with FWHM of 20 Å in order to detect fast moving prominence structures, ii) the maximum emission in the HeI D3 line is at 30 kK and the minimal at 100 kK, and iii) the ratio of emission in the HeI D3 line to the VL emission can provide a useful diagnostic for the temperature of prominence structures. This ratio is up to 10 for hot prominence structures, up to 100 for cool structures and up to 1000 for warm structures.

## **Hot prominence detected in the core of a coronal mass ejection**

### **II. Analysis of the C iii line detected by SOHO/UVCS**

[S. Jejić](#)<sup>1,2</sup>, [R. Susino](#)<sup>3</sup>, [P. Heinzel](#)<sup>1</sup>, [E. Džifčáková](#)<sup>1</sup>, [A. Bemporad](#)<sup>3</sup> and [U. Anzer](#)<sup>4</sup>

A&A 607, A80 (2017)

<https://www.aanda.org/articles/aa/pdf/2017/11/aa31364-17.pdf>

Context. We study the physics of erupting prominences in the core of coronal mass ejections (CMEs) and present a continuation of a previous analysis.

Aims. We determine the kinetic temperature and microturbulent velocity of an erupting prominence embedded in the core of a CME that occurred on **August 2, 2000** using the Ultraviolet Coronagraph and Spectrometer observations (UVCS) on board the Solar and Heliospheric Observatory (SOHO) simultaneously in the hydrogen L $\alpha$  and C iii lines. We develop the non-LTE (departures from the local thermodynamic equilibrium – LTE) spectral diagnostics based on L $\alpha$  and L $\beta$  measured integrated intensities to derive other physical quantities of the hot erupting prominence. Based on this, we synthesize the C iii line intensity to compare it with observations.

**Methods.** Our method is based on non-LTE modeling of eruptive prominences. We used a general non-LTE radiative-transfer code only for optically thin prominence points because optically thick points do not allow the direct determination of the kinetic temperature and microturbulence from the line profiles. The input parameters of the code were the kinetic temperature and microturbulent velocity derived from the  $L\alpha$  and C iii line widths, as well as the integrated intensity of the  $L\alpha$  and  $L\beta$  lines. The code runs in three loops to compute the radial flow velocity, electron density, and effective thickness as the best fit to the  $L\alpha$  and  $L\beta$  integrated intensities within the accuracy defined by the absolute radiometric calibration of UVCS data.

**Results.** We analyzed 39 observational points along the whole erupting prominence because for these points we found a solution for the kinetic temperature and microturbulent velocity. For these points we ran the non-LTE code to determine best-fit models. All models with  $\tau_0(L\alpha) \leq 0.3$  and  $\tau_0(\text{C iii}) \leq 0.3$  were analyzed further, for which we computed the integrated intensity of the C iii line using a two-level atom. The best agreement between computed and observed integrated intensity led to 30 optically thin points along the prominence. The results are presented as histograms of the kinetic temperature, microturbulent velocity, effective thickness, radial flow velocity, electron density, and gas pressure. We also show the relation between the microturbulence and kinetic temperature together with a scatter plot of computed versus observed C iii integrated intensities and the ratio of the computed to observed C iii integrated intensities versus kinetic temperature.

**Conclusions.** The erupting prominence embedded in the CME is relatively hot with a low electron density, a wide range of effective thicknesses, a rather narrow range of radial flow velocities, and a microturbulence of about 25 km s<sup>-1</sup>. This analysis shows a disagreement between observed and synthetic intensities of the C iii line, the reason for which most probably is that photoionization is neglected in calculations of the ionization equilibrium. Alternatively, the disagreement might be due to non-equilibrium processes.

## **Spectroscopic Observations and Modelling of Impulsive Alfvén Waves Along a Polar Coronal Jet**

P. [Jelínek](#), A.K. Srivastava, K. Murawski, P. Kayshap, B.N. Dwivedi

A&A 581, A131 2015

Using the Hinode/EIS 2" spectroscopic observations, we study the intensity, velocity, and FWHM variations of the strongest Fe XII 195.12 Å line along the jet to find the signature of Alfvén waves. We simulate numerically the impulsively generated Alfvén waves within the vertical Harris current-sheet, forming the jet plasma flows, and mimicking their observational signatures. Using the FLASH code and the atmospheric model with embedded weakly expanding magnetic field configuration within a vertical Harris current-sheet, we solve the two and half-dimensional (2.5-D) ideal magnetohydrodynamic (MHD) equations to study the evolution of Alfvén waves and vertical flows forming the plasma jet. At a height of ~5 Mm from the base of the jet, the red-shifted velocity component of Fe XII 195.12 Å line attains its maximum (5 km s<sup>-1</sup>) which converts into a blue-shifted one between the altitude of 5–10 Mm. The spectral intensity continuously increases up to 10 Mm, while FWHM still exhibits the low values with almost constant trend. This indicates that the reconnection point within the jet's magnetic field topology lies in the corona 5–10 Mm from its footpoint anchored in the Sun's surface. Beyond this height, FWHM shows a growing trend. This may be the signature of Alfvén waves that impulsively evolve due to reconnection and propagate along the jet. From our numerical data, we evaluate space- and time- averaged Alfvén waves velocity amplitudes at different heights in the jet's current-sheet, which contribute to the non-thermal motions and spectral line broadening. The synthetic width of Fe XII 195.12 Å line exhibits similar trend of increment as in the observational data, possibly proving the existence of impulsively generated (by reconnection) Alfvén waves which propagate along the jet. 22 April, 2009.

## **Modelling the Effect of Mass-Draining on Prominence Eruptions**

Jack M. [Jenkins](#), [Matthew Hopwood](#), [Pascal Démoulin](#), [Gherardo Valori](#), [Guillaume Aulanier](#), [David M. Long](#), [Lidia van Driel-Gesztelyi](#)

ApJ 873 49 2019

<https://arxiv.org/pdf/1901.10970.pdf>

<https://doi.org/10.3847/1538-4357/ab037a>

Quiescent solar prominences are observed to exist within the solar atmosphere for up to several solar rotations. Their eruption is commonly preceded by a slow increase in height that can last from hours to days. This increase in the prominence height is believed to be due to their host magnetic flux rope transitioning through a series of neighbouring quasi-equilibria before the main loss-of-equilibrium that drives the eruption. Recent work suggests that the removal of prominence mass from a stable, quiescent flux rope is one possible cause for this change in height. However, these conclusions are drawn from observations and are subject to interpretation. Here we present a simple model to quantify the effect of "mass-draining" during the pre-eruptive height-evolution of a solar flux rope. The flux rope is modeled as a line current suspended within a background potential magnetic field. We first show that the inclusion of mass, up to 10<sup>12</sup>-kg, can modify the height at which the line current experiences loss-of-equilibrium by up to 14%. Next, we show that the rapid removal of mass prior to the loss-of-equilibrium can allow the height of the flux rope to increase sharply and without upper bound as it approaches its loss-of-equilibrium point. This indicates that the critical height for the loss-of-equilibrium can occur at a range of heights depending explicitly on the amount and evolution of mass within

the flux rope. Finally, we demonstrate that for the same amount of drained mass, the effect on the height of the flux rope is up to two order of magnitude larger for quiescent than for active region prominences.

### **Understanding the Role of Mass-Unloading in Filament Eruptions**

Jack **Jenkins**, [David M Long](#), [Lidia van Driel-Gesztelyi](#), [Jack Carlyle](#)

Solar Phys. 2018, 293:7

<https://arxiv.org/pdf/1711.02565.pdf>

We describe a partial filament eruption on **11 December 2011** which demonstrates that the inclusion of mass is an important next step for understanding solar eruptions. Observations from the \textit{Solar Terrestrial Relations Observatory Behind} (STEREO-B) and the \textit{Solar Dynamics Observatory} (SDO) spacecraft were used to remove line-of-sight projection effects in filament motion and correlate the effect of plasma dynamics with the evolution of the filament height. Flux cancellation and nearby flux emergence are shown to have played a role in increasing the height of the filament prior to eruption. The two viewpoints allow the quantitative estimation of a large mass-unloading, the subsequent radial expansion, and the eruption of the filament to be investigated. A 1.8 to 4.1 lower-limit ratio between gravitational and magnetic tension forces was found. We therefore conclude that following the loss-of-equilibrium of the flux rope, the radial expansion of the flux rope was restrained by the filamentary material until 70% of the mass had evacuated the structure through mass-unloading.

Coronal mass ejections (CMEs) are sources of major geomagnetic disturbances. On **2013 May 10**, a CME crossed the signal path between the MErcury Surface, Space ENvironment, GEochemistry, and Ranging (MESSENGER) spacecraft and Earth. Using the MESSENGER signal, characteristics of the density, velocity, and magnetic field properties of the crossing plasma were measured. An anomalously strong event occurred in the plasma trailing the CME's passage that correlated with a wave mode conversion, indicating a potential reconnection region. We determine that the plasma following CMEs should be considered when studying how CMEs evolve in interplanetary space and the severity of their geomagnetic impact.

### **Multi-fluid Model of a Sun-grazing Comet in the Rapidly Ionizing, Magnetized Low Corona**

Y.-D. **Jia**<sup>1</sup>, C. T. Russell<sup>1</sup>, W. Liu<sup>2</sup>, and Y. S. Shou

2014 ApJ 796 42

Two Sun-grazing comets were recently imaged in the low solar corona by space telescopes in unprecedented detail, revealing a wide range of new phenomena. This sparked growing interest in the interaction of comets with the coronal plasma and magnetic field and their diagnostic potential as solar probes. However, interpretation of such rich observational data requires profound understanding of relevant physical processes in an unexplored regime. Here advanced numerical modeling can provide critical clues. To this end, we present a prototype, multi-fluid, magnetohydrodynamic model of a steady-state comet in the low solar corona. These simulation results are compared with previously modeled comets in the solar wind environment. By inspecting their projection and column densities, we find a dominance of O<sup>6+</sup> ions in the cometary tail, which can explain the observed extreme ultraviolet emission. The tail is found to be comparable to recent EUV images of these comets. In addition, the comet tail appears wider when the observer's line of sight is perpendicular rather than parallel to the local magnetic field. This is opposite to the trend in the interplanetary space permeated in the solar wind, because the ratio between dynamic pressure and magnetic pressure is an order of magnitude smaller than at 1 AU. On the other hand, we find that iron ions in the comet head build up to a density comparable to that of oxygen ions, but are unlikely to form a visible tail because of the shorter mean free paths of the neutrals.

### **From fundamental theory to realistic modeling of the birth of solar eruptions.**

**Jiang, C.**

Sci. China Earth Sci. 67, 3765–3788 (2024).

<https://doi.org/10.1007/s11430-023-1402-3>

Solar eruptions, primarily manifested as solar flares, filament eruptions and coronal mass ejections, represent explosive releases of magnetic energy stored in the solar corona, with the potential to drive severe space weather. The initiation of solar eruptions remains an open question, leading to various theoretical models that are inferred from observations. However, these models are subjects of debate due to the absence of direct measurements of the three-dimensional (3D) magnetic fields in the corona. Numerical simulations, based on solving magnetohydrodynamics (MHD) equations that govern the macroscopic dynamics of solar corona, serve as a touchstone for testing these theoretical models. One early proposed model suggested that eruptions could be triggered by reconnection within a single sheared magnetic arcade, which is known as the tether-cutting reconnection model, but it was never confirmed through 3D MHD simulations until very recently. Consequently, two models have gained more popularity: one involving the eruption of a twisted magnetic flux rope (MFR) due to ideal instability (or loss of equilibrium), and the other known as the breakout eruption, which requires a quadrupolar configuration with a delicately located magnetic null point. Other mixed mechanisms,

involving both ideal instability and reconnection, are also proposed in association with localized magnetic flux emergence. Now with the validation of the tether-cutting model, the fundamental mechanisms are boiled down to two types of models, one primarily based on the ideal instability of a pre-existing MFR, and the other based on the reconnection of sheared field lines with or without an MFR. Recently, the modelling of the birth of solar eruption using observed data-based MHD simulations has advanced rapidly, becoming a crucial research tool in the study of the initiation mechanisms. These realistic modellings reveal a higher level of complexity compared to all currently available theories and idealized models.

## **Magnetic Reconnection as the Key Mechanism in Sunspot Rotation Leading to Solar Eruption**

[Chaowei Jiang](#), [Xueshang Feng](#), [Xinkai Bian](#), [Peng Zou](#), [Aiyong Duan](#), [Xiaoli Yan](#), [Qiang Hu](#), [Wen He](#), [Xinyi Wang](#), [Pingbing Zuo](#), [Yi Wang](#)

ApJ 2023

<https://arxiv.org/pdf/2308.09928.pdf>

The rotation of sunspots around their umbral center has long been considered as an important process in leading to solar eruptions, but the underlying mechanism remains unclear. A prevailing physical picture on how sunspot rotation leads to eruption is that, by twisting the coronal magnetic field lines from their footpoints, the rotation can build up a magnetic flux rope and drive it into some kinds of ideal magnetohydrodynamics (MHD) instabilities which initiate eruptions. Here with a data-inspired MHD simulation we studied the rotation of a large sunspot in solar active region NOAA 12158 leading to a major eruption, and found that it is distinct from prevailing theories based on ideal instabilities of twisted flux rope. The simulation suggests that, through successive rotation of the sunspot, the coronal magnetic field is sheared with a central current sheet created progressively within the sheared arcade before the eruption, but without forming a flux rope. Then the eruption is instantly triggered once fast reconnection sets in at the current sheet, while a highly twisted flux rope is created during the eruption. Furthermore, the simulation reveals an intermediate evolution stage between the quasi-static energy-storage phase and the impulsive eruption-acceleration phase. This stage may correspond to slow-rise phase in observation and it enhances building up of the current sheet.

## **Data-driven MHD simulation of a sunspot rotating active region leading to solar eruption**

[Chaowei Jiang](#), [Xueshang Feng](#), [Xinkai Bian](#), [Peng Zou](#), [Aiyong Duan](#), [Xiaoli Yan](#), [Qiang Hu](#), [Wen He](#), [Xinyi Wang](#), [Pingbing Zuo](#), [Yi Wang](#)

A&A 2023

<https://arxiv.org/pdf/2308.06977.pdf>

Solar eruptions are the leading driver of space weather, and it is vital for space weather forecast to understand in what conditions the solar eruptions can be produced and how they are initiated. The rotation of sunspots around their umbral center has long been considered as an important condition in causing solar eruptions. To unveil the underlying mechanisms, here we carried out a data-driven magnetohydrodynamics simulation for the event of a large sunspot with rotation for days in solar active region NOAA 12158 leading to a major eruption. The photospheric velocity as recovered from the time sequence of vector magnetograms are inputted directly at the bottom boundary of the numerical model as the driving flow. Our simulation successfully follows the long-term quasi-static evolution of the active region until the fast eruption, with magnetic field structure consistent with the observed coronal emission and onset time of simulated eruption matches rather well with the observations. Analysis of the process suggests that through the successive rotation of the sunspot the coronal magnetic field is sheared with a vertical current sheet created progressively, and once fast reconnection sets in at the current sheet, the eruption is instantly triggered, with a highly twisted flux rope originating from the eruption. This data-driven simulation stresses magnetic reconnection as the key mechanism in sunspot rotation leading to eruption. **6–11 September 2014**

## **A model of failed solar eruption initiated and destructed by magnetic reconnection**

[Chaowei Jiang](#), [Aiyong Duan](#), [Peng Zou](#), [Zhenjun Zhou](#), [Xinkai Bian](#), [Xueshang Feng](#), [Pingbing Zuo](#), [Yi Wang](#)

MNRAS Volume 525, Issue 4, November 2023, Pages 5857–5867,

<https://doi.org/10.1093/mnras/stad2658>

<https://arxiv.org/pdf/2307.15847.pdf>

Solar eruptions are explosive disruption of coronal magnetic fields, and often launch coronal mass ejections into the interplanetary space. Intriguingly, many solar eruptions fail to escape from the Sun, and the prevailing theory for such failed eruption is based on ideal MHD instabilities of magnetic flux rope (MFR); that is, a MFR runs into kink instability and erupts but cannot reach the height for torus instability. Here, based on numerical MHD simulation, we present a new model of failed eruption in which magnetic reconnection plays a leading role in the initiation and failure of the eruption. Initially, a core bipolar potential field is embedded in a background bipolar field, and by applying shearing and converging motions to the core field, a current sheet is formed within the core field. Then, tether-cutting reconnection is triggered at the current sheet, first slow for a while and becoming fast, driving an erupting MFR. Eventually, the rise of MFR is halted by the downward magnetic tension force of the overlying field, although the MFR apex has well exceeded the critical height of torus instability. More importantly, during the rise of the MFR, it experiences a significant rotation around the vertical axis (with a direction contrary to that predicted by kink instability), rendering the field direction at the rope apex almost inverse to the overlying field. As a result, a strong current sheet is

formed between the MFR and the overlying flux, and reconnection occurring in this current sheet ruins completely the MFR.

## **Data-driven modeling of solar coronal magnetic field evolution and eruptions**

Chaowei **Jiang**, Xueshang Feng, Yang Guo, Qiang Hu

The Innovation **2022**

[https://www.cell.com/the-innovation/fulltext/S2666-6758\(22\)00032-7](https://www.cell.com/the-innovation/fulltext/S2666-6758(22)00032-7)

<https://doi.org/10.1016/j.xinn.2022.100236>

Magnetic fields play a fundamental role in the structure and dynamics of the solar corona. As they are driven by their footpoint motions on the solar surface, which transport energy from the interior of the Sun into its atmosphere, the coronal magnetic fields are stressed continuously with buildup of magnetic nonpotentiality in the form of topology complexity (magnetic helicity) and local electric currents (magnetic free energy). The accumulated nonpotentiality is often released explosively by solar eruptions, manifested as solar flares and coronal mass ejections, during which magnetic energy is converted into mainly kinetic, thermal, and nonthermal energy of the plasma, which can cause adverse space weather. To reveal the physical mechanisms underlying solar eruptions, it is vital to know the three-dimensional (3D) structure and evolution of the coronal magnetic fields. Because of a lack of direct measurements, the 3D coronal magnetic fields are commonly studied using numerical modeling, whereas traditional models mostly aim for a static extrapolation of the coronal field from the observable photospheric magnetic field data. Over the last decade, dynamic models that are driven directly by observation magnetograms have been developed and applied successfully to study solar coronal magnetic field evolution as well as its eruption, which offers a novel avenue for understanding their underlying magnetic topology and mechanism. In this paper, we review the basic methodology of the data-driven coronal models, state-of-the-art developments, their typical applications, and new physics that have been derived using these models. Finally, we provide an outlook for future developments and applications of the data-driven models.

Frontiers in Physics 9:746576 **2021**

<https://arxiv.org/pdf/2109.08422.pdf>

<https://www.frontiersin.org/articles/10.3389/fphy.2021.746576/full>

<https://doi.org/10.3389/fphy.2021.746576>

Magnetic flux ropes (MFRs) constitute the core structure of coronal mass ejections (CMEs), but hot debates remain on whether the MFR forms before or during solar eruptions. Furthermore, how flare reconnection shapes the erupting MFR is still elusive in three dimensions. Here we studied a new MHD simulation of CME initiation by tether-cutting magnetic reconnection in a single magnetic arcade. The simulation follows the whole life, including the birth and subsequent evolution, of an MFR during eruption. In the early phase, the MFR is partially separated from its ambient field by a magnetic quasi-separatrix layer (QSL) that has a double-J shaped footprint on the bottom surface. With the ongoing of the reconnection, the arms of the two J-shaped footprints continually separate from each other, and the hooks of the J shaped footprints expand and eventually become closed almost at the eruption peak time, and thereafter the MFR is fully separated from the un-reconnected field by the QSL. We further studied the evolution of the toroidal flux in the MFR and compared it with that of the reconnected flux. Our simulation reproduced an evolution pattern of increase-to-decrease of the toroidal flux, which is reported recently in observations of variations in flare ribbons and transient coronal dimming. The increase of toroidal flux is owing to the flare reconnection in the early phase that transforms the sheared arcade to twisted field lines, while its decrease is a result of reconnection between field lines in the interior of the MFR in the later phase.

## **A fundamental mechanism of solar eruption initiation**

Solar eruptions are spectacular magnetic explosions in the Sun's corona, and how they are initiated remains unclear. Prevailing theories often rely on special magnetic topologies that may not generally exist in the pre-eruption source region of corona. Here, using fully three-dimensional magnetohydrodynamic simulations with high accuracy, we show that solar eruptions can be initiated in a single bipolar configuration with no additional special topology. Through photospheric shearing motion alone, an electric current sheet forms in the highly sheared core field of the magnetic arcade during its quasi-static evolution. Once magnetic reconnection sets in, the whole arcade is expelled impulsively, forming a fast-expanding twisted flux rope with a highly turbulent reconnecting region underneath. The simplicity and efficacy of this scenario argue strongly for its fundamental importance in the initiation of solar eruptions.

## Formation and Eruption of an Active Region Sigmoid. II. Magnetohydrodynamic Simulation of a Multistage Eruption

[sci-hub.tw/10.3847/1538-4357/aadd08](http://sci-hub.tw/10.3847/1538-4357/aadd08)

Solar eruptions, mainly eruptive flares with coronal mass ejections, represent the most powerful drivers of space weather. Due to the low plasma- $\beta$  nature of the solar corona, solar eruption has its roots in the evolution of the coronal magnetic field. Although various theoretical models of the eruptive magnetic evolution have been proposed, they still oversimplify the realistic process in observation, which shows a much more complex process due to the invisible complex magnetic environment. In this paper, we continue our study of a complex sigmoid eruption in solar active region 11283, which is characterized by a multipolar configuration embedding a null-point topology and a sigmoidal magnetic flux rope. Based on extreme ultraviolet observations, it has been suggested that a three-stage magnetic reconnection scenario might explain the complex flare process. Here we reproduce the complex magnetic evolution during the eruption using a data-constrained high-resolution magnetohydrodynamic (MHD) simulation. The simulation clearly demonstrates three reconnection episodes, which occurred in sequence in different locations in the corona. Through these reconnections, the initial sigmoidal flux rope breaks one of its legs, and quickly gives birth to a new tornado-like magnetic structure that is highly twisted and has multiple connections to the Sun due to the complex magnetic topology. The simulated magnetic field configuration and evolution are found to be consistent with observations of the corona loops, filaments, and flare ribbons. Our study demonstrates that significant insight into a realistic, complex eruption event can be gained by a numerical MHD simulation that is constrained or driven by observed data. **2011 September 6**

## Data-driven magnetohydrodynamic modelling of a flux-emerging active region leading to solar eruption

Chaowei [Jiang](#), S. T. Wu, Xuesheng Feng, Qiang Hu

Nature Communications 7:11522 2016

<http://www.nature.com/ncomms/2016/160516/ncomms11522/pdf/ncomms11522.pdf>

Solar eruptions are well-recognized as major drivers of space weather but what causes them remains an open question. Here we show how an eruption is initiated in a non-potential magnetic flux-emerging region using magnetohydrodynamic modelling driven directly by solar magnetograms. Our model simulates the coronal magnetic field following a long-duration quasi-static evolution to its fast eruption. The field morphology resembles a set of extreme ultraviolet images for the whole process. Study of the magnetic field suggests that in this event, the key transition from the pre-eruptive to eruptive state is due to the establishment of a positive feedback between the upward expansion of internal stressed magnetic arcades of new emergence and an external magnetic reconnection which triggers the eruption. Such a nearly realistic simulation of a solar eruption from origin to onset can provide important insight into its cause, and also has the potential for improving space weather modelling. **6-8 September 2011**

## A Comparison Study of a Solar Active-Region Eruptive Filament and a Neighboring Non-Eruptive Filament

Chaowei [Jiang](#), S. T. Wu, [Xueshang Feng](#), [Qiang Hu](#)

RAA 2015

<http://arxiv.org/pdf/1508.05113v1.pdf>

Solar active region (AR) 11283 is a very magnetically complex region and it has produced many eruptions. However, there exists a non-eruptive filament in the plage region just next to an eruptive one in the AR, which gives us an opportunity to perform a comparison analysis of these two filaments. The coronal magnetic field extrapolated using a CESE-MHD-NLFFF code (Jiang & Feng 2013) reveals that two magnetic flux ropes (MFRs) exist in the same extrapolation box supporting these two filaments, respectively. Analysis of the magnetic field shows that the eruptive MFR contains a bald-patch separatrix surface (BPSS) co-spatial very well with a pre-eruptive EUV sigmoid, which is consistent with the BPSS model for coronal sigmoids. The magnetic dips of the non-eruptive MFRs match  $H\{\alpha\}$  observation of the non-eruptive filament strikingly well, which strongly supports the MFR-dip model for filaments. Compared with the non-eruptive MFR/filament (with a length of about 200 Mm), the eruptive MFR/filament is much smaller (with a length of about 20 Mm), but it contains most of the magnetic free energy in the extrapolation box and holds a much higher free energy density than the non-eruptive one. Both the MFRs are weakly twisted and cannot trigger kink instability. The AR eruptive MFR is unstable because its axis reaches above a critical height for torus instability, at which the overlying closed arcades can no longer confine the MFR stably. On the contrary, the quiescent MFR is very firmly held by its overlying field, as its axis apex is far below the torus-instability threshold height. Overall, this comparison investigation supports that MFR can exist prior to eruption and the ideal MHD instability can trigger MFR eruption. **September 6-7, 2011**

## Testing a Solar Coronal Magnetic Field Extrapolation Code with the Titov-Demoulin Magnetic Flux Rope Model

Chaowei **Jiang**, Xueshang Feng

RAA 2015

<http://arxiv.org/pdf/1507.01910v1.pdf>

In the solar corona, magnetic flux rope is believed to be a fundamental structure accounts for magnetic free energy storage and solar eruptions. Up to the present, the extrapolation of magnetic field from boundary data is the primary way to obtain fully three-dimensional magnetic information of the corona. As a result, the ability of reliable recovering coronal magnetic flux rope is important for coronal field extrapolation. In this paper, our coronal field extrapolation code (CESE-MHD-NLFFF, Jiang & Feng 2012) is examined with an analytical magnetic flux rope model proposed by Titov & Demoulin (1999), which consists of a bipolar magnetic configuration holding an semi-circular line-tied flux rope in force-free equilibrium. By using only the vector field in the bottom boundary as input, we test our code with the model in a representative range of parameter space and find that the model field is reconstructed with high accuracy. Especially, the magnetic topological interfaces formed between the flux rope and the surrounding arcade, i.e., the "hyperbolic flux tube" and "bald patch separatrix surface", are also reliably reproduced. By this test, we demonstrate that our CESE-MHD-NLFFF code can be applied to recovering magnetic flux rope in the solar corona as long as the vector magnetogram satisfies the force-free constraints.

## Interaction between an emerging flux region and a pre-existing fan-spine dome observed by IRIS and SDO

Fayu **Jiang**, Jun Zhang, Shuhong Yang

Publications of the Astronomical Society of Japan 2015

<http://arxiv.org/pdf/1503.04505v2.pdf>

We present multi-wavelength observations of a fan-spine dome in the active region NOAA 11996 with the Interface Region Imaging Spectrograph (IRIS) and the Atmospheric Imaging Assembly on board the Solar Dynamics Observatory (SDO) on **March 9, 2014**. The destruction of the fan-spine topology owing to the interaction between its magnetic fields and an nearby emerging flux region (EFR) is firstly observed. The line-of-sight magnetograms from the Helioseismic and Magnetic Imager on board the SDO reveal that the dome is located on the mixed magnetic fields, with its rim rooted in the redundant positive polarity surrounding the minority parasitic negative fields. The fan surface of the dome consists of a filament system and recurring jets are observed along its spine. The jet occurring around 13:54 UT is accompanied with a quasi-circular ribbon that brightens in the clockwise direction along the bottom rim of the dome, which may indicate an occurrence of slipping reconnection in the fan-spine topology. The EFR emerges continuously and meets with the magnetic fields of the dome. Magnetic cancellations take place between the emerging negative polarity and the outer positive polarity of the dome's fields, which lead to the rise of the loop connecting the EFR and brightenings related to the dome. A single Gaussian fit to the profiles of the IRIS SI IV 1394 Å line is used in the analysis. It appears that there are two rising components along the slit, except for the rise in the line-of-sight direction. The cancellation process repeats again and again. Eventually the fan-spine dome is destroyed and a new connectivity is formed. We suggest that magnetic reconnection between the EFR and the magnetic fields of the fan-spine dome in the process is responsible for the destruction of the dome.

## Interaction and Merging of two Sinistral Filaments

Yunchun **Jiang**<sup>1</sup>, Jiayan Yang<sup>1</sup>, Haimin Wang<sup>2</sup>, Haisheng Ji<sup>3</sup>, Yu Liu<sup>1</sup>, Haidong Li<sup>1</sup>, and Jianping Li  
2014 ApJ 793 14

In this paper, we report the interaction and subsequent merging of two sinistral filaments (F1 and F2) occurring at the boundary of AR 9720 on **2001 December 6**. The two filaments were close and nearly perpendicular to each other. The interaction occurred after F1 was erupted and the eruption was impeded by a more extended filament channel (FC) standing in the way, in which F2 was embedded. The erupted material ran into FC along its axis, causing F1 and F2 to merge into a single structure that subsequently underwent a large-amplitude to-and-fro motion. A significant plasma heating process was observed in the merging process, making the mixed material largely disappear from the H $\alpha$  passband, but appear in Extreme Ultraviolet Telescope 195?? images for a while. These observations can serve as strong evidence of merging reconnection between the two colliding magnetic structures. A new sinistral filament was formed along FC after the cooling of the merged and heated material. No coronal mass ejection was observed to be associated with the event; though, the eruption was accompanied by a two-ribbon flare with a separation motion, indicating that the eruption had failed. This event shows that, in addition to overlying magnetic fields, such an interaction is an effective restraint to make a filament eruption fail in this way.

## Formation and Eruption of an Active Region Sigmoid: I. Study by Nonlinear Force-Free Field Modeling

Chaowei **Jiang**, S. T. Wu, Xueshang Feng, Qiang Hu

E-print, Oct 2013, File; 2014 ApJ 780 55

<http://arxiv.org/abs/1310.8196>

We present a magnetic analysis of the formation and eruption of an active region (AR) sigmoid in AR 11283 from **2011 September 4 to 6**. To follow the quasi-static evolution of the coronal magnetic field, we reconstruct a time sequence of static fields using a recently developed nonlinear force-free field model constrained by the SDO/HMI vector magnetograms. A detailed analysis of the fields compared with the SDO/AIA observations suggests the following scenario for the evolution of the region. Initially, a new bipole emerges into the negative polarity of a pre-existing bipolar AR, forming a null point topology between the two flux systems. A weakly twisted flux rope (FR) is then built up slowly in the embedded core region, largely through flux-cancellation photospheric reconnections, forming a bald patch separatrix surface (BPSS) separating the FR from its ambient field. The FR grows gradually until its axis runs into a torus instability (TI) domain near the end of the third day, and the BPSS also develops a fully S-shape. Unlike in the case of standard TI, the FR does not erupt instantly since it is still attached at the photosphere along the bald patch (BP) portion of the polarity inversion line. The combined effects of the TI-driven expansion of the FR and the line-tying at the BP tear the FR into two parts with the upper portion freely expelled and the lower portion remaining behind the post-flare arcades. This process dynamically perturbs the BPSS and results in the transient enhanced brightening of the sigmoid. The accelerated expansion of the upper portion of the FR strongly pushes its envelope flux near the null point and triggers breakout reconnection at the null, as evidenced by a remarkable circular flare ribbon, which further facilitates the eruption. We discuss the important implications of these results for the formation and disruption of sigmoid region with an FR.

### **MHD Simulation of a Sigmoid Eruption of Active Region 11283**

Chaowei **Jiang**, Xueshang Feng, S. T. Wu, Qiang Hu

E-print, June **2013**, ApJ 771 L30

Current magnetohydrodynamic (MHD) simulations of the initiation of solar eruptions are still commonly carried out with idealized magnetic field models, whereas the realistic coronal field prior to eruptions can possibly be reconstructed from the observable photospheric field. Using a nonlinear force-free field extrapolation prior to a sigmoid eruption in AR 11283 as the initial condition in a MHD model, we successfully simulate the realistic initiation process of the eruption event, as is confirmed by a remarkable resemblance to the SDO/AIA observations. Analysis of the pre-eruption field reveals that the envelope flux of the sigmoidal core contains a coronal null and furthermore the flux rope is prone to a torus instability. Observations suggest that reconnection at the null cuts overlying tethers and likely triggers the torus instability of the flux rope, which results in the eruption. This kind of simulation demonstrates the capability of modeling the realistic solar eruptions to provide the initiation process. **2011 September 6**.

presented observations of three successive filament eruptions from different locations on **2003 November 19** and interpreted these sympathetic eruptions from coronal dimming investigations.

### **Evidence for a Magnetic Flux Rope in Observations of a Solar Prominence-Cavity System**

Patricia R. **Jibben**, Katharine K. Reeves, and Yingna Su

Front. Astron. Space Sci. 3:10. **2016**

<https://www.frontiersin.org/articles/10.3389/fspas.2016.00010/full>

<https://doi.org/10.3389/fspas.2016.00010>

Coronal cavities are regions of low coronal emission that usually sit above solar prominences. These systems can exist for days or months before erupting. The magnetic structure of the prominence-cavity system during the quiescent period is important to understanding the pre-eruption phase. We describe observations of a coronal cavity situated above a solar prominence observed on the western limb as part of an Interface Region Imaging Spectrograph (IRIS) and Hinode coordinated Observation Program (IHOP 264). During the observation run, an inflow of hot plasma observed by the Hinode X-Ray Telescope (XRT) envelopes the coronal cavity and triggers an eruption of chromospheric plasma near the base of the prominence. During and after the eruption, bright X-ray emission forms within the cavity and above the prominence. IRIS and the Hinode EUV Imaging Spectrometer (EIS) show strong blue shifts in both chromospheric and coronal lines during the eruption. The Hinode Solar Optical Telescope (SOT) Ca II H-line data show bright emission during the ejection with complex, turbulent, flows near the prominence and along the cavity wall. These observations suggest a cylindrical flux rope best represents the cavity structure with the ejected material flowing along magnetic field lines supporting the cavity. We also find evidence for heating of the plasma inside the cavity after the flows. A model of the magnetic structure of the cavity comprised of a weakly twisted flux rope can explain the observed loops in the X-ray and EUV data. Observations from the Coronal Multichannel Polarimeter (CoMP) are compared to predicted models and are inconclusive. We find that more sensitive measurements of the magnetic field strength along the line-of-sight are needed to verify this configuration.

### **Exploring the Dynamics of CME-Driven Shocks by Comparing Numerical Modeling and Observations**

<https://arxiv.org/pdf/2409.18020>

Shocks driven by coronal mass ejections (CMEs) are primary drivers of gradual solar energetic particle (SEP) events, posing significant risks to space technology and astronauts. Concurrently, particles accelerated at these shocks may also propagate back to the Sun, potentially generating gamma-ray emissions through pion decay. We incorporated advanced modeling and multi-messenger observations to explore the role of CME-driven shocks in gamma-ray emissions and SEPs. Motivated by Fermi-LAT long-duration solar flares, we used the AWSoM MHD model to investigate the connection between the shocks and the properties of observed gamma-ray emissions. By coupling the AWSoM with iPATH model, we evaluate the impact of shock evolution complexity near the Sun on SEP intensity and spectra. Our result points to the importance of accurate background coronal and solar wind modeling, as well as detailed observations of CME source regions, in advancing our understanding of CME-driven shocks and the dynamics of associated energetic particles. **7 Mar 2012, 17 May 2012, 11 Apr 2013, 1 Sep 2014, 17 Jul 2021, 28 Oct 2021**

### Coronal Dimming as a Proxy for Stellar Coronal Mass Ejections

Meng **Jin**, [Mark C. M. Cheung](#), [Marc L. DeRosa](#), [Nariaki V. Nitta](#), [Carolus J. Schrijver](#), [Kevin France](#), [Adam Kowalski](#), [James P. Mason](#), [Rachel Osten](#)

Proceedings of IAU Symposium No. 354 - Solar and Stellar Magnetic Fields: Origins and Manifestations **2020**

<https://arxiv.org/pdf/2002.06249.pdf>

Solar coronal dimmings have been observed extensively in the past two decades and are believed to have close association with coronal mass ejections (CMEs). Recent study found that coronal dimming is the only signature that could differentiate powerful ares that have CMEs from those that do not. Therefore, dimming might be one of the best candidates to observe the stellar CMEs on distant Sun-like stars. In this study, we investigate the possibility of using coronal dimming as a proxy to diagnose stellar CMEs. By simulating a realistic solar CME event and corresponding coronal dimming using a global magnetohydrodynamics model (AWSoM: Alfvén-wave Solar Model), we first demonstrate the capability of the model to reproduce solar observations. We then extend the model for simulating stellar CMEs by modifying the input magnetic flux density as well as the initial magnetic energy of the CME flux rope. Our result suggests that with improved instrument sensitivity, it is possible to detect the coronal dimming signals induced by the stellar CMEs. **2011 February 15**

### Chromosphere to 1 AU Simulation of the 2011 March 7th Event: A Comprehensive Study of Coronal Mass Ejection Propagation

M. **Jin**, W. B. Manchester, B. van der Holst, I. Sokolov, G. Toth, A. Vourlidas, C. A. de Koning, T. I. Gombosi

ApJ **2016**

<https://arxiv.org/pdf/1611.08897v1.pdf>

[http://www.lmsal.com/~jinmeng/papers/mjin17a\\_apj.pdf](http://www.lmsal.com/~jinmeng/papers/mjin17a_apj.pdf)

We perform and analyze results of a global magnetohydrodynamic (MHD) simulation of the fast coronal mass ejection (CME) that occurred on **2011 March 7**. The simulation is made using the newly developed Alfvén Wave Solar Model (AWSoM), which describes the background solar wind starting from the upper chromosphere and extends to  $24 R_{\odot}$ . Coupling AWSoM to an inner heliosphere (IH) model with the Space Weather Modeling Framework (SWMF) extends the total domain beyond the orbit of Earth. Physical processes included in the model are multi-species thermodynamics, electron heat conduction (both collisional and collisionless formulations), optically thin radiative cooling, and Alfvén-wave turbulence that accelerates and heats the solar wind. The Alfvén-wave description is physically self-consistent, including non-Wentzel-Kramers-Brillouin (WKB) reflection and physics-based apportioning of turbulent dissipative heating to both electrons and protons. Within this model, we initiate the CME by using the Gibson-Low (GL) analytical flux rope model and follow its evolution for days, in which time it propagates beyond STEREO A. A detailed comparison study is performed using remote as well as *in situ* observations. Although the flux rope structure is not compared directly due to lack of relevant ejecta observation at 1 AU in this event, our results show that the new model can reproduce many of the observed features near the Sun (e.g., CME-driven extreme ultraviolet (EUV) waves, deflection of the flux rope from the coronal hole, "double-front" in the white light images) and in the heliosphere (e.g., shock propagation direction, shock properties at STEREO A).

### Data Constrained Coronal Mass Ejections in A Global Magnetohydrodynamics Model

M. **Jin**, W. B. Manchester, B. van der Holst, I. Sokolov, G. Toth, R. E. Mullinix, A. Taktakishvili, A. Chulaki, T. I. Gombosi

ApJ **834** 173 **2017**

<https://arxiv.org/pdf/1605.05360v1.pdf>

[http://www.lmsal.com/~jinmeng/papers/mjin17b\\_apj.pdf](http://www.lmsal.com/~jinmeng/papers/mjin17b_apj.pdf)

We present a first-principles-based coronal mass ejection (CME) model suitable for both scientific and operational purposes by combining a global magnetohydrodynamics (MHD) solar wind model with a flux rope-driven CME model. Realistic CME events are simulated self-consistently with high fidelity and forecasting capability by constraining initial flux rope parameters with observational data from GONG, SOHO/LASCO, and STEREO/COR. We automate this process so that minimum manual intervention is required in specifying the CME initial state. With the newly developed

data-driven Eruptive Event Generator Gibson-Low (EEGGL), we present a method to derive Gibson-Low (GL) flux rope parameters through a handful of observational quantities so that the modeled CMEs can propagate with the desired CME speeds near the Sun. A test result with CMEs launched with different Carrington rotation magnetograms are shown. Our study shows a promising result for using the first-principles-based MHD global model as a forecasting tool, which is capable of predicting the CME direction of propagation, arrival time, and ICME magnetic field at 1 AU (see companion paper by Jin et al. 2016b).

See [Introduction](#) about three different categories of the CME models

## **A Numerical Study of Long-Range Magnetic Impacts during Coronal Mass Ejections**

M. [Jin](#), C. J. Schrijver, M. C. M. Cheung, M. L. DeRosa, N. V. Nitta, A. M. Title

ApJ 820 16 2016 File

[http://www.lmsal.com/~schryver/Public/ms/LongRangeImpacts\\_ApJ.pdf](http://www.lmsal.com/~schryver/Public/ms/LongRangeImpacts_ApJ.pdf)

With the global view and high-cadence observations from SDO/AIA and STEREO, many spatially separated solar eruptive events appear to be coupled. However, the mechanisms for "sympathetic" events are still largely unknown. In this study, we investigate the impact of an erupting flux rope on surrounding solar structures through large-scale magnetic coupling. We build a realistic environment of the solar corona on **2011 February 15** using a global magnetohydrodynamics (MHD) model and initiate coronal mass ejections (CMEs) in active region (AR) 11158 by inserting Gibson-Low analytical flux ropes. We show that a CME's impact on the surrounding structures depends not only on the magnetic strength of these structures and their distance to the source region, but also on the interaction between the CME with the large-scale magnetic field. Within the CME expansion domain where the flux rope field directly interacts with the solar structures, expansion-induced reconnection often modifies the overlying field, thereby increasing the decay index. This effect may provide a primary coupling mechanism underlying the sympathetic eruptions. The magnitude of the impact is found to depend on the orientation of the erupting flux rope, with the largest impacts occurring when the flux rope is favorably oriented for reconnecting with the surrounding regions. Outside the CME expansion domain, the influence of the CME is mainly through field line compression or post-eruption relaxation. Based on our numerical experiments, we discuss a way to quantify the eruption impact, which could be useful for forecasting purposes.

## **NUMERICAL SIMULATIONS OF CORONAL MASS EJECTION ON 2011 MARCH 7: ONE-TEMPERATURE AND TWO-TEMPERATURE MODEL COMPARISON**

M. [Jin](#)<sup>1</sup>, W. B. Manchester<sup>1</sup>, B. van der Holst<sup>1</sup>, R. Oran<sup>1</sup>, I. Sokolov<sup>1</sup>, G. Toth<sup>1</sup>, Y. Liu<sup>2</sup>, X. D. Sun<sup>2</sup>, and T. I. Gombosi

2013 ApJ 773 50

During Carrington rotation (CR) 2107, a fast coronal mass ejection (CME;  $>2000 \text{ km s}^{-1}$ ) occurred in active region NOAA 11164. This event is also associated with a solar energetic particle event. In this study, we present simulations of this CME with one-temperature (1T) and two-temperature (2T: coupled thermodynamics of the electron and proton populations) models. Both the 1T and 2T models start from the chromosphere with heat conduction and radiative cooling. The background solar wind is driven by Alfvén-wave pressure and heated by Alfvén-wave dissipation in which we have incorporated the balanced turbulence at the top of the closed field lines. The magnetic field of the inner boundary is set up using a synoptic map from Solar Dynamics Observatory/Heliographic and Magnetic Imager. The Titov-Démoulin flux-rope model is used to initiate the CME event. We compare the propagation of fast CMEs and the thermodynamics of CME-driven shocks in both the 1T and 2T CME simulations. Also, the synthesized white light images are compared with the Solar and Heliospheric Observatory/Large Angle and Spectrometric Coronagraph observations. Because there is no distinction between electron and proton temperatures, heat conduction in the 1T model creates an unphysical temperature precursor in front of the CME-driven shock and makes the shock parameters (e.g., shock Mach number, compression ratio) incorrect. Our results demonstrate the importance of the electron heat conduction in conjunction with proton shock heating in order to produce the physically correct CME structures and CME-driven shocks.

## **Magnetic Eruption from a Three-ribbon Flare**

Ju [Jing](#)<sup>1</sup>, Jeongwoo Lee<sup>1</sup>, Mia Mancuso<sup>1</sup>, Qin Li<sup>1</sup>, Nian Liu<sup>1</sup>, Satoshi Inoue<sup>1</sup>, Yan Xu<sup>1</sup>, and Haimin Wang<sup>1</sup>

2024 ApJ 972 110

<https://iopscience.iop.org/article/10.3847/1538-4357/ad5ce3/pdf>

We present observations and analysis of an eruptive M1.5 flare (SOL2014-08-01T18:13) in NOAA active region (AR) 12127, characterized by three flare ribbons, a confined filament between ribbons, and rotating sunspot motions as observed by the Solar Dynamics Observatory. The potential field extrapolation model shows a magnetic topology involving two intersecting quasi-separatrix layers (QSLs) forming a hyperbolic flux tube (HFT), which constitutes the fishbone structure for the three-ribbon flare. Two of the three ribbons show separation from each other, and the third ribbon is rather stationary at the QSL footpoints. The nonlinear force-free field extrapolation model implies the presence of a magnetic flux rope (MFR) structure between the two separating ribbons, which was unclear in the

observation. This suggests that the standard reconnection scenario for eruptive flares applies to the two ribbons, and the QSL reconnection for the third ribbon. We find rotational flows around the sunspot, which may have caused the eruption by weakening the downward magnetic tension of the MFR. The confined filament is located in the region of relatively strong strapping field. The HFT topology and the accumulation of reconnected magnetic flux in the HFT may play a role in holding it from eruption. This eruption scenario differs from the one typically known for circular ribbon flares, which is mainly driven by a successful inside-out eruption of filaments. Our results demonstrate the diversity of solar magnetic eruption paths that arises from the complexity of the magnetic configuration.

### **Statistical Analysis of Torus and Kink Instabilities in Solar Eruptions**

Ju [Jing](#), [Chang Liu](#), [Jeongwoo Lee](#), [Hantao Ji](#), [Nian Liu](#), [Yan Xu](#), [Haimin Wang](#)

2018 *ApJ* **864** 138

<https://arxiv.org/pdf/1808.08924.pdf>

[sci-hub.tw/10.3847/1538-4357/aad6e4](https://sci-hub.tw/10.3847/1538-4357/aad6e4)

A recent laboratory experiment of ideal magnetohydrodynamic (MHD) instabilities reveals four distinct eruption regimes readily distinguished by the torus instability (TI) and helical kink instability (KI) parameters (Myers 2015). To establish its observational counterpart, we collect 38 solar flares (stronger than GOES class M5 in general) that took place within  $45^\circ$  of disk center during 2011–2017, 26 of which are associated with a halo or partial halo coronal mass ejection (CME) (i.e., ejective events), while the others are CMEless (i.e., confined events). This is a complete sample of solar events satisfying our selection criteria detailed in the paper. For each event, we calculate decay index  $n$  of the potential strapping field above the magnetic flux rope (MFR) in and around the flaring magnetic polarity inversion line (a TI parameter), and the unsigned twist number  $T_w$  of the non-linear force-free (NLFF) field lines forming the same MFR (a KI parameter). We then construct a  $n$ – $T_w$  diagram to investigate how the eruptiveness depends on these parameters. We find: (1)  $T_w$  appears to play little role in discriminating between confined and ejective events; (2) the events with  $n \geq 0.8$  are all ejective and all confined events have  $n \leq 0.8$ . However,  $n \geq 0.8$  is not a necessary condition for eruption, because some events with  $n \leq 0.8$  also erupted. In addition, we investigate the MFR's geometrical parameters, apex height and distance between footpoints, as a possible factor for the eruptiveness. We briefly discuss the difference of the present result for solar eruptions with that of the laboratory result in terms of the role played by magnetic reconnection. **2015-03-12**, **2015-06-22**

Research in Astronomy and Astrophysics (RAA) Vol 15, No 9 1537-1546 **2015**

<http://www.raa-journal.org/raa/index.php/raa/article/view/2313>

We compare two contrasting X-class flares in terms of magnetic free energy, relative magnetic helicity and decay index of the active regions (ARs) in which they occurred. The events in question are the eruptive X2.2 flare from AR 11158 accompanied by a halo coronal mass ejection (CME) and the confined X3.1 flare from AR 12192 with no associated CME. These two flares exhibit similar behavior of free magnetic energy and helicity buildup for a few days preceding them. A major difference between the two flares is found to lie in the time-dependent change of magnetic helicity of the ARs that hosted them. AR 11158 shows a significant decrease in magnetic helicity starting  $\sim 4$  hours prior to the flare, but no apparent decrease in helicity is observed in AR 12192. By examining the magnetic helicity injection rates in terms of sign, we confirmed that the drastic decrease in magnetic helicity before the eruptive X2.2 flare was not caused by the injection of reversed helicity through the photosphere but rather the CME-related change in the coronal magnetic field. Another major difference we find is that AR 11158 had a significantly larger decay index and therefore weaker overlying field than AR 12192. These results suggest that the coronal magnetic helicity and the decay index of the overlying field can provide a clue about the occurrence of CMEs.

### **Evolution of a Magnetic Flux Rope and its Overlying Arcade Based on Nonlinear Force-free Field Extrapolations**

Ju [Jing](#), [Chang Liu](#), [Jeongwoo Lee](#), [Shuo Wang](#), [Thomas Wiegelmann](#), [Yan Xu](#), and [Haimin Wang](#)

*ApJ* **784** L13, **2014**

E-print, March **2014**;

Dynamic phenomena indicative of slipping reconnection and magnetic implosion were found in a time series of nonlinear force-free field (NLFFF) extrapolations for the active region 11515, which underwent significant changes in the photospheric fields and produced five C-class flares and one M-class flare over five hours on **2012 July 2**. NLFFF extrapolation was performed for the uninterrupted 5 hour period from the 12 minute cadence vector magnetograms of the Helioseismic and Magnetic Imager on board the Solar Dynamic Observatory. According to the time-dependent NLFFF model, there was an elongated, highly sheared magnetic flux rope structure that aligns well with an H $\alpha$  filament. This long filament splits sideways into two shorter segments, which further separate from each other over time at a speed of 1–4 km s $^{-1}$ , much faster than that of the footpoint motion of the magnetic field. During the separation, the magnetic arcade arching over the initial flux rope significantly decreases in height from  $\sim 4.5$  Mm to less than 0.5 Mm. We discuss the reality of this modeled magnetic restructuring by relating it to the observations of the magnetic

cancellation, flares, a filament eruption, a penumbra formation, and magnetic flows around the magnetic polarity inversion line.

## **Intense Flare-CME Event of the Year 2015: Propagation and Interaction Effects between Sun and Earth's Orbit**

Abhishek [Johri](#), P.K. Manoharan

Solar Phys. **2016**

<http://arxiv.org/pdf/1603.04555v1.pdf>

In this paper, We report the interplanetary effects of a fast coronal mass ejection (CME) associated with the intense X2.7 flare that occurred on **05 May 2015**. The near-Sun signatures of the CME at low-coronal heights  $<2 \{R_{\odot}\}$  are obtained from the EUV images at 171  $\{\text{\AA}\}$  and metric radio observations. The intensity and duration of the CME-driven radio bursts in the near-Sun and interplanetary medium indicate this CME event to be an energetic one. The interplanetary scintillation data, along with the low-frequency radio spectrum, played a crucial role in understanding the radial evolution of the speed and expansion of the CME in the inner heliosphere as well as its interaction with a preceding slow CME. The estimation of the speed of the CME at several points along the Sun to 1 AU shows that i) the CME went through a rapid acceleration as well as expansion up to a height of  $\approx 6 \{R_{\odot}\}$ , and ii) the CME continued to propagate at speed  $\geq 800 \text{ kms}^{-1}$  between the Sun and 1 AU. These results show that the CME likely overcame the drag exerted by the ambient/background solar-wind with the support of its internal magnetic energy. When the CME interacted with a slow preceding CME, the turbulence level associated with the CME-driven disturbance increased significantly.

## **The visual complexity of coronal mass ejections follows the solar cycle**

[S. R. Jones](#), [C. J. Scott](#), [L. A. Barnard](#), [R. Highfield](#), [C. J. Lintott](#), [E. Baeten](#)

Space Weather e2020SW002556 **Volume18, Issue10 2020**

<https://doi.org/10.1029/2020SW002556>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2020SW002556>

The Heliospheric Imagers on board NASA's twin STEREO spacecraft show that coronal mass ejections (CMEs) can be visually complex structures. To explore this complexity, we created a citizen science project with the UK Science Museum, in which participants were shown pairs of CME images and asked to decide which image in each pair appeared the most 'complicated'. A Bradley-Terry model was then applied to these data to rank the CMEs by their 'complicatedness', or 'visual complexity'. This complexity ranking revealed that the annual average visual complexity values follow the solar activity cycle, with a higher level of complexity being observed at the peak of the cycle. The average complexity of CMEs observed by STEREO-A was also found to be significantly higher than those observed by STEREO-B. Visual complexity was found to be associated with CME size and brightness, but our results suggest that complexity may be influenced by the scale-sizes of structure in the CMEs. **15 June 2011**

## **Tracking CMEs using data from the Solar Stormwatch project; observing deflections and other properties**

Shannon R. [Jones](#), Luke A. Barnard, Christopher J. Scott, Mathew J. Owens, Julia Wilkinson

Space Weather Volume 15, Issue 9 September **2017** Pages 1125–1140

<http://sci-hub.cc/10.1002/2017SW001640>

With increasing technological dependence, society is becoming ever more affected by changes in the near-Earth space environment caused by space weather. The primary driver of these hazards are coronal mass ejections (CMEs). Solar Stormwatch is a citizen science project in which volunteers participated in several activities which characterized CMEs in the remote sensing images from the Sun Earth Connection Coronal and Heliospheric Investigation (SECCHI) instrument package on the twin STEREO spacecraft. Here we analyze the results of the "Track-it-back" activity, in which CMEs were tracked back through the COR1, COR2, and EUVI images. Analysis of the COR1, COR2, and EUVI data together allows CMEs to be studied consistently throughout the whole field of view spanned by these instruments (out to 15 RS). A total of 4783 volunteers took part in this activity, creating a data set containing 23,801 estimates of CME timing, location, and size. We used these data to produce a catalogue of 41 CMEs, which is the first to consistently track CMEs through each of these instruments. We assess how the CME speeds, propagation directions, and widths vary as the CMEs propagate through the fields of view of the different imagers. In particular, we compare the observed CME deflections between the COR1 and COR2 fields of view to the separation between the CME source region and the heliospheric current sheet (HCS), demonstrating that in general, these CMEs appear to deflect toward the HCS, consistent with other modeling studies of CME propagation.

## **LOCALIZED PLASMA DENSITY ENHANCEMENTS OBSERVED IN STEREO COR1**

Shaella I. [Jones](#)<sup>1,2</sup> and Joseph M. Davila<sup>2</sup>

Astrophysical Journal, 701:1906–1910, **2009**

Measurements of solar wind speed in the solar corona, where it is primarily accelerated, have proven elusive. One of the more successful attempts has been the tracking of outward-moving density inhomogeneities in whitelight coronagraph images. These inhomogeneities, or "blobs," have been treated as passive tracers of the ambient

solar wind. Here we report on the extension of these observations to lower altitudes using the *STEREO* COR1 coronagraph, and discuss the implications of these measurements for theories about the origin of these features.

### **High-resolution observations of recurrent jets from an arch filament system**

<https://www.aanda.org/articles/aa/pdf/2024/11/aa49715-24.pdf>

Solar jets are collimated plasma ejections along magnetic field lines observed in hot (EUV jets) and cool (chromospheric surges) temperature diagnostics. Their trigger mechanisms and the relationship between hot and cool jets are still not completely understood. We aim to investigate the generation of a sequence of active region solar jets and their evolution from the photospheric to the coronal heights. Using the synergy of high spatial and temporal resolution observations by the SST, along with the SDO, we analyze a sequence of solar jets originating in a mixed polarity region between the leading and following sunspots of an active region. We use a NFFF extrapolation technique for deriving the magnetic field topology of the active region. A mixed polarity region is formed over a long period (24 hours) with persistent magnetic flux emergence. This region has been observed as an arch filament system (AFS) in chromospheric SST observations. In this region, negative polarities surrounded by positive polarities create a fan-surface with a null point at a height of 6 Mm detected in the NFFF extrapolation. SST observations in H-beta spectral line reveal a large flux rope over the AFS and moving from the North to South, causing successive EUV and cool jets to move in the East-West direction and later towards the South along the long open loops. The high resolution SST observations (0.038 arcsec per pixel) resolve the dark area observed at the jet base and reveal the existence of an AFS with an extended cool jet which may be the result of a peeling-like mechanism of the AFS. Based on the combined analysis of SST and AIA observations along with extrapolated magnetic topology, it is suggested that the magnetic reconnection site may move southward by approximately 20 Mm until it reaches a region where the open magnetic field lines are oriented North-South. **23-24 Jun 2022**

### **Generic low-atmosphere signatures of swirled-anemone jets**

<https://arxiv.org/pdf/2404.13171>

<https://doi.org/10.1051/0004-6361/202449553>

<https://www.aanda.org/articles/aa/pdf/2024/07/aa49553-24.pdf>Context. Solar jets are collimated plasma flows moving along magnetic field lines and accelerated at low altitude following magnetic reconnection. Several of them originate from anemone-shaped low-lying arcades and the most impulsive ones tend to be relatively wider and display untwisting motions. Aims. We aim to establish typical behaviours and observational signatures in the low atmosphere that can occur in response to the coronal development of such impulsive jets. Methods. We analysed an observed solar jet associated with a circular flare ribbon, using high-resolution observations from SST coordinated with IRIS and SDO. We related specifically-identified features with those developing in a generic 3D line-tied numerical simulation of reconnection-driven jets, performed with the ARMS code. Results. We identified three features in the SST observations: the formation of a hook along the circular ribbon, the gradual widening of the jet through the apparent displacement of its kinked edge towards –and not away– from the presumed reconnection site, and the falling back of some of the jet plasma towards a footpoint offset from that of the jet itself. The 3D numerical simulation naturally accounts for these features which were not imposed a priori. Our analyses allow to interpret them in the context of the 3D geometry of the asymmetric swirled anemone loops and their sequences of reconnection with ambient coronal loops. Conclusions. Given the relatively-simple conditions in which the observed jet occurred, together with the generic nature of the simulation that comprised minimum assumptions, we predict that the specific features that we identified and interpreted are probably typical of every impulsive jet. **June 11, 2014**

### **Interaction of solar jets with filaments: Triggering of large-amplitude filament oscillations**

[Reetika Joshi](#), [Manuel Luna](#), [Brigitte Schmieder](#), [Fernando Moreno-Insertis](#), [Ramesh Chandra](#)

A&A 672, A15 2023

<https://arxiv.org/pdf/2301.13103.pdf>

<https://www.aanda.org/articles/aa/pdf/2023/04/aa45647-22.pdf>

Large-amplitude oscillations (LAOs) are often detected in filaments. Using multiwavelength observations, their origin can be traced back to the interaction with eruptions and jets. We present two different case studies as observational evidence in support of 2.5D MHD numerical experiments that show that the LAOs in the filament channels can be initiated by solar jets. In the two studied events, we can identify a quadrupolar configuration with an X-point at the top of the parasitic region suggestive of a classical null-point. A reconnection flow emanates from this structure leading to a jet that propagates along the filament channel. In both cases we can identify the quiescent and eruptive phases of the jet. The triggered LAOs have periods of around 70-80 minutes and are damped after a few oscillations. The minimum magnetic field intensity inferred with seismology for the filament turns out to be around 30 Gauss. We conclude that the two case studies are consistent with the recent numerical model of Luna and Moreno-Insertis (2021), in which the LAOs are initiated by jets. The relationship between the onset of the jet and filament oscillations is straight-forward for

the first case and less for the second case. In the second event, although there is some evidence, we cannot rule out other possibilities such as activity unrelated to the null-point or changes in the magnetic structure of the filament. Both jets are associated with very weak flares which did not launch any EUV wave. Therefore the role of EUV waves for triggering the filament oscillations can be eliminated for these two case. **3 Feb 2015, 5 Feb 2015**

## Study of Solar Jets and Related Flares

Thesis

[Reetika Joshi](#)

Thesis 2022

<https://arxiv.org/pdf/2206.02478.pdf>

Solar jets are ubiquitous transient collimated mass outflows in the solar atmosphere over a wide range of sizes from small scale nanojets to a few solar radii, embedded in the solar chromosphere to solar corona. Jets are frequently accompanied by solar flares and these flares provide the force to propagate the plasma material upward and could be accompanied by coronal mass ejections. These jets could act as a source for transporting a significant mass and energy from the lower solar atmosphere to the upper coronal heights and consequently heating the solar corona and accelerating the solar wind. Magnetic reconnection is believed to be the triggering reason behind these jet activity. The thesis entitled: Study of Solar Jets and Related Flares, includes various case studies with different mechanisms to set off the jet initiation, associated large scale eruptions and mounts strong observational evidences to validate the numerical experiments for the magnetic flux emergence models. Such studies on solar jets along with their magnetic origin contribute to resolve the scandalous coronal heating problem and provide the evidences for the existing theoretical models and open a new window for the interplanetary science. **April 15-16, 2014, March 14-15, 2015, April 4, 2017, March 22, 2019**

## Analysis of the Evolution of a Multi-Ribbon Flare and Failed Filament Eruption

[Reetika Joshi](#), [Cristina H. Mandrini](#), [Ramesh Chandra](#), [Brigitte Schmieder](#), [Germán D. Cristiani](#), [Cecilia Mac Cormack](#), [Pascal Démoulin](#), [Hebe Cremades](#)

Solar Phys. **297**, Article number: 81 2022

<https://arxiv.org/pdf/2206.00531.pdf>

<https://link.springer.com/content/pdf/10.1007/s11207-022-02021-5.pdf>

How filaments form and erupt are topics about which solar researchers have wondered since more than a century and that are still open to debate. We present observations of a filament formation, its failed eruption, and the associated flare (SOL2019-05-09T05:51) that occurred in active region (AR) 12740 using data from SDO, STEREO-A, IRIS, and NSO/GONG. AR 12740 was a decaying region formed by a very disperse following polarity and a strong leading spot, surrounded by a highly dynamic zone where moving magnetic features (MMFs) were seen constantly diverging from the spot. Our analysis indicates that the filament was formed by the convergence of fibrils at a location where magnetic flux cancellation was observed. Furthermore, we conclude that its destabilization was also related to flux cancellation associated to the constant shuffling of the MMFs. A two-ribbon flare occurred associated to the filament eruption; however, because the large-scale magnetic configuration of the AR was quadrupolar, two additional flare ribbons developed far from the two main ones. We model the magnetic configuration of the AR using a force-free field approach at the AR scale size. This local model is complemented by a global potential-field source-surface one. Based on the local model, we propose a scenario in which the filament failed eruption and flare are due to two reconnection processes, one occurring below the erupting filament, leading to the two-ribbon flare, and another one above it between the filament flux-rope configuration and the large-scale closed loops. Our computation of the reconnected magnetic flux added to the erupting flux rope, compared to that of the large-scale field overlying it, lets us conclude that the latter was large enough to prevent the filament eruption. A similar conjecture can be drawn from the computation of the magnetic tension derived from the global field model.

## Multi thermal atmosphere of a mini solar flare during magnetic reconnection observed with IRIS

[Reetika Joshi](#), [Brigitte Schmieder](#), [Akiko Tei](#), [Guillaume Aulanier](#), [Juraj Lörinčík](#), [Ramesh Chandra](#), [Petr Heinzel](#)

A&A Volume 645, id.A80, 19 pages 2021

<https://arxiv.org/pdf/2010.15401.pdf>

<https://www.aanda.org/articles/aa/pdf/2021/01/aa39229-20.pdf>

The Interface Region Imaging Spectrograph (IRIS) with its high spatial and temporal resolution brings exceptional plasma diagnostics of solar chromospheric and coronal activity during magnetic reconnection. The aim of this work is to study the fine structure and dynamics of the plasma at a jet base forming a mini flare between two emerging magnetic fluxes (EMFs) observed with IRIS and the Solar Dynamics Observatory (SDO) instruments. We proceed to a spatio-temporal analysis of IRIS spectra observed in the spectral ranges of Mg II, C II, and Si IV ions. Doppler velocities from Mg II lines are computed by using a cloud model technique. Strong asymmetric Mg II and C II line profiles with extended blue wings observed at the reconnection site (jet base) are interpreted by the presence of two chromospheric temperature clouds, one explosive cloud with blueshifts at 290 km/s and one cloud with smaller Dopplershift (around 36 km/s). Simultaneously at the same location (jet base), strong emission of several transition region lines (e.g. O IV and Si IV), emission of the Mg II triplet lines of the Balmer-continuum and absorption of identified chromospheric lines in Si IV broad profiles have been observed and analysed. Such observations of IRIS line and continuum emissions

allow us to propose a stratification model for the white-light mini flare atmosphere with multiple layers of different temperatures along the line of sight, in a reconnection current sheet. It is the first time that we could quantify the fast speed (possibly Alfvénic flows) of cool clouds ejected perpendicularly to the jet direction by using the cloud model technique. We conjecture that the ejected clouds come from plasma which was trapped between the two EMFs before reconnection or be caused by chromospheric-temperature (cool) upflow material like in a surge, during reconnection. **March 22, 2019** Movies are available at <https://www.aanda.org>

## Sequential Lid Removal in a Triple-Decker Chain of CME-Producing Solar Eruptions

Navin Chandra [Joshi](#), Alphonse C. Sterling, Ronald L. Moore, Bhuwan Joshi

ApJ **901** 38 **2020**

<https://arxiv.org/abs/2008.04525>

<https://doi.org/10.3847/1538-4357/abacd0>

We investigate the onsets of three consecutive coronal mass ejection (CME) eruptions in 12 hours from a large bipolar active region (AR) observed by SDO, STEREO, RHESSI, and GOES. Evidently, the AR initially had a “triple-decker” configuration: three flux ropes in a vertical stack above the polarity inversion line (PIL). Upon being bumped by a confined eruption of the middle flux rope, the top flux rope erupts to make the first CME and its accompanying AR–spanning flare arcade rooted in a far-apart pair of flare ribbons. The second CME is made by eruption of the previously-arrested middle flux rope, which blows open the flare arcade of the first CME and produces a flare arcade rooted in a pair of flare ribbons closer to the PIL than those of the first CME. The third CME is made by blowout eruption of the bottom flux rope, which blows open the second flare arcade and makes its own flare arcade and pair of flare ribbons. Flux cancellation observed at the PIL likely triggers the initial confined eruption of the middle flux rope. That confined eruption evidently triggers the first CME eruption. The lid-removal mechanism instigated by the first CME eruption plausibly triggers the second CME eruption. Further lid removal by the second CME eruption plausibly triggers the final CME eruption. **2013 May 22**

## The role of small-scale surface motions in the transfer of twist to a solar jet from a remote stable flux rope★

Reetika [Joshi](#), [Brigitte Schmieder](#), [Guillaume Aulanier](#), [Véronique Bommier](#), [Ramesh Chandra](#)

A&A **642**, A169 **2020**

<https://arxiv.org/pdf/2008.06887.pdf>

<https://doi.org/10.1051/0004-6361/202038562>

<https://www.aanda.org/articles/aa/pdf/2020/10/aa38562-20.pdf>

Jets often have a helical structure containing both hot and cooler, denser than the corona, ejected plasma. Different mechanisms are proposed to trigger jets by magnetic reconnection between the emergence of magnetic flux and environment, or induced by twisted photospheric motions bringing the system to instability. Multi-wavelength observations of a twisted jet observed with SDO/AIA and IRIS was selected to understand how the twist was injected in the jet because fortunately, IRIS slit was just crossing the reconnection site. We follow the magnetic history of the active region based on the analysis of HMI vector magnetic field computed with the UNNOFIT code. This AR is the result of the collapse of two emerging magnetic fluxes (EMF) overlaid by AFS well-observed with AIA, IRIS, and NVST in H-alpha. In the magnetic field maps, we evidenced the pattern of a long sigmoidal flux rope (FR) along the polarity inversion line between the two EMFs which is the site of the reconnection. Before the jet, there was an extension of the FR, and a part of it was detached and formed a small bipole with a bald patch (BP) region which dynamically became an X-current sheet over the dome of one EMF where the reconnection took place. At the time of the reconnection, the Mg II spectra exhibited a strong extension of the blue wing which is decreasing over a distance of 10 Mm (from -300 km/s to a few km/s). This is the signature of the transfer of the twist to the jet. Comparison with numerical magnetohydrodynamics (MHD) simulations confirmed the existence of the long FR. We conjecture that there is a transfer of twist to the jet during the extension of the FR to the reconnection site without FR eruption. The reconnection would start in the low atmosphere in the BP reconnection region and extend at an X-point along the current sheet formed above. **March 21-22, 2019**

## Cause and Kinematics of a Jet-Like CME

[Reetika Joshi](#), [Yuming Wang](#), [Ramesh Chandra](#), [Quanhao Zhang](#), [Lijuan Liu](#), [Xiaolei Li](#)

ApJ **901** 94 **2020**

<https://arxiv.org/pdf/2008.05651.pdf> File

<https://doi.org/10.3847/1538-4357/abaf5a>

In this article, we present the multi-viewpoint and multi-wavelength analysis of an atypical solar jet based on the data from Solar Dynamics Observatory, SOlar, and Heliospheric Observatory, and Solar TERrestrial RELations Observatory. It is usually believed that the coronal mass ejections (CMEs) are developed from the large scale solar eruptions in the lower atmosphere. However, the kinematical and spatial evolution of the jet on **2013 April 28** guide us that the jet was clearly associated with a narrow CME having a width of approx 25 degrees with a speed of 450 km/s. To better understand the link between the jet and the CME, we did the coronal potential field extrapolation from the line of sight magnetogram of the AR. The extrapolations present that the jet eruption follows exactly the same path of the open

magnetic field lines from the source region which provides the route for the jet material to escape from the solar surface towards the outer corona.

### **A case-study of multi-temperature coronal jets for emerging flux MHD models**

[Reetika Joshi](#), [Ramesh Chandra](#), [Brigitte Schmieder](#), [Fernando Moreno-Insertis](#), [Guillaume Aulanier](#), [Daniel Nóbrega-Siverio](#), [Pooja Devi](#)

A&A 639, A22 2020

<https://arxiv.org/pdf/2005.06064.pdf>

<https://www.aanda.org/articles/aa/pdf/2020/07/aa37806-20.pdf>

Context: Hot coronal jets are a basic observed feature of the solar atmosphere whose physical origin is still being actively debated. Aims: We study six recurrent jets occurring in the active region NOAA 12644 on **April 04, 2017**. They are observed in all the hot filters of AIA as well as cool surges in IRIS slit-jaw high spatial and temporal resolution images. Methods: The AIA filters allow us to study the temperature and the emission measure of the jets using the filter ratio method. We study the pre-jet phases by analyzing the intensity oscillations at the base of the jets with the wavelet technique. Results: A fine co-alignment of the AIA and IRIS data shows that the jets are initiated at the top of a canopy-like, double-chambered structure with cool emission on one side and hot emission in the other. The hot jets are collimated in the hot temperature filters, have high velocities (around 250 km/s) and accompanied by the cool surges and ejected kernels both moving at about 45 km/s. In the pre-phase of the jets, at their base we find quasi-periodic intensity oscillations in phase with small ejections; they have a period between 2 and 6 minutes and are reminiscent of acoustic or MHD waves. Conclusions: This series of jets and surges provides a good case-study to test the 2D and 3D magnetohydrodynamic (MHD) models that result from magnetic flux emergence. The double-chambered structure found in the observations corresponds to the cold and hot loop regions found in the models beneath the current sheet that contains the reconnection site. The cool surge with kernels is comparable with the cool ejection and plasmoids that naturally appear in the models.

### **Generalisation of the Magnetic Field Configuration of typical and atypical Confined Flares**

Navin Chandra [Joshi](#), [Xiaoshuai Zhu](#), [Brigitte Schmieder](#), [Guillaume Aulanier](#), [Miho Janvier](#), [Bhuwan Joshi](#), [Tetsuya Magara](#), [Ramesh Chandra](#), [Satoshi Inoue](#)

ApJ 2018

<https://arxiv.org/pdf/1811.01228.pdf>

Atypical flares cannot be naturally explained with standard models. To predict such flares, we need to define their physical characteristics, in particular, their magnetic environment, and identify pairs of reconnected loops. Here, we present in detail a case-study of a confined flare preceded by flux cancellation that leads to the formation of a filament. The slow rise of the non-eruptive filament favours the growth and reconnection of overlying loops. The flare is only of C5.0 class but it is a long duration event. The reason is that it is comprised of three successive stages of reconnection. A non-linear force-free field extrapolation and a magnetic topology analysis allow us to identify the loops involved in the reconnection process and build a reliable scenario for this atypical confined flare. The main result is that a curved magnetic polarity inversion line in active regions is a key ingredient for producing such atypical flares. A comparison with previous extrapolations for typical and atypical confined flares leads us to propose a cartoon for generalizing the concept. **2014 May 15**

### **A Major Geoeffective CME from NOAA 12371: Initiation, CME–CME Interactions, and Interplanetary Consequences**

Bhuwan [Joshi](#), M. Syed Ibrahim, A. Shanmugaraju, D. Chakrabarty

[Solar Physics](#) July 2018, 293:107

<http://sci-hub.tw/http://link.springer.com/10.1007/s11207-018-1325-2>

In this article, we present a multi-wavelength and multi-instrument investigation of a halo coronal mass ejection (CME) from active region NOAA 12371 on **21 June 2015** that led to a major geomagnetic storm of minimum  $Dst = -204$  nT. The observations from the Atmospheric Imaging Assembly onboard the Solar Dynamics Observatory in the hot EUV channel of 94 Å confirm the CME to be associated with a coronal sigmoid that displayed an intense emission ( $T \sim 6$  MK) from its core before the onset of the eruption. Multi-wavelength observations of the source active region suggest tether-cutting reconnection to be the primary triggering mechanism of the flux rope eruption. Interestingly, the flux rope eruption exhibited a two-phase evolution during which the “standard” large-scale flare reconnection process originated two composite M-class flares. The eruption of the flux rope is followed by the coronagraphic observation of a fast, halo CME with linear projected speed of 1366 km s<sup>-1</sup>. The dynamic radio spectrum in the decameter-hectometer frequency range reveals multiple continuum-like enhancements in type II radio emission which imply the interaction of the CME with other preceding slow speed CMEs in the corona within  $\approx 10 \sim 90 R_{\odot}$ . The scenario of CME–CME interaction in the corona and interplanetary medium is further confirmed by the height–time plots of the CMEs occurring during 19–21 June. In situ measurements of solar wind magnetic field and plasma parameters at 1 AU exhibit two distinct magnetic clouds, separated by a magnetic hole. Synthesis of near-Sun observations, interplanetary radio emissions, and in situ measurements at 1 AU reveal complex processes of CME–CME interactions right from the source active region to the corona and interplanetary medium that have played a crucial role towards the large enhancement of the geoeffectiveness of the halo CME on 21 June 2015.

## Multiple Solar Jets from NOAA AR 12644

Reetika [Joshi](#), [Ramesh Chandra](#)

XXIXth IAU General Assembly Aug 2015? **2018**

<https://arxiv.org/pdf/1806.07063.pdf>

We present here the observations of solar jets observed on **April 04, 2017** from NOAA active region (AR) 12644 using high temporal and spatial resolution AIA instrument. We have observed around twelve recurring jets during the whole day. Magnetic flux emergence and cancellation have been observed at the jet location. The multi-band observations evidenced that these jets were triggered due to the magnetic reconnection at low coronal null-point.

## Flux Rope Breaking and Formation of a Rotating Blowout Jet

MNRAS 476, Issue 1, p.1286-1298 **2018**

<https://arxiv.org/pdf/1802.01798.pdf>

We analyzed a small flux rope eruption converted into a helical blowout jet in a fan-spine configuration using multi-wavelength observations taken by SDO, which occurred near the limb on **2016 January 9**. In our study, first, we estimated the fan-spine magnetic configuration with the potential field calculation and found a sinistral small filament inside it. The filament along with the flux rope erupted upward and interacted with the surrounding fan-spine magnetic configuration, where the flux rope breaks in the middle section. We observed compact brightening, flare ribbons and post-flare loops underneath the erupting filament. The northern section of the flux rope reconnected with the surrounding positive polarity, while the southern section straightened. Next, we observed the untwisting motion of the southern leg, which was transformed into a rotating helical blowout jet. The sign of the helicity of the mini-filament matches the one of the rotating jet. This is consistent with the jet models presented by Adams et al. (2014) and Sterling et al. (2015). We focused on the fine thread structure of the rotating jet and traced three blobs with the speed of 60-120 km/s, while the radial speed of the jet is approx 400 km/s. The untwisting motion of the jet accelerated plasma upward along the collimated outer spine field lines, and it finally evolved into a narrow coronal mass ejection at the height of approx 9 R<sub>sun</sub>. On the basis of the detailed analysis, we discussed clear evidence of the scenario of the breaking of the flux rope and the formation of the helical blowout jet in the fan-spine magnetic configuration.

## Observational and model analysis of a two-ribbon flare possibly induced by a neighbouring blowout jet

Bhuvan [Joshi](#) (USO/PRL, India), [Julia K. Thalmann](#) (Univ. of Graz, Austria), [Prabir K. Mitra](#) (USO/PRL, India), [Ramesh Chandra](#) (Kumaun Univ., India), [Astrid M. Veronig](#) (Univ. of Graz, Austria)

ApJ **851** 29 **2017**

<https://arxiv.org/pdf/1710.08099.pdf>

In this paper, we present unique observations of a blowout coronal jet that possibly triggered a two-ribbon confined C1.2 flare in a bipolar solar active region NOAA 12615 on **2016 December 5**. The jet activity initiates at chromospheric/transition-region heights with a small brightening that eventually grows in a larger volume with well developed standard morphological jet features, viz., base and spire. The spire widens up with a collimated eruption of cool and hot plasma components, observed in the 304 and 94 Å channels of AIA, respectively. The speed of the plasma ejection, which forms the jet's spire, was higher for the hot component (~200 km/s) than the cooler one (~130 km/s). The NLFF model of coronal fields at pre- and post-jet phases successfully reveal opening of previously closed magnetic field lines with a rather inclined/low-lying jet structure. The peak phase of the jet emission is followed by the development of a two-ribbon flare that shows coronal loop emission in HXRs up to ~25 keV energy. The coronal magnetic fields rooted at the location of EUV flare ribbons, derived from the NLFF model, demonstrate the pre-flare phase to exhibit an "X-type" configuration while the magnetic fields at the post-flare phase are more or less parallel oriented. The comparisons of multi-wavelength measurements with the magnetic field extrapolations suggest that the jet activity likely triggered the two-ribbon flare by perturbing the field in the interior of the active region.

## Slippage of Jets Explained by the Magnetic Topology of NOAA Active Region 12035

R. [Joshi](#), [B. Schmieder](#), [R. Chandra](#), [G. Aulanier](#), [F.P. Zuccarello](#), [W. Uddin](#)

Solar Phys. 292:152 **2017**

<https://arxiv.org/pdf/1709.02791.pdf>

In this study, we present the investigation of eleven recurring solar jets originated from two different sites (site 1 and site 2) close to each other (~ 11 Mm) in the NOAA active region (AR) 12035 during **15--16 April 2014**. The jets were observed by the Atmospheric Imaging Assembly (AIA) telescope onboard the Solar Dynamics Observatory (SDO) satellite. Two jets were observed by the Aryabhata Research Institute of Observational Sciences (ARIES), Nainital, India telescope in H-alpha. On 15 April flux emergence is important in site 1 while on 16 April flux emergence and cancellation mechanisms are involved in both sites. The jets of both sites have parallel trajectories and move to the south with a speed between 100 and 360 km/s. We observed some connection between the two sites with some transfer of brightening. The jets of site 2 occurred during the second day and have a tendency to move towards the jets of site 1 and merge with them. We conjecture that the slippage of the jets could be explained by the complex topology of the

region with the presence of a few low-altitude null points and many quasi-separatrix layers (QSLs), which could intersect with one another.

### **Onset of a Large Ejective Solar Eruption from a Typical Coronal-Jet-Base Field Configuration**

Navin Chandra **Joshi**, Alphonse C. Sterling, Ronald L. Moore, [Tetsuya Magara](#), [Young-Jae Moon](#)

ApJ 845 26 2017

<https://arxiv.org/pdf/1706.09176.pdf>

<http://sci-hub.cc/10.3847/1538-4357/aa7c1b>

Utilizing multiwavelength observations and magnetic field data from SDO/AIA, SDO/HMI, GOES and RHESSI, we investigate a large-scale ejective solar eruption of **2014 December 18** from active region NOAA 12241. This event produced a distinctive three-ribbon flare, having two parallel ribbons corresponding to the ribbons of a standard two-ribbon flare, and a larger-scale third quasi-circular ribbon offset from the other two ribbons. There are two components to this eruptive event. First, a flux rope forms above a strong-field polarity-inversion line and erupts and grows as the parallel ribbons turn on, grow, and spread part from that polarity-inversion line; this evolution is consistent with the tether-cutting-reconnection mechanism for eruptions. Second, the eruption of the arcade that has the erupting flux rope in its core under goes magnetic reconnection at the null point of a fan dome that envelops the erupting arcade, resulting in formation of the quasi-circular ribbon; this is consistent with the breakout reconnection mechanism for eruptions. We find that the parallel ribbons begin well before (12 min) circular ribbon onset, indicating that tether-cutting reconnection (or a non-ideal MHD instability) initiated this event, rather than breakout reconnection. The overall setup for this large-scale (circular-ribbon diameter 100000 km) eruption is analogous to that of coronal jets (base size 10000 km), many of which, according to recent findings, result from eruptions of small-scale minifilaments. Thus these findings confirm that eruptions of sheared-core magnetic arcades seated in fan-spine null-point magnetic topology happen on a wide range of size scales on the Sun.

### **Formation and eruption of a flux rope from the sigmoid active region NOAA 11719 and associated M6.5 flare: A multi-wavelength study**

Bhuvan **Joshi** (USO/PRL, India), Upendra Kushwaha (USO/PRL, India), Astrid M. Veronig (Univ. of Graz, Austria), Sajal Kumar Dhara (USO/PRL, India), A. Shanmugaraju (Arul Anandhar College, India), Yong-Jae Moon (Kyung Hee Univ., South Korea)

ApJ 834 42 2017

<https://arxiv.org/pdf/1701.00967v1.pdf>

<http://sci-hub.cc/doi/10.3847/1538-4357/834/1/42>

We investigate the formation, activation and eruption of a flux rope from the sigmoid active region NOAA 11719 by analyzing E(UV), X-ray and radio measurements. During the pre-eruption period of ~7 hours, the AIA 94 Å images reveal the emergence of a coronal sigmoid through the interaction between two J-shaped bundles of loops which proceeds with multiple episodes of coronal loop brightenings and significant variations in the magnetic flux through the photosphere. These observations imply that repetitive magnetic reconnections likely play a key role in the formation of the sigmoidal flux rope in the corona and also contribute toward sustaining the temperature of the flux rope higher than the ambient coronal structures. Notably, the formation of the sigmoid is associated with the fast morphological evolution of an S-shaped filament channel in the chromosphere. The sigmoid activates toward eruption with the ascend of a large flux rope in the corona which is preceded by the decrease of photospheric magnetic flux through the core flaring region suggesting tether-cutting reconnection as a possible triggering mechanism. The flux rope eruption results in a two-ribbon M6.5 flare with a prolonged rise phase of ~21 min. The flare exhibits significant deviation from the standard flare model in the early rise phase during which a pair of J-shaped flare ribbons form and apparently exhibit converging motions parallel to the polarity inversion line which is further confirmed by the motions of HXR footpoint sources. In the later stages, the flare follows the standard flare model and the source region undergoes a complete sigmoid-to-arcade transformation. **11 Apr 2013**

### **PRE-ERUPTION OSCILLATIONS IN THIN AND LONG FEATURES IN A QUIESCENT FILAMENT**

Anand D. **Joshi**<sup>1,2</sup>, Yoichiro Hanaoka<sup>1</sup>, Yoshinori Suematsu<sup>1</sup>, Satoshi Morita<sup>1</sup>, Vasyl Yurchyshyn<sup>2,3</sup>, and Kyung-Suk Cho

2016 ApJ 833 243

<http://sci-hub.cc/doi/10.3847/1538-4357/833/2/243>

We investigate the eruption of a quiescent filament located close to an active region. Large-scale activation was observed in only half of the filament in the form of pre-eruption oscillations. Consequently only this half erupted nearly 30 hr after the oscillations commenced. Time-slice diagrams of 171 Å images from the Atmospheric Imaging Assembly were used to study the oscillations. These were observed in several thin and long features connecting the filament spine to the chromosphere below. This study traces the origin of such features and proposes their possible interpretation. Small-scale magnetic flux cancellation accompanied by a brightening was observed at the footpoint of the features shortly before their appearance, in images recorded by the Helioseismic and Magnetic Imager. A slow rise of the

filament was detected in addition to the oscillations, indicating a gradual loss of equilibrium. Our analysis indicates that a change in magnetic field connectivity between two neighbouring active regions and the quiescent filament resulted in a weakening of the overlying arcade of the filament, leading to its eruption. It is also suggested that the oscillating features are filament barbs, and the oscillations are a manifestation during the pre-eruption phase of the filaments. **2013 August 14**

### **Pre-flare coronal jet and evolutionary phases of a solar eruptive prominence associated with M1.8 flare: SDO and RHESSI observations**

Bhuwan **Joshi** (USO/PRL, India), Upendra Kushwaha (USO/PRL, India), Astrid Veronig (University of Graz, Austria), Kyung-Suk Cho (KASI, South Korea)

ApJ **832** 130 **2016**

<https://arxiv.org/pdf/1611.03629v1.pdf>

We investigate triggering, activation, and ejection of a solar eruptive prominence that occurred in a multi-polar flux system of active region NOAA 11548 on **2012 August 18** by analyzing data from AIA on board SDO, RHESSI, and EUVI/SECCHI on board STEREO. Prior to the prominence activation, we observed striking coronal activities in the form of a blowout jet which is associated with rapid eruption of a cool flux rope. Further, the jet-associated flux rope eruption underwent splitting and rotation during its outward expansion. These coronal activities are followed by the prominence activation during which it slowly rises with a speed of  $\sim 12$  km/s while the region below the prominence emits gradually varying EUV and thermal X-ray emissions. From these observations, we propose that the prominence eruption is a complex, multi-step phenomenon in which a combination of internal (tether-cutting reconnection) and external (i.e., pre-eruption coronal activities) processes are involved. The prominence underwent catastrophic loss of equilibrium with the onset of the impulsive phase of an M1.8 flare suggesting large-scale energy release by coronal magnetic reconnection. We obtained signatures of particle acceleration in the form of power law spectra with hard electron spectral index ( $\delta \sim 3$ ) and strong HXR footpoint sources. During the impulsive phase, a hot EUV plasmoid was observed below the apex of the erupting prominence that ejected in the direction of the prominence with a speed of  $\sim 177$  km/s. The temporal, spatial and kinematic correlations between the erupting prominence and the plasmoid imply that the magnetic reconnection supported the fast ejection of prominence in the lower corona.

### **Interaction of Two Filament Channels of Different Chiralities**

Navin Chandra **Joshi**, Boris Filippov, Brigitte Schmieder, [Tetsuya Magara](#), [Young-Jae Moon](#), [Wahab Uddin](#)

ApJ **825** 123 **2016**

<http://arxiv.org/pdf/1605.01812v1.pdf>

We present observations of interactions between the two filament channels of different chiralities and associated dynamics that occurred during **2014 April 18 -- 20**. While two flux ropes of different helicity with parallel axial magnetic fields can only undergo a bounce interaction when they are brought together, the observations at the first glance show that the heated plasma is moving from one filament channel to the other. The SDO/AIA 171 Å observations and the PFSS magnetic field extrapolation reveal the presence of fan-spine magnetic configuration over the filament channels with a null point located above them. Three different events of filament activations, partial eruptions, and associated filament channel interactions have been observed. The activation initiated in one filament channel seems to propagate along the neighbour filament channel. We believe that the activation and partial eruption of the filaments bring the field lines of flux ropes containing them closer to the null point and trigger the magnetic reconnection between them and the fan-spine magnetic configuration. As a result, the hot plasma moves along the outer spine line toward the remote point. Utilizing the present observations, for the first time we have discussed how two different-chirality filament channels can interact and show interrelation.

### **Chain Reconnections observed in Sympathetic Eruptions**

Navin Chandra **Joshi**, Brigitte Schmieder, Tetsuya Magara, Yang Guo, Guillaume Aulanier

ApJ **820** 126 **2016 File**

<http://arxiv.org/pdf/1602.07792v1.pdf>

The nature of various plausible causal links between sympathetic events is still a controversial issue. In this work, we present multi-wavelength observations of sympathetic eruptions, associated flares and coronal mass ejections (CMEs) occurring on **2013 November 17** in two close-by active regions. Two filaments i.e., F1 and F2 are observed in between the active regions. Successive magnetic reconnections, caused by different reasons (flux cancellation, shear and expansion) have been identified during the whole event. The first reconnection occurred during the first eruption via flux cancellation between the sheared arcades overlying filament F2, creating a flux rope and leading to the first double ribbon solar flare. During this phase we observed the eruption of overlying arcades and coronal loops, which leads to the first CME. The second reconnection is believed to occur between the expanding flux rope of F2 and the overlying arcades of the filament F1. We suggest that this reconnection destabilized the equilibrium of filament F1, which further facilitated its eruption. The third stage of reconnection occurred in the wake of the erupting filament F1 between the legs of overlying arcades. This may create a flux rope and the second double ribbon flare and a second CME. The fourth reconnection was between the expanding arcades of the erupting filament F1 and the nearby ambient field, which

produced the bi-directional plasma flows towards both upward and downward. Observations and a nonlinear force-free field extrapolation confirm the possibility of reconnection and the causal link between the magnetic systems.

**Хорошее Введение.**

### **Formation of Compound Flux Rope by The Merging of Two Filament Channels, Associated Dynamics and its Stability**

Navin Chandra **Joshi**, Tetsuya Magara, Satoshi Inoue

ApJ, 795 4 **2014**

<http://arxiv.org/pdf/1409.1359v1.pdf>

We present the observations of compound flux rope formation via merging of two nearby filament channels, associated dynamics and its stability that occurred on **2014 January 1** using multiwavelength data. We have also discussed the dynamics of cool and hot plasma moving along the newly formed compound flux rope. The merging started after the interaction between the southern leg of northward filament and the northern leg of the southward filament at around 01:21 UT and continue until a compound flux rope formed at around 01:33 UT. During the merging the cool filaments plasma heated up and started to move along the both side of the compound flux rope i.e., toward north (approx 265 km/s) and south (approx 118 km/s) from the point of merging. After travelling a distance of approx 150 Mm towards north the plasma become cool and started to returns back towards south ( approx 14 km/s) after 02:00 UT. The observations provide an clear example of compound flux rope formation via merging of two different flux ropes and occurrence of flare through tether cutting reconnection. However, the compound flux rope remained stable in the corona and made an confined eruption. The coronal magnetic field decay index measurements revealed that both the filaments and the compound flux rope axis lies within the stability domain (decay index less than 1.5), which may be the possible cause for their stability. The present study also deals with the relationship between the filaments chirality (sinistral) and the helicity (positive) of the surrounding flux rope.

### **Confined Partial Filament Eruption and its Reformation within a Stable Magnetic Flux Rope**

Navin Chandra **Joshi**, Abhishek K. Srivastava, Boris Filippov, Pradeep Kayshap, Wahab Uddin, Ramesh Chandra, Debi Prasad Choudhary, and B. N. Dwivedi

**2014** ApJ 787 11

We present observations of a confined partial eruption of a filament on **2012 August 4**, which restores its initial shape within 2 hr after eruption. From the Global Oscillation Network Group H $\alpha$  observations, we find that the filament plasma turns into dynamic motion at around 11:20 UT from the middle part of the filament toward the northwest direction with an average speed of 105 km s<sup>-1</sup>. A little brightening underneath the filament possibly shows the signature of low-altitude reconnection below the filament eruptive part. In Solar Dynamics Observatory/Atmospheric Imaging Assembly 171 Å images, we observe an activation of right-handed helically twisted magnetic flux rope that contains the filament material and confines it during its dynamical motion. The motion of cool filament plasma stops after traveling a distance of 215 Mm toward the northwest from the point of eruption. The plasma moves partly toward the right foot point of the flux rope, while most of the plasma returns after 12:20 UT toward the left foot point with an average speed of 60 km s<sup>-1</sup> to reform the filament within the same stable magnetic structure. On the basis of the filament internal fine structure and its position relative to the photospheric magnetic fields, we find filament chirality to be sinistral, while the activated enveloping flux rope shows a clear right-handed twist. Thus, this dynamic event is an apparent example of one-to-one correspondence between the filament chirality (sinistral) and the enveloping flux rope helicity (positive). From the coronal magnetic field decay index,  $n$ , calculation near the flux rope axis, it is evident that the whole filament axis lies within the domain of stability (i.e.,  $n < 1$ ), which provides the filament stability despite strong disturbances at its eastern foot point.

### **RHESSI AND TRACE OBSERVATIONS OF MULTIPLE FLARE ACTIVITY IN AR 10656 AND ASSOCIATED FILAMENT ERUPTION**

Bhuwan **Joshi**<sup>1</sup>, Upendra Kushwaha<sup>1</sup>, K.-S. Cho<sup>2</sup>, and Astrid M. Veronig

**2013** ApJ 771 1

We present Reuven Ramaty High Energy Solar Spectroscopic Imager (RHESSI) and Transition Region and Coronal Explorer (TRACE) observations of multiple flare activity that occurred in the NOAA active region 10656 over a period of 2 hr on **2004 August 18**. Out of four successive flares, three were class C events, and the final event was a major X1.8 solar eruptive flare. The activities during the pre-eruption phase, i.e., before the X1.8 flare, are characterized by three localized episodes of energy release occurring in the vicinity of a filament that produces intense heating along with non-thermal emission. A few minutes before the eruption, the filament undergoes an activation phase during which it slowly rises with a speed of  $\sim 12$  km s<sup>-1</sup>. The filament eruption is accompanied by an X1.8 flare, during which multiple hard X-ray (HXR) bursts are observed up to 100-300 keV energies. We observe a bright and elongated coronal structure simultaneously in E(UV) and 50-100 keV HXR images underneath the expanding filament during the period of HXR bursts, which provides strong evidence for ongoing magnetic reconnection. This phase is accompanied by very high plasma temperatures of  $\sim 31$  MK, followed by the detachment of the prominence from the solar source region. From the location, timing, strength, and spectrum of HXR emission, we conclude that the prominence eruption is driven by the distinct events of magnetic reconnection occurring in the current sheet below the erupting prominence. These multi-wavelength observations also suggest that the localized magnetic reconnections associated with different evolutionary stages of the filament in

the pre-eruption phase play an important role in destabilizing the active-region filament through the tether-cutting process, leading to large-scale eruption and X-class flare.

### **Study of Failed CME Core Associated with Asymmetric Filament Eruption**

**Joshi**, N. C.; Srivastava, A. K.; Filippov, B.; Uddin, W.; Kayshap, P.; Chandra, R.

E-print, April 2013, ApJ 771 65

<http://arxiv.org/abs/1304.6852>

We present the multi-wavelength observations of asymmetric filament eruption, associated CME and coronal downflows on **2012 June 17-18** during 20:00-05:00 UT. We use SDO/AIA, STEREO-B/SECCHI observations to understand the filament eruption scenario and its kinematics. While LASCO C2 observations have been analyzed to study the kinematics of the CME and associated downflows. SDO/AIA limb observations show that the filament exhibits whipping like asymmetric eruption. STEREO/EUVI disk observations reveal a two ribbon flare underneath the south-eastern part of the filament that is most probably occurred due to reconnection process in the coronal magnetic field in the wake of the filament eruption. The whipping like filament eruption later gives a slow CME in which the leading edge and the core propagate respectively with the average speed of approx 540 km s<sup>-1</sup> and approx 126 km s<sup>-1</sup> as observed in the LASCO C2 coronagraph. The CME core formed by the eruptive flux-rope shows the outer coronal downflows with the average speed of approx 56 km s<sup>-1</sup> after reaching up to approx 4.33 R<sub>sun</sub>. Initially, the core decelerates with approx 48 m s<sup>-2</sup>. The plasma first decelerates gradually up to the height of approx 4.33 R<sub>sun</sub> and then starts accelerating downward. We suggest a self-consistent model of a magnetic flux rope representing the magnetic structure of the CME core formed by eruptive filament that lost its previous stable equilibrium when reach at a critical height. With some reasonable parameters, and inherent physical conditions the model describes the non-radial ascending motion of the flux rope in the corona, its stopping at some height, and thereafter the downward motion, which are in good agreement with the observations.

### **ACCELERATION OF CORONAL MASS EJECTIONS FROM THREE-DIMENSIONAL RECONSTRUCTION OF STEREO IMAGES**

Anand D. **Joshi** and Nandita Srivastava

2011 ApJ 739 8, **File**

We employ a three-dimensional (3D) reconstruction technique for the first time to study the kinematics of six coronal mass ejections (CMEs), using images obtained from the COR1 and COR2 coronagraphs on board the twin STEREO spacecraft, and also the eruptive prominences (EPs) associated with three of them using images from the Extreme UltraViolet Imager. A feature in the EPs and leading edges (LEs) of all the CMEs was identified and tracked in images from the two spacecraft, and a stereoscopic reconstruction technique was used to determine the 3D coordinates of these features. True velocity and acceleration were determined from the temporal evolution of the true height of the CME features. Our study of the kinematics of the CMEs in 3D reveals that the CME LE undergoes maximum acceleration typically below 2 R<sub>sun</sub>. The acceleration profiles of CMEs associated with flares and prominences exhibit different behaviors. While the CMEs not associated with prominences show a bimodal acceleration profile, those associated with prominences do not. Two of the three associated prominences in the study show a high and increasing value of acceleration up to a distance of almost 4 R<sub>sun</sub>, but acceleration of the corresponding CME LE does not show the same behavior, suggesting that the two may not be always driven by the same mechanism. One of the CMEs, although associated with a C-class flare, showed unusually high acceleration of over 1500 m s<sup>-2</sup>. Our results therefore suggest that only the flare-associated CMEs undergo residual acceleration, which indicates that the flux injection theoretical model holds well for the flare-associated CMEs, but a different mechanism should be considered for EP-associated CMEs.

### **Multi-Wavelength Signatures of Magnetic Reconnection of a Flare-Associated Coronal Mass Ejection**

Bhuwan **Joshi**, P. K. Manoharan, Astrid M. Veronig, P. Pant, Kavita Pandey

Solar Phys., 242(1-2), Page: 143 – 158, 2007.

The study supports the standard CSHKP model of flares, which is consistent with nearly all eruptive flare models. More importantly, the results also contain evidence for breakout reconnection before the flare phase.

### **Measuring the magnetic origins of solar flares, CMEs and Space Weather**

[Philip Judge](#), [Matthias Rempel](#), [Rana Ezzedine](#), [Lucia Kleint](#), [Ricky Egeland](#), [Svetlana Berdyugina](#), [Thomas Berger](#), [Joan Burkepile](#), [Rebecca Centeno](#), [Giuliana de Toma](#), [Mausumi Dikpati](#), [Yuhong Fan](#), [Holly Gilbert](#), [Daniela Lacatus](#)

ApJ 917 27 2021

<https://arxiv.org/pdf/2106.07786.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac081f/pdf>

<https://doi.org/10.3847/1538-4357/ac081f>

We take a broad look at the problem of identifying the magnetic solar causes of space weather. With the lackluster performance of extrapolations based upon magnetic field measurements in the photosphere, we identify a region in the

near UV part of the spectrum as optimal for studying the development of magnetic free energy over active regions. Using data from SORCE, Hubble Space Telescope, and SKYLAB, along with 1D computations of the near-UV (NUV) spectrum and numerical experiments based on the MURaM radiation-MHD and HanleRT radiative transfer codes, we address multiple challenges. These challenges are best met through a combination of near UV lines of bright  $\text{Mg II}$ , and lines of  $\text{Fe II}$  and  $\text{Fe I}$  (mostly within the 4s–4p transition array) which form in the chromosphere up to  $2 \times 10^4$  K. Both Hanle and Zeeman effects can in principle be used to derive vector magnetic fields. However, for any given spectral line the  $\tau=1$  surfaces are generally geometrically corrugated owing to fine structure such as fibrils and spicules. By using multiple spectral lines spanning different optical depths, magnetic fields across nearly-horizontal surfaces can be inferred in regions of low plasma  $\beta$ , from which free energies, magnetic topology and other quantities can be derived. Based upon the recently-reported successful suborbital space measurements of magnetic fields with the CLASP2 instrument, we argue that a modest space-borne telescope will be able to make significant advances in the attempts to predict solar eruptions. Difficulties associated with blended lines are shown to be minor in an Appendix.

## A Comparison of Solar X-Ray Flare Timescales and Peak Temperatures with Associated Coronal Mass Ejections

S. W. Kahler<sup>1</sup> and A. G. Ling<sup>2</sup>

2022 ApJ 934 175

<https://iopscience.iop.org/article/10.3847/1538-4357/ac7e56/pdf>

Recent work has shown that plots of solar flare X-ray peak temperatures,  $T_m$ , versus log peak fluxes,  $F_p$ , show statistically significant separations of lower  $T_m$  flares with fast ( $V_{cme} \geq 1000 \text{ km s}^{-1}$ ) and wide ( $W_{cme} = 360^\circ$ ) strong coronal mass ejections (CMEs) from higher  $T_m$  flares with no CMEs or slow ( $V_{cme} < 1000 \text{ km s}^{-1}$ ) or narrow ( $< 360^\circ$ ) weak CMEs. We extend that statistical separation to CME kinetic energies,  $E_{cme}$ . Flares with long-duration timescales also have well-known associations with fast CMEs and solar energetic ( $E > 10 \text{ MeV}$ ) particle events. Using a data set of  $585 \geq M3.0$  GOES X-ray flares, we ask whether longer flare timescales (rise times, TR; durations from onset to half-power decay, TD; decay times to half power, Td; and decay times to C2, TC2) also statistically discriminate among the three groups of CMEs for speeds, widths, and energies. All log–log plots of flare timescales versus  $F_p$  produce significant separations of the three groups of CMEs generally better than those of  $T_m$  versus log  $F_p$ . We use separations of CME distribution medians to sort the four flare timescales as effective discriminants among the three CME groups. Separations between the confined flares (no-CMEs) and weak CMEs are generally smaller than those between the weak CMEs and strong CMEs. A combination of  $T_m$  and TC2 provides optimum group separations, but  $T_m$  and log TD or log Td appears best for CME forecasting purposes. **2002 July 3, 2004 November 7, 2006 December 13, 2012 March 7** **Table 4** Appendix Table of 585 M3 Flares with Timescales and CME Associations (This table is available in its entirety in machine-readable form.)

## The Role of Peak Temperatures in Solar X-Ray Flare Associations with CME Speeds and Widths and in Flare Size Distributions

S. W. Kahler<sup>1</sup> and A. G. Ling<sup>2</sup>

2020 ApJ 901 63

<https://doi.org/10.3847/1538-4357/abae5e>

Recently, we reported that solar X-ray flares with relatively low peak (0.05–0.3 nm)/(0.1–0.8 nm) ratios  $R$ , a proxy for peak flare temperature  $T$ , were preferentially associated not only with solar energetic ( $E > 10 \text{ MeV}$ ) particle (SEP) events, but also with fast ( $V_{cme} \geq 1000 \text{ km s}^{-1}$ ) coronal mass ejections (CMEs) that produce the SEP events. Flares associated with a characteristic CME speed  $V_{cme}$  range from small and cool to large and hot, and cooler X-ray flares were preferentially associated with broader CME widths. Here we increase the list of analyzed Geostationary Operational Environmental Satellite flares from the previous 450 to 588 and validate the earlier results with flare peak X-ray temperatures  $T$  from the TEBBS (Temperature and Emission measure-based Background Subtraction) method catalog. Power-law size distributions of flare peak fluxes  $F_p$  are increasingly steeper for X-ray flares with (1) fast ( $V_{cme} \geq 1000 \text{ km s}^{-1}$ ); (2) slow ( $V_{cme} < 1000 \text{ km s}^{-1}$ ); and (3) no CMEs; in each case flares of larger  $F_p$  are characteristically hotter. The power-law size distribution of SEP event peak intensities  $I_p$  is flatter than any of the X-ray  $F_p$  distributions or a distribution formed from the product of the steep SEP  $I_p$  dependence on  $V_{cme}$  and the  $V_{cme}$  number distributions.

## Temperatures of Large Solar X-ray Events and Associated CME Speeds

S. Kahler,\* A. Ling

36th International Cosmic Ray Conference -ICRC2019- July 24th - August 1st, 2019 Madison, WI, U.S.A.

<https://pos.sissa.it/358/1089/pdf>

Recently we [1] repeated an earlier analysis by [2,3] showing that large ( $> M3$ ) solar X-ray flares associated with solar energetic particle (SEP) events have significantly lower peak X-ray flux ratios  $R$  of 0.04–0.5/0.1–0.8 nm, proxies for flare peak temperatures, than those without SEP events. Since we expect SEP events to be produced by shocks ahead of fast coronal mass ejections (CMEs), this would imply that an X-ray flare of a given peak flux is more likely to have a fast CME and associated SEP event when it has a relatively smaller  $R$ . We examine the role played by the ratios  $R$  in correlations between X-ray peak flare fluxes and CME speeds  $V_{cme}$ , and then compare CMEs widths  $W$ , speeds  $V_{cme}$ , X-ray flare durations  $\Delta T$ , and  $R$  with each other. We resolve the apparent conflict between a global scaling model of

eruptive events showing  $V_{cme}$  scaling with higher  $R$  and our confirmation that the [2,3] analysis implies faster CMEs are associated with flares of lower  $R$ .

### **Ratios of SEP/Suprathermal Intensities and Associated CME Speeds**

S. Kahler,\* A. Ling

36th International Cosmic Ray Conference -ICRC2019- July 24th - August 1st, 2019 Madison, WI, U.S.A.

<https://pos.sissa.it/358/1091/pdf>

Recently [1] have found correlations between peak intensities  $I_p$  of  $E > 10$  MeV SEP events and suprathermal H and He ion intensities observed in situ at 1 AU around the onsets of SEP events. The correlations depend on the solar source longitudes of the driver CMEs and the kind of solar wind (SW) (transient or normal) at the SEP event onset. How the 1 AU suprathermals are related to the solar coronal seed population of SEPs is not known. In a previous study [2] with a similar result, the ratio  $R$  of 20-MeV  $I_p$  to the 2-MeV H suprathermal backgrounds were plotted against CME speeds  $V_{cme}$ . In contrast to the usual strong correlations between  $I_p$  and  $V_{cme}$ , [2] found the dependence of  $R$  on  $V_{cme}$  to be very weak, suggesting that the primary factor determining  $I_p$  of SEP events may be the source seed population, rather than  $V_{cme}$ . We extend that work [1,2] by plotting both  $R$  and  $\log I_p$  against  $\log V_{cme}$  for various types of SW and different source longitudes to look for the dependences of  $R$  on  $V_{cme}$ . We confirm the lower correlations found for  $R$  and  $V_{cme}$ , but  $V_{cme}$  retains its role as an independent factor in SEP production. The better  $R$  correlation using 1.28-2.56 MeV H suggests a more significant role for lower energy 0.16-0.32 MeV H as shock seed particles. Conclusions of variations of  $R$  correlations among different SW types and solar longitudes are limited by the statistics of the SEP events.

### **Do Solar Coronal Holes Affect the Properties of Solar Energetic Particle Events?**

S. W. Kahler, C. N. Arge, S. Akiyama, N. Gopalswamy

Solar Physics, February 2014, Volume 289, Issue 2, pp 657-673; **File**

The intensities and timescales of gradual solar energetic particle (SEP) events at 1 AU may depend not only on the characteristics of shocks driven by coronal mass ejections (CMEs), but also on large-scale coronal and interplanetary structures. It has long been suspected that the presence of coronal holes (CHs) near the CMEs or near the 1-AU magnetic footpoints may be an important factor in SEP events. We used a group of 41  $E \approx 20$  MeV SEP events with origins near the solar central meridian to search for such effects. First we investigated whether the presence of a CH directly between the sources of the CME and of the magnetic connection at 1 AU is an important factor. Then we searched for variations of the SEP events among different solar wind (SW) stream types: slow, fast, and transient. Finally, we considered the separations between CME sources and CH footpoint connections from 1 AU determined from four-day forecast maps based on Mount Wilson Observatory and the National Solar Observatory synoptic magnetic-field maps and the Wang–Sheeley–Arge model of SW propagation. The observed in-situ magnetic-field polarities and SW speeds at SEP event onsets tested the forecast accuracies employed to select the best SEP/CH connection events for that analysis. Within our limited sample and the three analytical treatments, we found no statistical evidence for an effect of CHs on SEP event peak intensities, onset times, or rise times. The only exception is a possible enhancement of SEP peak intensities in magnetic clouds. **Table**

### **A COMPARISON OF THE INTENSITIES AND ENERGIES OF GRADUAL SOLAR ENERGETIC PARTICLE EVENTS WITH THE DYNAMICAL PROPERTIES OF ASSOCIATED CORONAL MASS EJECTIONS**

S. W. Kahler<sup>1</sup> and A. Vourlidas

2013 ApJ 769 143

Gradual solar energetic particle (SEP) events observed at 1 AU are produced by shocks driven by coronal mass ejections (CMEs). Characterizations of the remotely imaged CMEs and of their associated SEP events observed in situ can be used to increase our ability to forecast SEP events and to understand better the physical connections between the two phenomena. We carry out a statistical comparison of the peak intensities  $I_{p20}$ , of 120 western-hemisphere 20 MeV SEP events with those of their associated CMEs observed by the Solar and Heliospheric Observatory/Large Angle and Spectrometric Coronagraph over the past solar cycle. For a subset of 96 events observed with the EPACT instrument on the Wind spacecraft we also compare the SEP 2 MeV peak intensities  $I_{p2}$ , power-law energy spectral exponents  $\gamma$ , total SEP energies  $E_{sep}$ , and 2 MeV  $\text{nuc}^{-1}$  H/He ratios with CME properties. New analyses of white-light CME images enable us to improve calculations of the CME masses and potential energies and then to determine two values of their kinetic energies based on frontal  $V$  (fr) and center-of-mass  $V$  (cm) speeds. Despite considerable scatter in the SEP and CME data, the large dynamical ranges of both the SEP and CME parameters allow us to determine statistical trends in the comparisons of the logs of the parameters.  $I_{p2}$ ,  $I_{p20}$ , and  $E_{sep}$  are significantly correlated with CME kinetic energies, masses, and speeds, while  $\gamma$  trends lower (harder). Those correlations are higher with  $V$  (fr) than with  $V$  (cm) parameters, indicating a less significant role for the body of the CME than for the CME front in SEP production. The high ratios ( $\geq 10\%$ ) of  $E_{sep}$  to CME energies found by Mewaldt et al. are confirmed, and the fits are consistent with a linear relationship between the two energies. The 2 MeV  $\text{nuc}^{-1}$  H/He ratios decrease with increasing CME speeds, which may be an effect of shock geometry. We discuss several factors that limit the estimates of both the SEP and CME energies.

## A COMPARISON OF SOLAR ENERGETIC PARTICLE EVENT TIMESCALES WITH PROPERTIES OF ASSOCIATED CORONAL MASS EJECTIONS

S. W. [Kahler](#)

2013 ApJ 769 110

The dependence of solar energetic proton (SEP) event peak intensities  $I_p$  on properties of associated coronal mass ejections (CMEs) has been extensively examined, but the dependence of SEP event timescales is not well known. We define three timescales of 20 MeV SEP events and ask how they are related to speeds  $v$  CME or widths  $W$  of their associated CMEs observed by LASCO/SOHO. The timescales of the EPACT/Wind 20 MeV events are  $T_O$ , the onset time from CME launch to SEP onset;  $T_R$ , the rise time from onset to half the peak intensity ( $0.5I_p$ ); and  $T_D$ , the duration of the SEP intensity above  $0.5I_p$ . This is a statistical study based on 217 SEP-CME events observed during 1996-2008. The large number of SEP events allows us to examine the SEP-CME relationship in five solar-source longitude ranges. In general, we statistically find that  $T_O$  declines slightly with  $v$  CME, and  $T_R$  and  $T_D$  increase with both  $v$  CME and  $W$ .  $T_O$  is inversely correlated with  $\log I_p$ , as expected from a particle background effect. We discuss the implications of this result and find that a background-independent parameter  $T_O+T_R$  also increases with  $v$  CME and  $W$ . The correlations generally fall below the 98% significance level, but there is a significant correlation between  $v$  CME and  $W$  which renders interpretation of the timescale results uncertain. We suggest that faster (and wider) CMEs drive shocks and accelerate SEPs over longer times to produce the longer  $T_R$  and  $T_D$  SEP timescales.

## DEFLECTIONS OF FAST CORONAL MASS EJECTIONS AND THE PROPERTIES OF ASSOCIATED SOLAR ENERGETIC PARTICLE EVENTS

S. W. [Kahler](#)<sup>1</sup>, S. Akiyama<sup>2</sup>, and N. Gopalswamy

2012 ApJ 754 100, [File](#)

The onset times and peak intensities of solar energetic particle (SEP) events at Earth have long been thought to be influenced by the open magnetic fields of coronal holes (CHs). The original idea was that a CH lying between the solar SEP source region and the magnetic footpoint of the 1 AU observer would result in a delay in onset and/or a decrease in the peak intensity of that SEP event. Recently, Gopalswamy et al. showed that CHs near coronal mass ejection (CME) source regions can deflect fast CMEs from their expected trajectories in space, explaining the appearance of driverless shocks at 1 AU from CMEs ejected near solar central meridian (CM). This suggests that SEP events originating in CME-driven shocks may show variations attributable to CH deflections of the CME trajectories. Here, we use a CH magnetic force parameter to examine possible effects of CHs on the timing and intensities of 41 observed gradual E  $\sim$  20 MeV SEP events with CME source regions within  $20^\circ$  of CM. We find no systematic CH effects on SEP event intensity profiles. Furthermore, we find no correlation between the CME leading-edge measured position angles and SEP event properties, suggesting that the widths of CME-driven shock sources of the SEPs are much larger than the CMEs. Independently of the SEP event properties, we do find evidence for significant CME deflections by CH fields in these events.

## Observational Properties of Coronal Mass Ejections [Review](#)

[Kahler](#) S.W.

Solar Eruptions and Energetic Particles, ed. N. Gopalswamy, R. Mewaldt, and J. Torsti, Geophysical Monograph 165, p. 21-32, 2006.

<https://sci-hub.ru/10.1029/165GM05>

Coronal mass ejections (CMEs) have been known and observed for over 30 years. The total number of observed CMEs is now approaching 10,000, most of them detected with the LASCO coronagraph on the SOHO spacecraft. We review statistical work on CME widths, latitudes, accelerations, speeds, masses, and rates of occurrence. Solar-cycle variations of these parameters are presented. Recent work has focused on CME internal properties and compositions and on CME dynamics, particularly at low ( $< 3 R_o$ ) altitudes. The challenges to understand the magnetic topology of narrow ( $< 20$  deg width) CMEs, to determine the relationship of coronal holes to CMEs, and to observe magnetic reconnection that effects magnetic disconnections of CMEs from the Sun are discussed.

## Solar flares and coronal mass ejections. [\(Review\)](#)

[Kahler](#), S.W.,

1992. Ann Rev. Astron. Astrophys. 30, 113-141.

<http://sci-hub.ru/10.1146/annurev.aa.30.090192.000553>

<https://articles.adsabs.harvard.edu/pdf/1992ARA%26A..30..113K>

This review addresses two basic questions. First, how did we form such a fundamentally incorrect view of the effects of flares after so much observational and theoretical work? Second, what is the observational and theoretical evidence to support a primary role for CMEs, and what can we say about the relationship between flares and CMEs? In Section 2 we present flare and CME observations in a historical context to show the changing perspective between the two phenomena. In Section 3 we discuss the coronal phenomena that bear on the relationship between flares and CMEs. Interplanetary effects are discussed in Section 4.

## The Evolution of Quasi-Separatrix Layer in Two Solar Eruptive Events

Kang [Kai-Feng](#), Yan Xiao-li, Xu Zhi, Wu Ning, Lin Jun

[Chinese Astronomy and Astrophysics](#) Volume 42, Issue 3 Pages 386-420 2018

<https://www.sciencedirect.com/journal/chinese-astronomy-and-astrophysics/vol/42/issue/3>

Quasi-separatrix layer, also called as QSL, is a region where magnetic connectivity changes drastically, and mostly well coincides with the location of flare ribbons in observations. The research on the relations of this topological structure with the 3-dimensional magnetic reconnection, and solar flares has attracted more and more attention. In this paper, using the theory of QSL we investigate a C5.7 classical two-ribbon solar flare (event 1) which occurred at AR11384 on **2011 December 26**, and an M6.5 solar flare (event 2) which occurred at AR12371 on **2015 June 22**, respectively. Combining the multi-wavelength data of AIA (Atmospheric Imaging Assembly) and vector magnetograms of HMI (Helioseismic and Magnetic Imager) onboard SDO (Solar Dynamics Observatory), we extrapolate the coronal magnetic field using the PF (Potential Field) and NLFFF (Nonlinear Force Free Field) models, and calculate the evolution of the AR (Active Region) magnetic free energy. Then, we calculate the logarithmic distribution of Q-factors (magnetic squashing factor) at different heights above the solar photosphere with the results of the PF and NLFFF extrapolations, in order to determine the location of QSL. Afterward, we investigate the evolutionary relation between the QSLs at different heights above the solar photosphere and the flare ribbons observed at the corresponding heights. Finally, we study the multi-wavelength evolution features of the 2 flare events, and obtain by calculation the mean slip velocities of magnetic lines in the event 2 at 304 Å and 335 Å to be 4.6 km s<sup>-1</sup> and 6.3 km s<sup>-1</sup>, respectively. We find that the calculated location of QSL in the chromosphere and corona is in good agreement with the location of flare ribbons at the same height, and the QSLs at different heights have almost the same evolutionary behavior in time as the flare ribbons of the corresponding heights, which highlights the role of QSL in the research of 3D magnetic reconnection and solar flare, and we suggest that the energy release in the flare of event 2 may be triggered by the magnetic reconnection at the place of QSL. We also suggest that the QSL is very important for us to study the essential relation between the 3D and 2D magnetic reconnections.

## Kinematic study of radio-loud CMEs associated with solar flares and DH type II radio emissions during solar cycles 23 and 24

[P. Pappa Kalaivani](#), [O. Prakash](#), [A. Shanmugaraju](#), [G. Michalek](#), [G. Selvarani](#)

Solar Phys. 2022

<https://arxiv.org/pdf/2204.07968.pdf>

We have statistically analyzed 379 radio-loud (RL) CMEs and their associated flares during the period 1996 - 2019 covering both solar cycles (SC) 23 and 24. We classified them into two sets of populations based on the observation period: i) 235 events belong to SC 23 (August 1996 - December 2008) and ii) 144 events belong to SC 24 (January 2009 - December 2019). The average residual acceleration of RL CMEs in SC 24 ( $-17.39 \pm 43.51 \text{ m s}^{-2}$ ) is two times lower than that of the RL CMEs in SC 23 ( $-8.29 \pm 36.23 \text{ m s}^{-2}$ ), which means that deceleration of RL CMEs in SC 24 is twice as fast as in SC 23. RL CMEs of SC 23 ( $1443 \pm 504 \text{ km s}^{-1}$ ;  $13.82 \pm 7.40 \text{ \textcircled{R}}$ ) reach their peak speed at higher altitudes than RL CMEs of SC 24 ( $1920 \pm 649 \text{ km s}^{-1}$ ;  $12.51 \pm 7.41 \text{ \textcircled{R}}$ ). We also observed that the mean apparent widths of RL CMEs in SC 23 are less than in SC 24 which is statistically significant. SC 23 has a lower average CME nose height ( $3.85 \text{ \textcircled{R}}$ ) at the start time of DH type II bursts than that of SC 24 ( $3.46 \text{ \textcircled{R}}$ ). The starting frequencies of DH type II bursts associated with RL CMEs for SC 24 are significantly larger (formed at lower heights) than that of SC 23. We found that there is a good correlation between the drift rates and the mid-frequencies of DH type II radio bursts for both the solar cycles ( $\text{R} = 0.80$ ,  $\epsilon = 1.53$ ). Most of the RL CMEs kinematics and their associated solar flare properties are found similar for SC 23 and SC 24. We concluded that the reduced total pressure in the heliosphere for SC 24 enables RL CMEs to expand wider and decelerate faster, resulting in DH type II radio emissions at lower heights than SC 23.

## Analysis of type II and type III radio bursts associated with SEPs from non-interacting/interacting radio-loud CMEs

[P Pappa Kalaivani](#), [O Prakash](#), [A Shanmugaraju](#), [Li Feng](#), [Lei Lu](#), [Weiqun Gan](#), [G Michalek](#)

Astrophysics 2021

<https://arxiv.org/pdf/2107.09955.pdf>

We analyze radio bursts observed in events with interacting/non-interacting CMEs that produced major SEPs ( $I_p > 10 \text{ MeV}$ ) from April 1997 to December 2014. We compare properties of meter (m), deca-hectometer (DH) type II as well as DH type III bursts, and time lags for interacting-CME-associated (IC) events and non-interacting-CME-associated (NIC) events. About 70% of radio emissions were observed in events of both types from meters to kilometers. We found high correlations between the drift rates and mid-frequencies of type II radio bursts calculated as the mean geometric between their starting and ending frequencies for both NIC and IC-associated events (Correlation coefficient  $\text{R}^2 = 0.98$ , power-law index  $\epsilon = 1.68 \pm 0.16$  and  $\text{R}^2 = 0.93$ ,  $\epsilon = 1.64 \pm 0.19$  respectively). We also found a correlation between the frequency drift rates of DH type II bursts and space speeds of CMEs in NIC-associated events. The absence of such correlation for IC-associated events confirms that the shock speeds changed in CME-CME interactions. For the events with western source locations, the mean peak intensity of SEPs in IC-associated events is four times larger than that in NIC-associated SEP events. From the mean time lags between the start times of SEP events and the start of m, DH type II, and DH type III radio bursts, we inferred that particle enhancements in NIC-

associated SEP events occurred earlier than in IC-associated SEP events. The difference between NIC events and IC events in the mean values of parameters of type II and type III bursts is statistically insignificant. **18 Apr 2014**

### **Eruptive Solar Prominence at 37 GHz**

J. [Kallunki](#), M. Tornikoski

[Solar Physics](#) July 2017, 292:84

On **27 June 2012**, an eruptive solar prominence was observed in the extreme ultraviolet (EUV) and radio wavebands. At the Aalto University Metsähovi Radio Observatory (MRO) it was observed at 37 GHz. It was the first time that the MRO followed a radio prominence with dense sampling in the millimetre wavelengths. This prompted us to study the connection of the 37 GHz event with other wavelength domains. At 37 GHz, the prominence was tracked to a height of around  $1.6 R_{\odot}$ – $1.6 R_{\odot}$ , at which the loop structure collapsed. The average velocity of the radio prominence was  $55 \pm 6$  km s<sup>-1</sup>– $155 \pm 6$  km s<sup>-1</sup>. The brightness temperature of the prominence varied between  $800 \pm 100$  K and  $3200 \pm 100$  K. We compared our data with the Solar Dynamic Observatory (SDO)/Atmospheric Imaging Assembly (AIA) instrument's 304 Å EUV data, and found that the prominence behaves very similarly in both wavelengths. The EUV data also reveal flaring activity nearby the prominence. We present a scenario in which this flare works as a trigger that causes the prominence to move from a stable stage to an acceleration stage.

### **Gnevyshev Peaks in the CME Average Speeds in Cycle 23**

R. P. [Kane](#)

*Solar Phys.*, 261(1), Page: 209 – 213, **2010**, [File](#)

Sunspots have a major 11-year cycle, but the three to four years near the maximum may show two or more peaks called Gnevyshev peaks. Earlier, it was reported that in Solar Cycle 23, the double peak in sunspot numbers was reflected in the electromagnetic radiations and coronal mass ejection (CME) frequencies in the solar atmosphere, but with phase differences. In this article, it is shown that the average CME speeds also show Gnevyshev peaks but with phase differences.

### **Fluctuations of Solar Activity during the Declining Phase of the 11-Year Sunspot Cycle**

R.P. [Kane](#)

*Solar Phys* (2009) 255: 163–168, DOI 10.1007/s11207-008-9303-8

### **Gnevyshev Peaks and Gaps for Coronal Mass Ejections of Different Widths Originating in Different Solar Position Angles**

R.P. [Kane](#)

*Solar Phys* (2008) 249: 369–380

<http://springerlink.com/content/h528p165342m2716/fulltext.pdf>

The sunspot number series at the peak of sunspot activity often has two or three peaks (Gnevyshev peaks; Gnevyshev, *Solar Phys.* **1**, 107, 1967; *Solar Phys.* **51**, 175, 1977). The sunspot group number (SGN) data were examined for 1997 – 2003 (part of cycle 23) and compared with data for coronal mass ejection (CME) events. It was noticed that they exhibited mostly two Gnevyshev peaks in each of the four latitude belts 0° – 10°, 10° – 20°, 20° – 30°, and >30°, in both N (northern) and S (southern) solar hemispheres. The SGN were confined to within latitudes ±50° around the Equator, mostly around ±35°, and seemed to occur later in lower latitudes, indicating possible latitudinal migration as in the Maunder butterfly diagrams. In CMEs, less energetic CMEs (of widths <71°) showed prominent Gnevyshev peaks during sunspot maximum years in almost all latitude belts, including near the poles. The CME activity lasted longer than the SGN activity. However, the CME peaks did not match the SGN peaks and were almost simultaneous at different latitudes, indicating no latitudinal migration. In energetic CMEs including halo CMEs, the Gnevyshev peaks were obscure and ill-defined. The solar polar magnetic fields show polarity reversal during sunspot maximum years, first at the North Pole and, a few months later, at the South Pole. However, the CME peaks and gaps did not match with the magnetic field reversal times, preceding them by several months, rendering any cause – effect relationship doubtful.

### **Latitude Dependence of the Variations of Sunspot Group Numbers (SGN) and Coronal Mass Ejections (CMEs) in Cycle 23**

R.P. [Kane](#)

*Solar Phys* (2008) 249: 355–367

<http://springerlink.com/content/y811g024vg2826n5/fulltext.pdf>

The 12-month running means of the conventional sunspot number  $R_z$ , the sunspot group numbers (SGN) and the frequency of occurrence of Coronal Mass Ejections (CMEs) were examined for cycle 23 (1996 – 2006). For the whole disc, the SGN and  $R_z$  plots were almost identical. Hence, SGN could be used as a proxy for  $R_z$ , for which latitude data are not available. SGN values were used for 5° latitude belts 0° – 5°, 5° – 10°, 10° – 15°, 15° – 20°, 20° – 25°, 25° – 30° and >30°, separately in each hemisphere north and south. Roughly, from latitudes 25° – 30° N to 20° – 25° N, the peaks seem to have occurred *later* for lower latitudes, from latitudes 20° – 25° N to 15° – 20° N, the peaks are stagnant or occur slightly *earlier*, and then from latitudes 15° – 20° N to 0° – 5° N, the peaks seem to have occurred again *later* for lower latitudes. Thus, some latitudinal migration is suggested, clearly in the northern hemisphere, not very clearly in the southern hemisphere,

first to the equator in 1998, stagnant or slightly poleward in 1999, and then to the equator again from 2000 onwards, the latter reminiscent of the Maunder butterfly diagrams. Similar plots for CME occurrence frequency also showed multiple peaks (two or three) in almost all latitude belts, but the peaks were almost simultaneous at all latitudes, indicating no latitudinal migration. For similar latitude belts, SGN and CME plots were dissimilar in almost all latitude belts except  $10^\circ - 20^\circ$  S. The CME plots had in general more peaks than the SGN plots, and the peaks of SGN often did not match with those of CME. In the CME data, it was noticed that whereas the values declined from 2002 to 2003, there was no further decline during 2003 – 2006 as one would have expected to occur during the declining phase of sunspots, where 2007 is almost a year of sunspot minimum. An inquiry at GSFC-NASA revealed that the person who creates the preliminary list was changed in 2004 and the new person picks out more weak CMEs. Thus a subjectivity (overestimates after 2002) seems to be involved and hence, values obtained before and during 2002 are not directly comparable to values recorded after 2002, except for CMEs with widths exceeding  $60^\circ$ .

## **Similarities and Dissimilarities between the Variations of CME and Other Solar Parameters at Different Heliographic Latitudes and Time Scales**

R.P. Kane

Solar Phys (2008) 248: 177–190

From the LASCO CME (Coronal Mass Ejection) catalog, the occurrence frequencies of all CMEs (all strong and weak CMEs, irrespective of their widths) were calculated for 3-month intervals and their 12-month running means determined for cycle 23 (1996 – 2007) and were compared with those of other solar parameters. The annual values of all-CME frequency were very well correlated (+0.97) with sunspot numbers, but several other parameters also had similarly high correlations. Comparisons of 12-month running means indicated that the sunspot numbers were very well correlated with solar electromagnetic radiations (Lyman- $\alpha$ , 2800-MHz flux, coronal green line index, solar flare indices, and X-ray background); but for corpuscular radiations [proton fluxes, solar energetic particles (SEP), CMEs, interplanetary CMEs (ICMEs), and stream interaction regions (SIR)] and solar open magnetic fields, the correlations were lower. A notable feature was the appearance of two peaks during 2000 – 2002, and those double peaks in different parameters matched approximately except for proton fluxes and SEP and SIR frequencies. When hemispheric intensities were considered, north – south asymmetries appeared, more in some parameters than in others. When intensities in smaller latitude belts ( $10^\circ$ ) were compared, sunspot group numbers (SGN) were found to be confined mostly to latitudes within  $\pm 30^\circ$  of the solar equator, showing *two* peaks in all latitude belts, and during the course of the 11-year cycle, the double peaks shifted from middle to equatorial solar latitudes, just as seen in the Maunder butterfly diagrams. In contrast, CME frequency was comparable at all latitude belts (including high, near-polar latitudes), having more than two peaks in almost all latitude belts, and the peaks were almost simultaneous in all latitude belts. Thus, the matching of SGN peaks with those of CME peaks was poor. Incidentally, the CME frequency data for all events (all widths) after 2003 are not comparable to earlier data, owing to inclusion of very weak (narrow) CMEs in later years. The frequencies are comparable with earlier data only for widths exceeding about  $70^\circ$ .

The 12-month running means of the conventional sunspot number  $R_z$ , the sunspot group numbers (SGN) and the frequency of occurrence of Coronal Mass Ejections (CMEs) were examined for cycle 23 (1996 – 2006). For the whole disc, the SGN and  $R_z$  plots were almost identical. Hence, SGN could be used as a proxy for  $R_z$ , for which latitude data are not available. SGN values were used for  $5^\circ$  latitude belts  $0^\circ - 5^\circ$ ,  $5^\circ - 10^\circ$ ,  $10^\circ - 15^\circ$ ,  $15^\circ - 20^\circ$ ,  $20^\circ - 25^\circ$ ,  $25^\circ - 30^\circ$  and  $>30^\circ$ , separately in each hemisphere north and south. Roughly, from latitudes  $25^\circ - 30^\circ$  N to  $20^\circ - 25^\circ$  N, the peaks seem to have occurred *later* for lower latitudes, from latitudes  $20^\circ - 25^\circ$  N to  $15^\circ - 20^\circ$  N, the peaks are stagnant or occur slightly *earlier*, and then from latitudes  $15^\circ - 20^\circ$  N to  $0^\circ - 5^\circ$  N, the peaks seem to have occurred again *later* for lower latitudes. Thus, some latitudinal migration is suggested, clearly in the northern hemisphere, not very clearly in the southern hemisphere, first to the equator in 1998, stagnant or slightly poleward in 1999, and then to the equator again from 2000 onwards, the latter reminiscent of the Maunder butterfly diagrams. Similar plots for CME occurrence frequency also showed multiple peaks (two or three) in almost all latitude belts, but the peaks were almost simultaneous at all latitudes, indicating no latitudinal migration. For similar latitude belts, SGN and CME plots were dissimilar in almost all latitude belts except  $10^\circ - 20^\circ$  S. The CME plots had in general more peaks than the SGN plots, and the peaks of SGN often did not match with those of CME. In the CME data, it was noticed that whereas the values declined from 2002 to 2003, there was no further decline during 2003 – 2006 as one would have expected to occur during the declining phase of sunspots, where 2007 is almost a year of sunspot minimum. An inquiry at GSFC-NASA revealed that the person who creates the preliminary list was changed in 2004 and the new person picks out more weak CMEs. Thus a subjectivity (overestimates after 2002) seems to be involved and hence, values obtained before and during 2002 are not directly comparable to values recorded after 2002, except for CMEs with widths exceeding  $60^\circ$ .

## **COMPARISON OF THE VARIATIONS OF CMEs AND ICMEs WITH THOSE OF OTHER SOLAR AND INTERPLANETARY PARAMETERS DURING SOLAR CYCLE 23**

R. P. KANE

Solar Physics (2006) 233: 107–115

This paper examines the variations of coronal mass ejections (CMEs) and interplanetary CMEs (ICMEs) during solar cycle 23 and compares these with those of several other indices. During cycle 23, solar and interplanetary parameters had an increase from 1996 (sunspot minimum) to ~2000, but the interval 1998–2002 had short-term fluctuations. Sunspot numbers had peaks in 1998,

1999, 2000 (largest), 2001 (second largest), and 2002. Other solar indices had matching peaks, but the peak in 2000 was larger than the peak in 2001 only for a few indices, and smaller or equal for other solar indices. The solar open magnetic flux had very different characteristics for different solar latitudes. The high solar latitudes ( $45^\circ$ – $90^\circ$ ) in both N and S hemispheres had flux evolutions *anti-parallel* to sunspot activity. Fluxes in low solar latitudes ( $0^\circ$ – $45^\circ$ ) evolved roughly parallel to sunspot activity, but the finer structures (peaks etc. during sunspot maximum years) did not match with sunspot peaks. Also, the low latitude fluxes had considerable N–S asymmetry. For CMEs and ICMEs, there were increases similar to sunspots during 1996–2000, and during 2000–2002, there was good matching of peaks. But the peaks in 2000 and 2001 for CMEs and ICMEs had similar sizes, in contrast to the 2000 peak being greater than the 2001 peak for sunspots. Whereas ICMEs started decreasing from 2001 onwards, CMEs continued to remain high in 2002, probably due to extra contribution from high-latitude prominences, which had no equivalent interplanetary ICMEs or shocks. Cosmic ray intensity had features matching with those of sunspots during 2000–2001, with the 2000 peak (on a reverse scale, actually a cosmic ray decrease or trough) larger than the 2001 peak. However, cosmic ray decreases started with a delay and ended with a delay with respect to sunspot activity.

## Data-driven MHD simulation of successive solar plasma eruptions

[Takafumi Kaneko](#), [Sung-Hong Park](#), [Kanya Kusano](#)

ApJ **909** 155 2021

<https://arxiv.org/pdf/2101.12395.pdf>

<https://doi.org/10.3847/1538-4357/abe414>

Solar flares and plasma eruptions are sudden releases of magnetic energy stored in the plasma atmosphere. To understand the physical mechanisms governing their occurrences, three-dimensional magnetic fields from the photosphere up to the corona must be studied. The solar photospheric magnetic fields are observable, whereas the coronal magnetic fields cannot be measured. One method for inferring coronal magnetic fields is performing data-driven simulations, which involves time-series observational data of the photospheric magnetic fields with the bottom boundary of magnetohydrodynamic simulations. We developed a data-driven method in which temporal evolutions of the observational vector magnetic field can be reproduced at the bottom boundary in the simulation by introducing an inverted velocity field. This velocity field is obtained by inversely solving the induction equation and applying an appropriate gauge transformation. Using this method, we performed a data-driven simulation of successive small eruptions observed by the Solar Dynamics Observatory and the Solar Magnetic Activity Telescope in November 2017. The simulation well reproduced the converging motion between opposite-polarity magnetic patches, demonstrating successive formation and eruptions of helical flux ropes. **2017 November 4-5**

## Simulation Study of Solar Plasma Eruptions Caused by Interactions between Emerging Flux and Coronal Arcade Fields

T. [Kaneko](#), T. Yokoyama

2014 ApJ 796 44

<http://arxiv.org/pdf/1410.0189v1.pdf>

We investigate the triggering mechanisms of plasma eruptions in the solar atmosphere due to interactions between emerging flux and coronal arcade fields by using two-dimensional MHD simulations. We perform parameter surveys with respect to arcade field height, magnetic field strength, and emerging flux location. Our results show that two possible mechanisms exist, and which mechanism is dominant depends mostly on emerging flux location. One mechanism appears when the location of emerging flux is close to the polarity inversion line (PIL) of an arcade field. This mechanism requires reconnection between the emerging flux and the arcade field, as pointed out by previous studies. The other mechanism appears when the location of emerging flux is around the edge of an arcade field. This mechanism does not require reconnection between the emerging flux and the arcade field but does demand reconnection in the arcade field above the PIL. Furthermore, we found that the eruptive condition for this mechanism can be represented by a simple formula.

## Onset Mechanism of M6.5 Solar Flare Observed in Active Region 12371

Jihye [Kang](#), [Satoshi Inoue](#), [Kanya Kusano](#), [Sung-Hong Park](#), [Yong-Jae Moon](#)

ApJ **2019**

<https://arxiv.org/pdf/1911.05337.pdf>

We studied a flare onset process in terms of stability of a three-dimensional (3D) magnetic field in active region 12371 producing an eruptive M6.5 flare in **2015 June 22**. In order to reveal the 3D magnetic structure, we first extrapolated the 3D coronal magnetic fields based on time series of the photospheric vector magnetic fields under a nonlinear force-free field (NLFFF) approximation. The NLFFFs nicely reproduced the observed sigmoidal structure which is widely considered as pre-eruptive magnetic configuration. We, in particular, found that the sigmoid is composed of two branches of sheared arcade loops. On the basis of the NLFFFs, we investigated the sheared arcade loops to explore the onset process of the eruptive flare using three representative MHD instabilities: the kink, torus and double arc instabilities. The double arc instability, recently proposed by Ishiguro & Kusano, is a double arc loop can be more easily destabilized than a torus loop. Consequently, the NLFFFs are found to be quite stable against the kink and torus instabilities. However, the sheared arcade loops formed prior to the flare possibly becomes unstable against the double arc instability. As a possible scenario on the onset process of the M6.5 flare, we suggest three-step process: (1) double arc loop are formed by the sheared arcade loops through the tether-cutting reconnection during an early phase of the flare, (2) the double arc instability contributes to the expansion of destabilized double arc loops and (3) finally, the torus instability makes the full eruption.

## **Spectropolarimetric Radio Imaging of Faint Gyrosynchrotron Emission from a CME : A Possible Indication of the Insufficiency of Homogeneous Models**

[Devojyoti Kansabanik](#), [Surajit Mondal](#), [Divya Oberoi](#)

ApJ **968** 55 **2024**

<https://arxiv.org/pdf/2404.14714.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ad43e9/pdf>

The geo-effectiveness of coronal mass ejections (CMEs) is determined primarily by their magnetic fields. Modeling of Gyrosynchrotron (GS) emission is a promising remote sensing technique to measure the CME magnetic field at coronal heights. However, faint GS emission from CME flux ropes is hard to detect in the presence of bright solar emission from the solar corona. With high dynamic-range spectropolarimetric meter wavelength solar images provided by the Murchison Widefield Array, we have detected faint GS emission from a CME out to  $\sim 8.3 R_{\odot}$ , the largest heliocentric distance reported to date. High-fidelity polarimetric calibration also allowed us to robustly detect circularly polarized emission from GS emission. For the first time in literature, Stokes V detection has jointly been used with Stokes I spectra to constrain GS models. One expects that the inclusion of polarimetric measurement will provide tighter constraints on GS model parameters. Instead, we found that homogeneous GS models, which have been used in all prior works, are unable to model both the total intensity and circular polarized emission simultaneously. This strongly suggests the need for using inhomogeneous GS models to robustly estimate the CME magnetic field and plasma parameters. **3-4 May 2014**

## **A Double-decker Flux Rope Model for the Solar Eruption on 2012 March 10**

Nishu [Karna](#)<sup>1</sup>, Suman Dhaka<sup>2</sup>, Antonia Savcheva<sup>3</sup>, Jie Zhang<sup>2</sup>, and Bernhard Kliem<sup>4</sup>

**2024** ApJ 961 11

<https://iopscience.iop.org/article/10.3847/1538-4357/ad1187/pdf>

We present a magnetic configuration of a compound solar eruption observed on **2012 March 10**, from NOAA AR 11429 near the disk center, which displayed a soft X-ray sigmoid before the eruption. We constructed a series of magnetic field models, including double-decker flux rope configurations, using the flux rope insertion method. This produces three-dimensional coronal magnetic field models constrained by the photospheric magnetogram and observed EUV coronal structures. We used different combinations of flux rope paths. We found that two flux ropes sharing the same path at different heights quickly experience a partial merging in the initial iteration of the magnetofrictional relaxation process. Different paths with less than 30% overlap allowed us to construct stable double-decker structures. The high spatial and temporal resolution of the Solar Dynamics Observatory/Atmospheric Imaging Assembly facilitated the selection of a best-fit model that matches the observations best. Moreover, by varying fluxes in this validated nonlinear force-free field double-decker configuration, we successfully reproduce all three scenarios of eruptions of double-decker configurations: (i) eruption due to the instability of higher flux rope; (ii) eruption due to rising lower flux rope and merging with higher flux rope; and (iii) eruption due to the instability of both flux ropes. This demonstrates that magnetofrictional simulation can capture the large-scale magnetic structure of eruptions for a realistic field configuration at eruption onset.

## **Magnetofrictional Modeling of an Erupting Pseudostreamer**

Nishu [Karna](#)<sup>1</sup>, Antonia Savcheva<sup>1,2</sup>, Sarah Gibson<sup>3</sup>, Svetlin Tassev<sup>1</sup>, Katharine K. Reeves<sup>1</sup>, Edward E. DeLuca<sup>1</sup>, and Kévin Dalmasse<sup>4</sup>

**2021** ApJ 913 47

<https://doi.org/10.3847/1538-4357/abf2b8>

In this study, we present the magnetic configuration of an erupting pseudostreamer observed on **2015 April 19**, on the southwest limb of the Sun, with a prominence cavity embedded inside. The eruption resulted in a partial halo coronal mass ejection. The prominence eruption begins with a slow rise and then evolves to a fast-rise phase. We analyze this erupting pseudostreamer using the flux-rope insertion method and magnetofrictional relaxation to establish a sequence of plausible out-of-equilibrium magnetic configurations. This approach allows the direct incorporation of observations of structures seen in the corona (filament and cavity) to appropriately model the pseudostreamer based on SDO/HMI line-of-sight photospheric magnetograms. We also perform a topological analysis in order to determine the location of quasiseparatrix layers (QSLs) in the models, producing Q-maps to examine how the QSL locations progress in the higher iterations. We found that the axial flux in our best-fit unstable model was a factor of 20 times higher than we found in our marginally stable case. We computed the average magnetic field strength of the prominence and found that the unstable model exhibits twice the average field strength of the stable model. The eruption height from our modeling matches very well with the prominence eruption height measured from the AIA observation. The Q-maps derived from the model reproduce structures observed in LASCO/C2. Thus, the modeling and topological analysis results are fully consistent with the observed morphological features, implying that we have captured the large magnetic structure of the erupting filament in our magnetofrictional simulation.

## **Solar Eruptions in Nested Magnetic Flux Systems**

Judith T. **Karpen**<sup>1</sup>, Pankaj Kumar<sup>1,2</sup>, Peter F. Wyper<sup>3</sup>, C. Richard DeVore<sup>1</sup>, and Spiro K. Antiochos<sup>4</sup>  
2024 ApJ 966 27

<https://iopscience.iop.org/article/10.3847/1538-4357/ad2eaa/pdf>

The magnetic topology of erupting regions on the Sun is a key factor in the energy buildup and release, and the subsequent evolution of flares and coronal mass ejections (CMEs). The presence/absence of null points and separatrices dictates whether and where current sheets form and magnetic reconnection occurs. Numerical simulations show that energy buildup and release via reconnection in the simplest configuration with a null, the embedded bipole, is a universal mechanism for solar eruptions. Here we demonstrate that a magnetic topology with nested bipoles and two nulls can account for more complex dynamics, such as failed eruptions and CME–jet interactions. We investigate the stalled eruption of a nested configuration on **2013 July 13** in NOAA Active Region 11791, in which a small bipole is embedded within a large transequatorial pseudo-streamer containing a null. In the studied event, the inner active region erupted, ejecting a small flux rope behind a shock accompanied by a flare; the flux rope then reconnected with pseudo-streamer flux and, rather than escaping intact, mainly distorted the pseudo-streamer null into a current sheet. EUV and coronagraph images revealed a weak shock and a faint collimated outflow from the pseudo-streamer. We analyzed Solar Dynamics Observatory and Solar TERrestrial RELations Observatory observations and compared the inferred magnetic evolution and dynamics with three-dimensional magnetohydrodynamics simulations of a simplified representation of this nested fan-spine system. The results suggest that the difference between breakout reconnection at the inner null and at the outer null naturally accounts for the observed weak jet and stalled ejection. We discuss the general implications of our results for failed eruptions.

## **Reconnection-Driven Coronal-Hole Jets with Gravity and Solar Wind**

J. T. **Karpen**, C. R. DeVore, S. K. Antiochos, E. Pariat

2017 ApJ 834 62

<http://arxiv.org/pdf/1606.09201v1.pdf>

Coronal-hole jets occur ubiquitously in solar coronal holes, at EUV and X-ray bright points associated with intrusions of minority magnetic polarity. The embedded-bipole model for these jets posits that they are driven by explosive, fast reconnection between the stressed closed field of the embedded bipole and the open field of the surrounding coronal hole. Previous numerical studies in Cartesian geometry, assuming uniform ambient magnetic field and plasma while neglecting gravity and solar wind, demonstrated that the model is robust and can produce jet-like events in simple configurations. We have extended these investigations by including spherical geometry, gravity, and solar wind in a nonuniform, coronal hole-like ambient atmosphere. Our simulations confirm that the jet is initiated by the onset of a kink-like instability of the internal closed field, which induces a burst of reconnection between the closed and external open field, launching a helical jet. Our new results demonstrate that the jet propagation is sustained through the outer corona, in the form of a traveling nonlinear Alfvén wave front trailed by slower-moving plasma density enhancements that are compressed and accelerated by the wave. This finding agrees well with observations of white-light coronal-hole jets, and can explain microstreams and torsional Alfvén waves detected in situ in the solar wind. We also use our numerical results to deduce scaling relationships between properties of the coronal source region and the characteristics of the resulting jet, which can be tested against observations.

## **THE MECHANISMS FOR THE ONSET AND EXPLOSIVE ERUPTION OF CORONAL MASS EJECTIONS AND ERUPTIVE FLARES**

J. T. **Karpen**<sup>1</sup>, S. K. Antiochos<sup>1</sup>, and C. R. DeVore

2012 ApJ 760 81

We have investigated the onset and acceleration of coronal mass ejections (CMEs) and eruptive flares. To isolate the eruption physics, our study uses the breakout model, which is insensitive to the energy buildup process leading to the eruption. We performed 2.5D simulations with adaptive mesh refinement that achieved the highest overall spatial resolution to date in a CME/eruptive flare simulation. The ultra-high resolution allows us to separate clearly the timing of the various phases of the eruption. Using new computational tools, we have determined the number and evolution of all X- and O-type nulls in the system, thereby tracking both the progress and the products of reconnection throughout the computational domain. Our results show definitively that CME onset is due to the start of fast reconnection at the breakout current sheet. Once this reconnection begins, eruption is inevitable; if this is the only reconnection in the system, however, the eruption will be slow. The explosive CME acceleration is triggered by fast reconnection at the flare current sheet. Our results indicate that the explosive eruption is caused by a resistive instability, not an ideal process. Moreover, both breakout and flare reconnections begin first as a form of weak tearing characterized by slowly evolving plasmoids, but eventually transition to a fast form with well-defined Alfvénic reconnection jets and rapid flux transfer. This transition to fast reconnection is required for both CME onset and explosive acceleration. We discuss the key implications of our results for CME/flare observations and for theories of magnetic reconnection.

## **Early Evolution of Earth-Directed Coronal Mass Ejections in the Vicinity of Coronal Holes.**

**Karuppiah**, S., Dumbović, M., Martinić, K. et al.

Sol Phys 299, 87 (2024).

<https://doi.org/10.1007/s11207-024-02319-6>

We investigate the deflection and rotation behaviour of 49 Earth-directed coronal mass ejections (CMEs) spanning the period from 2010 to 2020 aiming to understand the potential influence of coronal holes (CHs) on their trajectories. Our analysis incorporates data from coronagraphic observations captured from multiple vantage points, as well as extreme ultraviolet (EUV) observations utilised to identify associated coronal signatures such as solar flares and filament eruptions. For each CME, we perform a 3D reconstruction using the Graduated Cylindrical Shell (GCS) model. We perform the GCS reconstruction in multiple time steps, from the time at which the CME enters the field of view (FOV) of the coronagraphs to the time it exits. We analyse the difference in the longitude, latitude, and inclination between the first and last GCS reconstructions as possible signatures of deflection/rotation. Furthermore, we examine the presence of nearby CHs at the time of eruption and employ the Collection of Analysis Tools for Coronal Holes (CATCH) to estimate relevant CH parameters, including magnetic-field strength, centre of mass, and area. To assess the potential influence of CHs on the deflection and rotation of CMEs, we calculate the Coronal Hole Influence Parameter (CHIP) for each event and analyse its relationship with their trajectories. A statistically significant difference is observed between CHIP force and the overall change in a CME's direction in the lower corona. The overall change in a CME's direction accounts cumulatively for the change in latitude, longitude, and rotation. This suggests that the CHIP force in the low corona has a significant influence on the overall change in the direction of Earth-directed CMEs. However, as the CME evolves outward, the CHIP force becomes less effective in causing deflection or rotation at greater distances. Additionally, we observe a negative correlation between the deflection rate of the CMEs and their velocity, suggesting that higher velocities are associated with lower deflection rates. Hence, the velocity of a CME, along with the magnetic field from CHs, appears to play a significant role in the deflection of CMEs. By conducting this comprehensive analysis, we aim to enhance our understanding of the complex interplay between CHs, CME trajectories, and relevant factors such as velocity and magnetic-field strength.

### **Statistical Relation between Solar Flares and Coronal Mass Ejections with Respect to Sigmoidal Structures in Active Regions**

Y. [Kawabata](#), Y. [Iida](#), T. [Doi](#), S. [Akiyama](#), S. [Yashiro](#), T. [Shimizu](#)

ApJ **869** 99 **2018** <https://doi.org/10.3847/1538-4357/aaebfc>

<https://arxiv.org/pdf/1810.10808.pdf>

[sci-hub.tw/10.3847/1538-4357/aaebfc](https://sci-hub.tw/10.3847/1538-4357/aaebfc)

Statistical dependencies among features of coronal mass ejections (CMEs), solar flares, and sigmoidal structures in soft-X-ray images were investigated. We applied analysis methods to all the features in the same way in order to investigate the reproducibility of the correlations among them, which may be found from the combination of previous statistical studies. The samples of 211 M-class and X-class flares, which were observed between 2006 and 2015 by Hinode/X-ray telescope, Solar and Heliospheric Observatory/Large Angle and Spectrometric Coronagraph, and GOES, were examined statistically. Five kinds of analysis were performed: Occurrence rate analysis, linear-correlation analysis, association analysis, the Kolmogorov--Smirnov test, and Anderson-Darling test. The analyses show three main results. First, the sigmoidal structure and long duration events (LDEs) has stronger dependency on the CME occurrence than large X-ray class events in on-disk events. Second, for the limb events, the significant dependency exists between LDEs and CME occurrence, and between X-ray class and CME occurrence. Third, there existed 32.4% of on-disk flare events, which had sigmoidal structure and were not accompanied by CMEs. However, the occurrence probability of CMEs without sigmoidal structures is very small, 8.8 %, in on-disk events. While the first and second results are consistent with previous studies, we newly provided the difference between the on-disk events and limb events. The third result that non-sigmoidal regions produce less eruptive events is also different from previous results. We suggest that sigmoidal structures in soft X-ray images will be a helpful feature for CME prediction regarding on-disk flare events.

### **Velocity Structure and Temperature Dependence of Extreme-Ultraviolet Jet Observed by Hinode**

Toshiki [Kawai](#), [Natsuo Kanda](#), [Shinsuke Imada](#)

Solar Phys. **294**:74 **2019**

<https://arxiv.org/pdf/1904.10271.pdf>

[sci-hub.se/10.1007/s11207-019-1469-8](https://sci-hub.se/10.1007/s11207-019-1469-8)

The acceleration mechanism of EUV/X-ray jets is still unclear. For the most part, there are two candidates for the mechanism. One is magnetic reconnection, and the other is chromospheric evaporation. We observed a relatively compact X-ray jet that occurred between 10:50 - 11:10 UT on **February 18, 2011** by using the Solar Dynamics Observatory/Atmospheric Imaging Assembly, and the X-ray Telescope, Solar Optical Telescope, and EUV Imaging Spectrometer aboard Hinode. Our results are as follows: 1) The EUV and X-ray observations show the general characteristics of X-ray jets, such as an arch structure straddling a polarity inversion line, a jet bright point shown at one side of the arch leg, and a spire above the arch. 2) The multi-wavelength observations and Ca II H-band image show the existence of a low-temperature (~10 000K) plasma (i.e., filament) at the center of the jet. 3) In the magnetogram and Ca II H-band image, the filament exists over the polarity inversion line and arch structure is also straddling it. In addition, magnetic cancellation occurs around the jet a few hours before and after the jet is observed. 4) The temperature distribution of the accelerated plasma, which was estimated from Doppler velocity maps, the calculated differential emission measure, and synthetic spectra show that there is no clear dependence between the plasma velocity and its

temperature. For the third result above, observational results suggest that magnetic cancellation is probably related to the occurrence of the jet and filament formation. This result suggests that the trigger of the jet is magnetic cancellation rather than an emerging magnetic arch flux. The fourth result indicates that acceleration of the plasma accompanied by an X-ray jet seems to be caused by magnetic reconnection rather than chromospheric evaporation.

### Updating Measures of CME Arrival Time Errors

[C. Kay](#), [E. Palmerio](#), [P. Riley](#), [M. L. Mays](#), [T. Nieves-Chinchilla](#), [M. Romano](#), [Y. M. Collado-Vega](#), [C. Wiegand](#), [A. Chulaki](#)

Space Weather [Volume22, Issue7](#) e2024SW003951 2024

<https://doi.org/10.1029/2024SW003951>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2024SW003951>

Coronal mass ejections (CMEs) drive space weather effects at Earth and the heliosphere. Predicting their arrival is a major part of space weather forecasting. In 2013, the Community Coordinated Modeling Center started collecting predictions from the community, developing an Arrival Time Scoreboard (ATSB). Riley et al. (2018, <https://doi.org/10.1029/2018sw001962>) analyzed the first 5 years of the ATSB, finding a bias of a few hours and uncertainty of order 15 hr. These metrics have been routinely quoted since 2018, but have not been updated despite continued predictions. We revise analysis of the ATSB using a sample 3.5 times the size of that in the original study. We find generally the same overall metrics, a bias of  $-2.5$  hr, mean absolute error of 13.2 hr, and standard deviation of 17.4 hr, with only a slight improvement comparing between the previously-used and new sets. The most well-established, frequently-submitted model results tend to outperform those from seldomly-contributed models. These “best” models show a slight improvement over the 11 year span, with more scatter between the models during early times and a convergence toward the same error metrics in recent years. We find little evidence of any correlations between the arrival time errors and any other properties. The one noticeable exception is a tendency for late predictions for short transit times and vice versa. We propose that any model-driven systematic errors may be washed out by the uncertainties in CME reconstructions in characterization of the background solar wind, and suggest that improving these may be the key to better predictions.

### Collection, Collation, and Comparison of 3D Coronal CME Reconstructions

Catalogs

[C. Kay](#), [E. Palmerio](#)

Space Weather. [Volume22, Issue1](#) e2023SW003796 2024

<https://arxiv.org/pdf/2311.10712.pdf>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2023SW003796>

Predicting the impacts of coronal mass ejections (CMEs) is a major focus of current space weather forecasting efforts. Typically, CME properties are reconstructed from stereoscopic coronal images and then used to forward model a CME's interplanetary evolution. Knowing the uncertainty in the coronal reconstructions is then a critical factor in determining the uncertainty of any predictions. A growing number of catalogs of coronal CME reconstructions exist, but no extensive comparison between these catalogs has yet been performed. Here we develop a Living List of Attributes Measured in Any Coronal Reconstruction (LLAMACoRe), an online collection of individual catalogs, which we intend to continually update. In this first version, we use results from 24 different catalogs with 3D reconstructions using STEREO observations between 2007--2014. We have collated the individual catalogs, determining which reconstructions correspond to the same events. LLAMACoRe contains 2954 reconstructions for 1863 CMEs. Of these, 510 CMEs contain multiple reconstructions from different catalogs. Using the best-constrained values for each CME, we find that the combined catalog reproduces the generally known solar cycle trends. We determine the typical difference we would expect between two independent reconstructions of the same event and find values of 4.0 deg in the latitude, 8.0 deg in the longitude, 24.0 deg in the tilt, 9.5 deg in the angular width, 0.1 in the shape parameter  $\kappa$ , 115 km/s in the velocity, and  $2.5e15$  g in the mass. These remain the most probable values over the solar cycle, though we find more extreme outliers in the deviation toward solar maximum.

### OSPREDI: A Coupled Approach to Modeling CME-Driven Space Weather With Automatically Generated, User-Friendly Outputs

[C. Kay](#), [M. L. Mays](#), [Y. M. Collado-Vega](#)

Space Weather e2021SW002914 2022

<https://arxiv.org/pdf/2109.06960.pdf>

Coronal mass ejections (CMEs) drive space weather activity at Earth and throughout the solar system. Current CME-related space weather predictions rely on information reconstructed from coronagraphs, sometimes from only a single viewpoint, to drive a simple interplanetary propagation model, which only gives the arrival time or limited additional information. We present the coupling of three established models into OSPREDI (Open Solar Physics Rapid Ensemble Information), a new tool that describes Sun-to-Earth CME behavior, including the location, orientation, size, shape, speed, arrival time, and internal thermal and magnetic properties, on the timescale needed for forecasts. First, Forecasting a CME's Altered Trajectory (ForeCAT) describes the trajectory that a CME takes through the solar corona. Second, ANother Type of Ensemble Arrival Time Results simulates the propagation, including expansion and deformation, of a CME in interplanetary space and determines the evolution of internal properties via conservation laws. Finally, ForeCAT In situ Data Observer produces in situ profiles for a CME's interaction with a synthetic

spacecraft. OSPREI includes ensemble modeling by varying each input parameter to probe any uncertainty in their values, yielding probabilities for all outputs. Standardized visualizations are automatically generated, providing easily accessible, essential information for space weather forecasting. We show OSPREI results for a CMEs observed in the corona on **22 April and 09 May 2021**. We approach these CME as a forecasting proof-of-concept, using information analogous to what would be available in real time rather than fine-tuning input parameters to achieve a best fit for a detailed scientific study. The OSPREI “prediction” shows good agreement with the arrival time and in situ properties. **21 April 2021, 09 May 2021**

## Using the Coronal Evolution to Successfully Forward Model CMEs' In Situ Magnetic Profiles†

C. **Kay**, N. Gopalswamy

JGR 2017

Predicting the effects of a coronal mass ejection (CME) impact requires knowing if impact will occur, which part of the CME impacts, and its magnetic properties. We explore the relation between CME deflections and rotations, which change the position and orientation of a CME, and the resulting magnetic profiles at 1 AU. For 45 STEREO-era, Earth-impacting CMEs, we determine the solar source of each CME, reconstruct its coronal position and orientation, and perform a ForeCAT [Kay et al., 2015a] simulation of the coronal deflection and rotation. From the reconstructed and modeled CME deflections and rotations we determine the solar cycle variation and correlations with CME properties. We assume no evolution between the outer corona and 1 AU and use the ForeCAT results to drive the FIDO in situ magnetic field model [Kay et al., 2017a], allowing for comparisons with ACE and Wind observations. We do not attempt to reproduce the arrival time. On average FIDO reproduces the in situ magnetic field for each vector component with an error equivalent to 35% of the average total magnetic field strength when the total modeled magnetic field is scaled to match the average observed value. Random walk best fits distinguish between ForeCAT's ability to determine FIDO's input parameters and the limitations of the simple flux rope model. These best fits reduce the average error to 30%. The FIDO results are sensitive to changes of order a degree in the CME latitude, longitude, and tilt, suggesting that accurate space weather predictions require accurate measurements of a CME's position and orientation.

## Deflection and Rotation of CMEs from Active Region 11158

C. **Kay**, N. Gopalswamy, X. Hong, S. Yashiro

Solar Phys. 292:78 2017

<https://arxiv.org/pdf/1704.07694.pdf>

Between the **13 and 16 of February 2011** a series of coronal mass ejections (CMEs) erupted from multiple polarity inversion lines within active region 11158. For seven of these CMEs we use the Graduated Cylindrical Shell (GCS) flux rope model to determine the CME trajectory using both Solar Terrestrial Relations Observatory (STEREO) extreme ultraviolet (EUV) and coronagraph images. We then use the Forecasting a CME's Altered Trajectory (ForeCAT) model for nonradial CME dynamics driven by magnetic forces, to simulate the deflection and rotation of the seven CMEs. We find good agreement between the ForeCAT results and the reconstructed CME positions and orientations. The CME deflections range in magnitude between 10 degrees and 30 degrees. All CMEs deflect to the north but we find variations in the direction of the longitudinal deflection. The rotations range between 5°/mydeg and 50°/mydeg with both clockwise and counterclockwise rotations occurring. Three of the CMEs begin with initial positions within 2 degrees of one another. These three CMEs all deflect primarily northward, with some minor eastward deflection, and rotate counterclockwise. Their final positions and orientations, however, respectively differ by 20 degrees and 30 degrees. This variation in deflection and rotation results from differences in the CME expansion and radial propagation close to the Sun, as well as the CME mass. Ultimately, only one of these seven CMEs yielded discernible in situ signatures near Earth, despite the active region facing near Earth throughout the eruptions. We suggest that the differences in the deflection and rotation of the CMEs can explain whether each CME impacted or missed the Earth.

## Predicting the Magnetic Field of Earth-impacting CMEs

C. **Kay**<sup>1</sup>, N. Gopalswamy<sup>1</sup>, A. Reinard<sup>2</sup>, and M. Opher<sup>3</sup>

2017 ApJ 835 117 File

<http://sci-hub.cc/doi/10.3847/1538-4357/835/2/117>

Predicting the impact of coronal mass ejections (CMEs) and the southward component of their magnetic field is one of the key goals of space weather forecasting. We present a new model, the ForeCAT In situ Data Observer (FIDO), for predicting the in situ magnetic field of CMEs. We first simulate a CME using ForeCAT, a model for CME deflection and rotation resulting from the background solar magnetic forces. Using the CME position and orientation from ForeCAT, we then determine the passage of the CME over a simulated spacecraft. We model the CME's magnetic field using a force-free flux rope and we determine the in situ magnetic profile at the synthetic spacecraft. We show that FIDO can reproduce the general behavior of four observed CMEs. FIDO results are very sensitive to the CME's position and orientation, and we show that the uncertainty in a CME's position and orientation from coronagraph images corresponds to a wide range of in situ magnitudes and even polarities. This small range of positions and orientations also includes CMEs that entirely miss the satellite. We show that two derived parameters (the normalized angular distance between the CME nose and satellite position and the angular difference between the CME tilt and the position angle of the satellite with respect to the CME nose) can be used to reliably determine whether an impact or miss occurs.

We find that the same criteria separate the impacts and misses for cases representing all four observed CMEs. **2010 April 3, 2011 Feb 15, 2012 Jul 12, 2014 Sep 10**

### **Using ForeCAT Deflections and Rotations to Constrain the Early Evolution of CMEs**

C. Kay, M. Opher, R. C. Colaninno, A. Vourlidas

ApJ 827 70 **2016**

<http://arxiv.org/pdf/1606.03460v1.pdf>

To accurately predict the space weather effects of coronal mass ejection (CME) impacts at Earth one must know if and when a CME will impact Earth, and the CME parameters upon impact. Kay et al. (2015b) presents Forecasting a CME's Altered Trajectory (ForeCAT), a model for CME deflections based on the magnetic forces from the background solar magnetic field. Knowing the deflection and rotation of a CME enables prediction of Earth impacts, and the CME orientation upon impact. We first reconstruct the positions of the **2008 April 10 and the 2012 July 12** CMEs from the observations. The first of these CMEs exhibits significant deflection and rotation (34 degrees deflection and 58 degrees rotation), while the second shows almost no deflection or rotation (<3 degrees each). Using ForeCAT, we explore a range of initial parameters, such as the CME location and size, and find parameters that can successfully reproduce the behavior for each CME. Additionally, since the deflection depends strongly on the behavior of a CME in the low corona (Kay et al. (2015a, 2015b)), we are able to constrain the expansion and propagation of these CMEs in the low corona.

### **The Heliocentric Distance Where the Deflections and Rotations of Solar Coronal Mass Ejections Occur**

C. Kay, M. Opher

ApJL 811 L36 **2015**

<http://arxiv.org/pdf/1509.04948v1.pdf> File

Understanding the trajectory of a coronal mass ejection (CME), including any deflection from a radial path, and the orientation of its magnetic field is essential for space weather predictions. Kay et al. (2015b) developed a model, **Forecasting a CME's Altered Trajectory (ForeCAT)**, of CME deflections and rotation due to magnetic forces, not including the effects of reconnection. ForeCAT is able to reproduce the deflection of observed CMEs (Kay et al. 2015a). The deflecting CMEs tend to show a rapid increase of their angular momentum close to the Sun, followed by little to no increase at farther distances. Here we quantify the distance at which the CME deflection is "determined," which we define as the distance after which the background solar wind has negligible influence on the total deflection. We consider a wide range in CME masses and radial speeds and determine that the deflection and rotation of these CMEs can be well-described by assuming they propagate with constant angular momentum beyond 10 Rs. The assumption of constant angular momentum beyond 10 Rs yields underestimates of the total deflection at 1 AU of only 1% to 5% and underestimates of the rotation of 10%. Since the deflection from magnetic forces is determined by 10 Rs, non-magnetic forces must be responsible for any observed interplanetary deflections or rotations where the CME has increasing angular momentum. **April-May 2005**

### **Global Trends of CME Deflections Based on CME and Solar Parameters**

C. Kay, M. Opher, R. M. Evans

ApJ, 805 168 **2015**

<http://arxiv.org/pdf/1410.4496v1.pdf>

Accurate space weather forecasting requires knowledge of the trajectory of coronal mass ejections (CMEs),

including any deflections close to the Sun or through interplanetary space. Kay et al. 2013 introduced ForeCAT, a model of CME deflection resulting from the background solar magnetic field. For a magnetic field solution corresponding to Carrington Rotation (CR) 2029 (declining phase, **April-May 2005**), the majority of the CMEs deflected to the Heliospheric Current Sheet (HCS), the minimum in magnetic pressure on global scales. Most of the deflection occurred below 4 Rs. Here we extend ForeCAT to include a three dimensional description of the deflecting CME. We attempt to answer the following questions: a) Do all CMEs deflect to the magnetic minimum? and b) Does most deflection occur within the first few solar radii (~4 Rs)? Results for solar minimum and declining phase CMEs show that not every CME deflects to the magnetic minimum and that typically about half of the deflection occurs below 10 Rs. Slow, narrow, low mass CMEs in declining phase solar backgrounds with strong magnetic field and magnetic gradients exhibit the largest deflections. Local gradients related to active regions tend to cause the largest deviations from the deflection predicted by global magnetic gradients, but variations can also be seen for CMEs in the quiet sun regions of the declining phase CR.

## **Constraining the Mass and the Non-Radial Drag Coefficient of a Solar Coronal Mass Ejection**

C. **Kay**, L. F. G. dos Santos, M. Opher

ApJ Letters **801** L21 **2015**

<http://arxiv.org/pdf/1503.00664v1.pdf>

Decades of observations show that CMEs can deflect from a purely radial trajectory yet no consensus exists as to the cause of these deflections. Many of theories attribute the CME deflection to magnetic forces. We developed ForeCAT (Kay et al. 2013, Kay et al. 2015), a model for CME deflections based solely on magnetic forces, neglecting any reconnection effects. Here we compare ForeCAT predictions to the observed deflection of the **2008 December 12** CME and find that ForeCAT can accurately reproduce the observations. Multiple observations show that this CME deflected nearly  $30^\circ$  in latitude (Byrne et al. 2010, Gui et al. 2011) and  $4.4^\circ$  in longitude (Gui et al. 2011). From the observations, we are able to constrain all of the ForeCAT input parameters (initial position, radial propagation speed, and expansion) except the CME mass and the drag coefficient that affects the CME motion. By minimizing the reduced chi-squared,  $\chi^2_{\nu}$ , between the ForeCAT results and the observations we determine an acceptable mass range between  $4.5 \times 10^{14}$  and  $1 \times 10^{15}$  g and the drag coefficient less than 1.4 with a best fit at  $7.5 \times 10^{14}$  g and 0 for the mass and drag coefficient. ForeCAT is sensitive to the magnetic background and we are also able to constrain the rate at which the quiet sun magnetic field falls to be similar or to or fall slightly slower than the Potential Field Source Surface model.

## **FORECASTING A CORONAL MASS EJECTION'S ALTERED TRAJECTORY: ForeCAT**

C. **Kay**<sup>1</sup>, M. Opher<sup>1</sup>, and R. M. Evans

**2013** ApJ **775** 5

To predict whether a coronal mass ejection (CME) will impact Earth, the effects of the background on the CME's trajectory must be taken into account. We develop a model, ForeCAT (Forecasting a CME's Altered Trajectory), of CME deflection due to magnetic forces. ForeCAT includes CME expansion, a three-part propagation model, and the effects of drag on the CME's deflection. Given the background solar wind conditions, the launch site of the CME, and the properties of the CME (mass, final propagation speed, initial radius, and initial magnetic strength), ForeCAT predicts the deflection of the CME. Two different magnetic backgrounds are considered: a scaled background based on type II radio burst profiles and a potential field source surface (PFSS) background. For a scaled background where the CME is launched from an active region located between a coronal hole and streamer region, the strong magnetic gradients cause a deflection of  $81^\circ$  in latitude and  $264^\circ$  in longitude for a  $10^{15}$  g CME propagating out to 1 AU. Using the PFSS background, which captures the variation of the streamer belt (SB) position with height, leads to a deflection of  $16^\circ$  in latitude and  $41^\circ$  in longitude for the control case. Varying the CME's input parameters within observed ranges leads to the majority of CMEs reaching the SB within the first few solar radii. For these specific backgrounds, the SB acts like a potential well that forces the CME into an equilibrium angular position.

## **Multiwavelength observations of a breakout jet at an active region periphery**

**Pradeep Kayshap**, **Judith T. Karpen**, **Pankaj Kumar**

Solar Phys. Volume 299, article number 88 **2024**

<https://arxiv.org/pdf/2405.04766>

<https://doi.org/10.1007/s11207-024-02315-w>

We analysed Interface-Region Imaging Spectrograph (IRIS) and the Solar Dynamics Observatory/Atmospheric Imaging Assembly (SDO/AIA) observations of a small coronal jet that occurred at the solar west limb on **2014 August 29**. The jet source region, a small bright point, was located at an active-region periphery and contains a fan-spine topology with a mini-filament. Our analysis has identified key features and timings that motivate the following interpretation of this event. As the stressed core flux rises, a current sheet forms beneath it; the ensuing reconnection forms a flux rope above a flare arcade. When the rising filament-carrying flux rope reaches the stressed null, it triggers a jet via explosive interchange (breakout) reconnection. During the flux-rope interaction with the external magnetic field, we observed brightening above the filament and within the dome, along with a growing flare arcade. EUV images reveal quasi-

periodic ejections throughout the jet duration with a dominant period of 4 minutes, similar to coronal jetlets and larger jets. We conclude that these observations are consistent with the magnetic breakout model for coronal jets.

## Diagnostic of Homologous Solar Surge Plasma as observed by IRIS and SDO

[Pradeep Kayshap](#), [Rajdeep Singh Payal](#), [Sharad C. Tripathi](#), [Harihara Padhy](#)

MNRAS Volume 505, Issue 4, August 2021, Pages 5311–5326,

<https://doi.org/10.1093/mnras/stab1663>

<https://arxiv.org/pdf/2106.06222.pdf>

Surges have regularly been observed mostly in H $\alpha$  6563-Å and Ca-{\sc ii} 8542-Å. However, surge's response to other prominent lines of the interface-region (Mg-{\sc ii} k 2796.35-Å & h 2803.52-Å, O-{\sc iv} 1401.15-Å, Si-{\sc iv} 1402.77-Å) is not well studied. Here, the evolution and kinematics of six homologous surges are analysed using IRIS and AIA observations. These surges were observed on **7th July 2014**, located very close to the limb. DEM analysis is performed on these surges where the co-existence of cool ( $\log T/K = 6.35$ ) and relatively hot ( $\log T/K = 6.95$ ) components have been found at the base. This demonstrates that the bases of surges undergo substantial heating. During the emission of these surges in the above mentioned interface-region lines, being reported here for the first time, two peaks have been observed in the initial phase of emission, where one peak is found to be constant while other one as varying, i.e., non-constant (observed red to blueshifts across the surge evolution) in nature. This suggests the rotational motion of surge plasma. The heated base and rotating plasma suggests the occurrence of magnetic reconnection, most likely, as the trigger for homologous surges. During the emission of these surges, it is found that despite being optically thick (i.e.,  $R_{kh} < 2.0$ ), central reversal was not observed for Mg-{\sc ii} k & h lines. Further,  $R_{kh}$  increases with surge emission in time and it is found to have positive correlation with Doppler Velocity while negative with Gaussian width.

## Rotating Network Jets in the quiet Sun as Observed by IRIS

[P. Kayshap](#), [K. Murawski](#), [A.K. Srivastava](#), [B.N. Dwivedi](#)

A&A 616, A99 2018

<https://arxiv.org/pdf/1805.02517.pdf>

**Aims.** We perform a detailed observational analysis of network jets to understand their kinematics, rotational motion and underlying triggering mechanism(s). We have analyzed the quiet-Sun (QS) data.

**Methods.** IRIS high resolution imaging and spectral observations (SJI: Si iv 1400.0 \AA, Raster: Si iv 1393.75 \AA) are used to analyze the omnipresent rotating network jets in the transition-region (TR). In addition, we have also used Atmospheric Imaging Assembly (AIA) onboard Solar Dynamic Observation (SDO) observations.

**Results.** The statistical analysis of fifty-one network jets is performed to understand various their mean properties, e.g., apparent speed ( $140.16 \pm 39.41$  km/s), length ( $3.16 \pm 1.18$  Mm), lifetimes ( $105.49 \pm 51.75$  s). The Si iv 1393.75 \AA line has secondary component along with its main Gaussian, which is formed due to the high-speed plasma flows (i.e., network jets). The variation of Doppler velocity across these jets (i.e., blue shift on one edge and red shift on the other) signify the presence of inherited rotational motion. The statistical analysis predicts that the mean rotational velocity (i.e.,  $\Delta V$ ) is 49.56 km/s. The network jets have high angular velocity in comparison to the other class of solar jets.

**Conclusions.** The signature of network jets are inherited in TR spectral lines in terms of the secondary component of the Si iv 1393.75 \AA line. The rotational motion of network jets is omnipresent, which is reported firstly for this class of jet-like features. The magnetic reconnection seems to be the most favorable mechanism for the formation of these network jets. **14.12.2014**

## Origin of Macrospicule and Jet in Polar Corona by A Small-scale Kinked Flux-Tube

[Kayshap, P.](#); [Srivastava, A. K.](#); [Murawski, K.](#); [Tripathi, D.](#)

E-print, May 2013; ApJL 770 L3 2013

We report an observation of a small scale flux-tube that undergoes kinking and triggers the macrospicule and a jet on **November 11, 2010** in the north polar corona. The small-scale flux-tube emerged well before the triggering of macrospicule and as the time progresses the two opposite halves of this omega shaped flux-tube bent transversely and approached towards each other. After  $\sim 2$  minutes, the two approaching halves of the kinked flux-tube touch each-other and internal reconnection as well as energy release takes place at the adjoining location and a macrospicule was launched which goes upto a height of 12 Mm. Plasma starts moving horizontally as well as vertically upward along with the onset of macrospicule and thereafter converts into a large-scale jet which goes up to  $\sim 40$  Mm in the solar atmosphere with a projected speed of  $\sim 95$  km s $^{-1}$ . We perform 2-D numerical simulation by considering the VAL-C initial atmospheric conditions to understand the physical scenario of the observed macrospicule and associated jet. The simulation results show that reconnection generated velocity pulse in the lower solar atmosphere steepens into slow shock and the cool plasma is driven behind it in form of macrospicule. The horizontal surface waves also appeared with the shock fronts at different heights, which most likely drove and spread the large-scale jet associated with the macrospicule.

## THE KINEMATICS AND PLASMA PROPERTIES OF A SOLAR SURGE TRIGGERED BY CHROMOSPHERIC ACTIVITY IN AR11271

P. [Kayshap](#)<sup>1,2</sup>, Abhishek K. Srivastava<sup>1</sup>, and K. Murawski

2013 ApJ 763 24

We observe a solar surge in NOAA AR11271 using the Solar Dynamics Observatory (SDO) Atmospheric Imaging Assembly 304 Å image data on **2011 August 25**. The surge rises vertically from its origin up to a height of 65 Mm with a terminal velocity of 100 km s<sup>-1</sup>, and thereafter falls and fades gradually. The total lifetime of the surge was 20 minutes. We also measure the temperature and density distribution of the observed surge during its maximum rise and find an average temperature and a density of 2.0 MK and 4.1 × 10<sup>9</sup> cm<sup>-3</sup>, respectively. The temperature map shows the expansion and mixing of cool plasma lagging behind the hot coronal plasma along the surge. Because SDO/HMI temporal image data do not show any detectable evidence of significant photospheric magnetic field cancellation for the formation of the observed surge, we infer that it is probably driven by magnetic-reconnection-generated thermal energy in the lower chromosphere. The radiance (and thus the mass density) oscillations near the base of the surge are also evident, which may be the most likely signature of its formation by a reconnection-generated pulse. In support of the present observational baseline of the triggering of the surge due to chromospheric heating, we devise a numerical model with conceivable implementation of the VAL-C atmosphere and a thermal pulse as an initial trigger. We find that the pulse steepens into a slow shock at higher altitudes which triggers plasma perturbations exhibiting the observed features of the surge, e.g., terminal velocity, height, width, lifetime, and heated fine structures near its base.

## Invited **Review**: Short-term Variability with the Observations from the Helioseismic and Magnetic Imager (HMI) Onboard the Solar Dynamics Observatory (SDO): Insights into Flare Magnetism

Continuous vector magnetic-field measurements by the Helioseismic and Magnetic Imager (HMI) onboard the Solar Dynamics Observatory (SDO) allow us to study magnetic-field properties of many flares. Here, we review new observational aspects of flare magnetism described using SDO data, including statistical properties of magnetic-reconnection fluxes and their rates, magnetic fluxes of flare dimmings, and magnetic-field changes during flares. We summarize how these results, along with statistical studies of coronal mass ejections (CMEs), have improved our understanding of flares and the flare/CME feedback relationship. Finally, we highlight future directions to improve the current state of understanding of solar-flare magnetism using observations. **14 Sep 2011, 7 March 2012, Sep 2014**

## Ideal MHD instabilities for coronal mass ejections

**Review**

Rony [Keppens](#), [Yang Guo](#), [Kirit Makwana](#), [Zhixing Mei](#), [Bart Ripperda](#), [Chun Xia](#), [Xiaozhou Zhao](#)

Reviews of Modern Plasma Physics **2019**

<https://arxiv.org/pdf/1910.12659.pdf>

We review and discuss insights on ideal magnetohydrodynamic (MHD) instabilities that can play a role in destabilizing solar coronal flux rope structures. For single flux ropes, failed or actual eruptions may result from internal or external kink evolutions, or from torus unstable configurations. We highlight recent findings from 3D magnetic field reconstructions and simulations where kink and torus instabilities play a prominent role.

For interacting current systems, we critically discuss different routes to coronal dynamics and global eruptions, due to current channel coalescence or to tilt-kink scenarios. These scenarios involve the presence of two nearby current channels and are clearly distinct from the popular kink or torus instability. Since the solar corona is pervaded with myriads of magnetic loops -- creating interacting flux ropes typified by parallel or antiparallel current channels as exemplified in various recent observational studies -- coalescence or tilt-kink evolutions must be very common for destabilizing adjacent flux rope systems. Since they also evolve on ideal MHD timescales, they may well drive many sympathetic eruptions witnessed in the solar corona. Moreover, they necessarily lead to thin current sheets that are liable to reconnection. We review findings from 2D and 3D MHD simulations for tilt and coalescence evolutions, as well as on particle acceleration aspects derived from computed charged particle motions in tilt-kink disruptions and coalescing flux ropes. The latter were recently studied in two-way coupled kinetic-fluid models, where the complete phase-space information of reconnection is incorporated. **2002 May 27**

## A Transient Coronal Sigmoid in Active Region NOAA 11909: Build-up Phase, M-class Eruptive Flare, and Associated Fast Coronal Mass Ejection

[Hema Kharavat](#), [Bhuwan Joshi](#), [Prabir K. Mitra](#), [P. K. Manoharan](#) & [Christian Monstein](#)

[Solar Physics](#) volume 296, Article number: 99 (2021)

<https://link.springer.com/content/pdf/10.1007/s11207-021-01830-4.pdf>

<https://doi.org/10.1007/s11207-021-01830-4>

In this article, we investigate the formation and disruption of a coronal sigmoid from the active region (AR) NOAA 11909 on **07 December 2013**, by analyzing multi-wavelength and multi-instrument observations. Our analysis suggests that the formation of the sigmoid initiated  $\approx 1$  hour before its eruption through a coupling between two twisted coronal loop systems. This sigmoid can be well regarded as of ‘transient’ class due to its short lifetime as the eruptive activities started just after  $\approx 20$  min of its formation. A comparison between coronal and photospheric images suggests that the coronal sigmoid was formed over a simple  $\beta\beta$ -type AR which also possessed dispersed magnetic field structure in the photosphere. The line-of-sight photospheric magnetograms also reveal small-scale flux cancellation events near the polarity inversion line, and overall flux cancellation during the extended pre-eruption phase which suggest the role of tether-cutting reconnection toward the build-up of the flux rope. The disruption of the sigmoid proceeded with a two-ribbon eruptive M1.2 flare (SOL2013-12-07T07:29). In radio frequencies, we observe type III and type II bursts in meter wavelengths during the impulsive phase of the flare. The successful eruption of the flux rope leads to a fast coronal mass ejection (with a linear speed of  $\approx 1085$  km s $^{-1}$ ) in SOHO/LASCO field-of-view. During the evolution of the flare, we clearly observe typical “sigmoid-to-arcade” transformation. Prior to the onset of the impulsive phase of the flare, flux rope undergoes a slow rise ( $\approx 15$  km s $^{-1}$ ) which subsequently transitions into a fast eruption ( $\approx 110$  km s $^{-1}$ ). The two-phase evolution of the flux rope shows temporal associations with the soft X-ray precursor and impulsive phase emissions of the M-class flare, respectively, thus pointing toward a feedback relationship between magnetic reconnection and early CME dynamics.

### **Association of solar flares with coronal mass ejections accompanied by Deca-Hectometric type II radio burst for two solar cycles 23 and 24**

Hema [Kharayat](#), Lalan Prasad & Sumit Pant

[Astrophysics and Space Science](#) May 2018, 363:87

<http://sci-hub.tw/10.1007/s10509-018-3309-y>

The aim of present study is to find the association of solar flares with coronal mass ejections (CMEs) accompanied by Deca-Hectometric (DH) type II radio burst for the period 1997–2014 (solar cycle 23 and ascending phase of solar cycle 24). We have used a statistical analysis and found that 10–20° latitudinal belt of northern region and 80–90° longitudinal belts of western region of the sun are more effective for flare-CME accompanied by DH type II radio burst events. M-class flares (52%) are in good association with the CMEs accompanied by DH type II radio burst. Further, we have calculated the flare position and found that most frequent flare site is at the center of the CME span. However, the occurrence probability of all flares is maximum outside the CME span. X-class flare associated CMEs have maximum speed than that of M, C, and B-class flare associated CMEs. We have also found a good correlation between flare position and central position angle of CMEs accompanied by DH type II radio burst.

### **Deciphering the Evolution of Thermodynamic Properties and their Connection to the Global Kinematics of High-Speed Coronal Mass Ejections Using FRIS Model**

<https://watermark.silverchair.com/stae2523.pdf>

Most earlier studies have been limited to estimating the kinematic evolution of coronal mass ejections (CMEs), and only limited efforts have been made to investigate their thermodynamic evolution. We focus on the interplay of the thermal properties of CMEs with their observed global kinematics. We implement the Flux rope Internal State (FRIS) model to estimate variations in the polytropic index, heating rate per unit mass, temperature, pressure, and various internal forces. The model incorporates inputs of 3D kinematics obtained from the Graduated Cylindrical Shell (GCS) model. In our study, we chose nine fast-speed CMEs from 2010 to 2012. Our investigation elucidates that the selected fast-speed CMEs show a heat-release phase at the beginning, followed by a heat-absorption phase with a near-isothermal state in their later propagation phase. The thermal state transition, from heat release to heat absorption, occurs at around  $3(\pm 0.3)$  to  $7(\pm 0.7)$   $R_{\odot}$  for different CMEs. We found that the CMEs with higher expansion speeds experience a less pronounced sharp temperature decrease before gaining a near-isothermal state. The differential emission measurement (DEM) analysis findings, using multi-wavelength observation from SDO/AIA, also show a heat release state of CMEs at lower coronal heights. We also find the dominant internal forces influencing CME radial expansion at varying distances from the Sun. Our study shows the need to characterize the internal thermodynamic properties of CMEs better in both observational and modeling studies, offering insights for refining assumptions of a constant value of the polytropic index during the evolution of CMEs. **2010 Apr 03, 2011 Feb 15, 2011 Aug 04, 2011 Sep 24, 2011 Nov 26, 2012 Mar 07, 2012 Jun 14, 2012 Jul 12, 2012 Sep 28**

ApJ 958 92 2023

<https://arxiv.org/pdf/2310.06750.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ad00ba/pdf>

Coronal Mass Ejections (CMEs) are the most energetic expulsions of magnetized plasma from the Sun that play a crucial role in space weather dynamics. This study investigates the diverse kinematics and thermodynamic evolution of two CMEs (CME1: **2011 September 24** and CME2: **2018 August 20**) at coronal heights where thermodynamic measurements are limited. The peak 3D propagation speed of CME1 is high (1,885 km/s) with two-phase expansion (rapid and nearly constant), while the peak 3D propagation speed of CME2 is slow (420 km/s) with only a gradual expansion. We estimate the distance-dependent variations in the polytropic index, heating rate, temperature, and internal forces implementing the revised FRIS model, taking inputs of 3D kinematics estimated from the GCS model. We find CME1 exhibiting heat-release during its early-rapid acceleration decrease and jumps to the heat-absorption state during its constant acceleration phase. In contrast to CME1, CME2 shows a gradual transition from the near-adiabatic to the heat-absorption state during its gradually increasing acceleration. Our analysis reveals that although both CMEs show differential heating, they experience heat-absorption during their later propagation phases, approaching the isothermal state. The faster CME1 achieves an adiabatic state followed by an isothermal state at smaller distances from the Sun than the slower CME2. We also find that the expansion of CMEs is primarily influenced by centrifugal and thermal pressure forces, with the Lorentz force impeding expansion. Multi-wavelength observations of flux-ropes at source regions support the FRIS model-derived findings at initially observed lower coronal heights.

## Statistical Analysis of the Relation between Coronal Mass Ejections and Solar Energetic Particles

[Kosuke Kihara](#), [Yuwei Huang](#), [Nobuhiko Nishimura](#), [Nariaki V. Nitta](#), [Seiji Yashiro](#), [Kiyoshi Ichimoto](#), [Ayumi Asai](#)

ApJ 2020

<https://arxiv.org/pdf/2007.08062.pdf> File

To improve the forecasting capability of impactful solar energetic particle (SEP) events, the relation between coronal mass ejections (CMEs) and SEP events needs to be better understood. Here we present a statistical study of SEP occurrences and timescales with respect to the CME source locations and speeds, considering all 257 fast ( $v_{\text{CME}} \geq 900$  km/s) and wide (angular width  $\geq 60^\circ$ ) CMEs that occurred between December 2006 and October 2017. We associate them with SEP events at energies above 10 MeV. Examination of the source region of each CME reveals that CMEs more often accompany a SEP event if they originate from the longitude of E20-W100 relative to the observer. However, a SEP event could still be absent if the CME is  $< 2000$  km/s. For the associated CME-SEP pairs, we compute three timescales for each of the SEP events, following Kahler (2005, 2013); namely the timescale of the onset (TO), the rise time (TR), and the duration (TD). They are correlated with the longitude of the CME source region relative to the footpoint of the Parker spiral ( $\Delta\Phi$ ) and  $v_{\text{CME}}$ . The TO tends to be short for  $|\Delta\Phi| < 60^\circ$ . This trend is weaker for TR and TD. The SEP timescales are only weakly correlated with  $v_{\text{CME}}$ . Positive correlations of both TR and TD with  $v_{\text{CME}}$  are seen in poorly connected (large  $|\Delta\Phi|$ ) events. Additionally, TO appears to be negatively correlated with  $v_{\text{CME}}$  for events with small  $|\Delta\Phi|$ . **3 Sep 2013**

## Temporal and Periodic Variation of the MCMESI for the Last Two Solar Cycles; Comparison with the Number of Different Class X-Ray Solar Flares

A. [Kilcik](#), [P. Chowdhury](#), [V. Sarp](#), [V. Yurchyshyn](#), [B. Donmez](#), [J.P. Rozelot](#), [A. Ozguc](#)

Solar Phys. 2020

<https://arxiv.org/ftp/arxiv/papers/2008/2008.11506.pdf>

In this study we compared the temporal and periodic variations of the Maximum CME Speed Index (MCMESI) and the number of different class (C, M, and X) solar X-Ray flares for the last two solar cycles (Cycle 23 and 24). To obtain the correlation between the MCMESI and solar flare numbers the cross correlation analysis was applied to monthly data sets. Also to investigate the periodic behavior of all data sets the Multi Taper Method (MTM) and the Morlet wavelet analysis method were performed with daily data from 2009 to 2018. To evaluate our wavelet analysis Cross Wavelet Transform (XWT) and Wavelet Transform Coherence (WTC) methods were performed. Causal relationships between datasets were further examined by Convergence Cross Mapping (CCM) method. In results of our analysis we found followings; 1) The C class X-Ray flare numbers increased about 16 % during the solar cycle 24 compared to cycle 23, while all other data sets decreased; the MCMESI decreased about 16 % and the number of M and X class flares decreased about 32 %. 2) All the X-Ray solar flare classes show remarkable positive correlation with the MCMESI. While the correlation between the MCMESI and C class flares comes from the general solar cycle trend, it mainly results from the fluctuations in the data in case of the X class flares. 3) In general, all class flare numbers and the MCMESI show similar periodic behavior. 4) The 546 days periodicity detected in the MCMESI may not be of solar origin or at least the solar flares are not the source of this periodicity. 5) C and M Class solar flares have a stronger causative effect on the MCMESI compared to X class solar flares. However the only bidirectional causal relationship is obtained between the MCMESI and C class flare numbers.

## Maximum CME speed as an indicator of solar and geomagnetic activities

A. [Kilcik](#)1, V.B. Yurchyshyn1, V. Abramenko1, P.R. Goode1, N. Gopalswamy2, A. Ozguc3, J.P. Rozelot4  
BBSO Preprint #1456, 2010; Ap. J. 727:44 (6pp), 2011 January, File

We investigate the relationship between the monthly averaged maximal speeds of coronal mass ejections (CMEs), international sunspot number (ISSN) and the geomagnetic Dst and Ap indices covering the 1996-2008 time interval (solar cycle 23). Our new findings are as follows. i) There is a noteworthy relationship between monthly averaged maximum CME speeds and sunspot numbers, Ap and Dst indices. Various peculiarities in the monthly Dst index are better correlated with the fine structures in the CME speed profile than that in the ISSN data. ii) Unlike the sunspot numbers, the CME speed index does not exhibit a double peak maximum. Instead, the CME speed profile peaks during the declining phase of solar cycle 23. Similar to the Ap index, both CME speed and the Dst indices lag behind the sunspot numbers by several months. iii) CME number shows a double peak similar to that seen in the sunspot numbers. The CME occurrence rate remained very high even near the minimum of the solar cycle 23, when both sunspot number and the CME average maximum speed were reaching their minimum values. iv) A well defined peak of the Ap index between May 2002 and August 2004 was co-temporal with the excess of the mid-latitude coronal holes during solar cycle 23. The above findings suggest that the CME speed index may be a useful indicator of both solar and geomagnetic activity. It may have advantages over the sunspot numbers, because it better reflects the intensity of Earth directed solar eruptions.

## **A Statistical Study of the Relationship Between the Sunspot Number, Maximum CME Speed and Geomagnetic Indices**

A [Kilcik](#), V.B. Yurchyshyn, V. Abramenko, P.R. Goode, N. Gopalswamy, A. Ozguc and J.P. Rozelot  
BBSO Preprint #1424, 2010; **File**

We investigated the relationship between the monthly averaged maximal speeds of coronal mass ejections (CMEs), sunspot number (SSN) and the geomagnetic Dst and Ap indices covering the 1996-2008 time interval. The study was carried out using frequency and correlation analyses. Frequency analysis of the maximum speed of CMEs (or CME speed index) shows a cyclic behavior similar to that found for SSN and the Ap index. Our new findings are as follows. 1) Unlike the SSN, the CME speed index does not exhibit a double peak maximum. 2) The CME speed index has a correlative relationship with SSN and Dst and Ap indices (correlation coefficients are 0.76, -0.53, 0.68 respectively). Various peculiarities in the monthly Dst index are better correlated with the fine structures in the CME speed profile than that in the SSN data. 3) Similar to the Ap index, both CME speed and the Dst indices lag behind the sunspot numbers by several months. We thus conclude that CME speed index may be a good parameter to describe the geoeffectiveness of solar activity.

## **Estimating the Magnetic Structure of an Erupting CME Flux Rope From AR12158 Using Data-Driven Modeling**

[Emilia K. J. Kilpua](#)<sup>\*</sup>, Jens Pomoell, [Daniel Price](#), [Ranadeep Sarkar](#) and [Eleanna Asvestari](#)

Front. Astron. Space Sci., 8:631582. March 2021 |

<https://www.frontiersin.org/articles/10.3389/fspas.2021.631582/full>

<https://doi.org/10.3389/fspas.2021.631582>

We investigate here the magnetic properties of a large-scale magnetic flux rope related to a coronal mass ejection (CME) that erupted from the Sun on **September 12, 2014** and produced a well-defined flux rope in interplanetary space on **September 14–15, 2014**. We apply a fully data-driven and time-dependent magnetofrictional method (TMFM) using Solar Dynamics Observatory (SDO) magnetograms as the lower boundary condition. The simulation self-consistently produces a coherent flux rope and its ejection from the simulation domain. This paper describes the identification of the flux rope from the simulation data and defining its key parameters (e.g., twist and magnetic flux). We define the axial magnetic flux of the flux rope and the magnetic field time series from at the apex and at different distances from the apex of the flux rope. Our analysis shows that TMFM yields axial magnetic flux values that are in agreement with several observational proxies. The extracted magnetic field time series do not match well with in-situ components in direct comparison presumably due to interplanetary evolution and northward propagation of the CME. The study emphasizes also that magnetic field time-series are strongly dependent on how the flux rope is intercepted which presents a challenge for space weather forecasting.

## **Forecasting the Structure and Orientation of Earthbound Coronal Mass Ejections**

E. K. J. [Kilpua](#) [N. Lugaz](#) [L. Mays](#) [M. Temmer](#)

Space Weather 17 **Issue 4** Pages 498-526 2019

Space Weather Quarterly 16, issue 1, 6 -30 2019

[sci-hub.tw/10.1029/2018SW001944](http://sci-hub.tw/10.1029/2018SW001944)

Coronal Mass Ejections (CMEs) are the key drivers of strong to extreme space weather storms at the Earth that can have drastic consequences for technological systems in space and on ground. The ability of a CME to drive geomagnetic disturbances depends crucially on the magnetic structure of the embedded flux rope, which is thus essential to predict. The current capabilities in forecasting in advance (at least half-a-day before) the geoeffectiveness of a given CME is however severely hampered by the lack of remote-sensing measurements of the magnetic field in the corona and adequate tools to predict how CMEs deform, rotate and deflect during their travel through the coronal and interplanetary space as they interact with the ambient solar wind and other CMEs. These problems can lead not only to over- or underestimation of the severity of a storm, but also to forecasting “misses” and “false alarms” that are particularly difficult for the end-users. In this paper, we discuss the current status and future challenges and prospects related to forecasting of the magnetic structure and orientation of CMEs. We focus both on observational and modeling

(first-principle and semi-empirical) based approaches, and discuss the space- and ground-based observations that would be the most optimal for making accurate space weather predictions. We also cover the gaps in our current understanding related to the formation and eruption of the CME flux rope and physical processes that govern its evolution in the variable ambient solar wind background that complicate the forecasting.

## **Solar Sources of Interplanetary Coronal Mass Ejections During the Solar Cycle 23/24 Minimum**

E. K. J. [Kilpua](#), M. Mierla, A. N. Zhukov, L. Rodriguez, A. Vourlidas, B. Wood  
Solar Phys., 2014

We examine solar sources for 20 interplanetary coronal mass ejections (ICMEs) observed in 2009 in the near-Earth solar wind. We performed a detailed analysis of coronagraph and extreme ultraviolet (EUV) observations from the Solar Terrestrial Relations Observatory (STEREO) and Solar and Heliospheric Observatory (SOHO). Our study shows that the coronagraph observations from viewpoints away from the Sun–Earth line are paramount to locate the solar sources of Earth-bound ICMEs during solar minimum. SOHO/LASCO detected only six CMEs in our sample, and only one of these CMEs was wider than  $120^\circ$ . This demonstrates that observing a full or partial halo CME is not necessary to observe the ICME arrival. Although the two STEREO spacecraft had the best possible configuration for observing Earth-bound CMEs in 2009, we failed to find the associated CME for four ICMEs, and identifying the correct CME was not straightforward even for some clear ICMEs. Ten out of 16 (63 %) of the associated CMEs in our study were “stealth” CMEs, i.e. no obvious EUV on-disk activity was associated with them. Most of our stealth CMEs also lacked on-limb EUV signatures. We found that stealth CMEs generally lack the leading bright front in coronagraph images. This is in accordance with previous studies that argued that stealth CMEs form more slowly and at higher coronal altitudes than non-stealth CMEs. We suggest that at solar minimum the slow-rising CMEs do not draw enough coronal plasma around them. These CMEs are hence difficult to discern in the coronagraphic data, even when viewed close to the plane of the sky. The weak ICMEs in our study were related to both intrinsically narrow CMEs and the non-central encounters of larger CMEs. We also demonstrate that narrow CMEs (angular widths  $\leq 20^\circ$ ) can arrive at Earth and that an unstructured CME may result in a flux rope-type ICME.

## **STEREO observations of interplanetary coronal mass ejections and prominence deflection during solar minimum period**

E. K. J. [Kilpua](#)<sup>1</sup>, J. Pomoell<sup>1</sup>, A. Vourlidas<sup>3</sup>, R. Vainio<sup>1</sup>, J. Luhmann<sup>2</sup>, Y. Li<sup>2</sup>, P. Schroeder<sup>2</sup>, A. B. Galvin<sup>4</sup>, and K. Simunac

Ann. Geophys., 27, 4491–4503, 2009, [File](#)

[www.ann-geophys.net/27/4491/2009/](http://www.ann-geophys.net/27/4491/2009/)

In this paper we study the occurrence rate and solar origin of interplanetary coronal mass ejections (ICMEs) using data from the two Solar TERrestrial Relation Observatory (STEREO) and the Wind spacecraft. We perform a statistical survey of ICMEs during the late declining phase of solar cycle 23. Observations by multiple, well-separated spacecraft show that even at the time of extremely weak solar activity a considerable number of ICMEs were present in the interplanetary medium. Soon after the beginning of the STEREO science mission in January 2007 the number of ICMEs declined to less than one ICME per month, but in late 2008 the ICME rate clearly increased at each spacecraft although no apparent increase in the number of coronal mass ejections (CMEs) occurred. We suggest that the near-ecliptic ICME rate can increase due to CMEs that have been guided towards the equator from their high-latitude source regions by the magnetic fields in the polar coronal holes.

We consider two case studies to highlight the effects of the polar magnetic fields and CME deflection taking advantage of STEREO observations when the two spacecraft were in the quadrature configuration (i.e. separated by about 90 degrees). We study in detail the solar and interplanetary consequences of two CMEs that both originated from high-latitude source regions on **2 November 2008**. The first CME was slow (radial speed 298 km/s) and associated with a huge polar crown prominence eruption. The CME was guided by polar coronal hole fields to the equator and it produced a clear flux rope ICME in the near-ecliptic solar wind. The second CME (radial speed 438 km/s) originated from an active region 11007 at latitude  $35^\circ$  N. This CME propagated clearly north of the first CME and no interplanetary consequences were identified. The two case studies suggest that slow and elongated CMEs have difficulties overcoming the straining effect of the overlying field and as a consequence they are guided by the polar coronal fields and cause in-situ effects close to the ecliptic plane. The 3-D propagation directions and CME widths obtained by using the forward modelling technique were consistent with the solar and in-situ observations.

**Table 1.** ICMEs identified from the solar wind measurements by STA (A), STB (B) and Wind (W).

## **Triggering Mechanism for Eruption of Two Filaments Observed by the Solar Dynamics Observatory, Nobeyama Radioheliograph, and RHESSI**

Sujin [Kim](#)<sup>1</sup> and Vasyi Yurchyshyn<sup>2</sup>

2022 ApJL 932 L18

<https://iopscience.iop.org/article/10.3847/2041-8213/ac7236/pdf>

We investigate the eruptive process of two filaments, which is associated with an M-class flare that occurred in **2011 August 4**. The filaments are partly overlapped, one in the active region and the other just beside it, and erupt together as

a halo coronal mass ejection. For this study, we used the Atmospheric Imaging Assembly and the Heliospheric Magnetic Imager on board the Solar Dynamics Observatory, the Nobeyama Radioheliograph 17 GHz, and the RHESSI Hard X-ray satellite. We found three distinct phases in the microwave flux profile and in the rising pattern of the filaments during the event. In the first phase, there was weak nonthermal emission at 17 GHz and hard X-rays. Those nonthermal sources appeared on one edge of the western filament (F2) in the active region. The F2 began to be bright and rose upward rapidly, while the eastern filament (F1), which was extended to the quiet region, started to brighten from the peak time of the 17 GHz flux. In the second phase, the nonthermal emission weakened and the F2 rose up slowly, while the F1 began to rise up. In the third phase, two filaments erupted together. Since the F1 was stable for a long time in the quiet region, breaking the equilibrium state of the F1 would be decisive for the successful eruption of two filaments and it seems clear that the evolution of the F2 provoked the unstable F1. We suggest that tether-cutting reconnection between two overlapped filaments triggers the eruption of the two filaments as a tangled identity.

## **Relation of CME Speed and Magnetic Helicity in CME Source Regions on the Sun during the Early Phase of Solar Cycles 23 and 24**

R.-S. **Kim** S.-H. Park S. Jang K.-S. Cho B. S. Lee

Sol Phys (2017) 292: 66. doi:10.1007/s11207-017-1079-2

To investigate the relations between coronal mass ejection (CME) speed and magnetic field properties measured in the photospheric surface of CME source regions, we selected 22 disk CMEs in the rising and early maximum phases of the current Solar Cycle 24. For the CME speed, we used two-dimensional (2D) projected speed observed by the Large Angle and Spectroscopic Coronagraph onboard the Solar and Heliospheric Observatory (SOHO/LASCO), as well as a 3D speed calculated from the triangulation method using multi-point observations. Two magnetic parameters of CME source regions were considered: the average of magnetic helicity injection rate and the total unsigned magnetic flux. We then classified the selected CMEs into two groups, showing: i) a monotonically increasing pattern with one sign of helicity (group A: 16 CMEs) and ii) a pattern of significant helicity injection followed by its sign reversal (group B: 6 CMEs). We found that: 1) 3D speed generally shows better correlations with the magnetic parameters than the 2D speed for 22 CME events in Solar Cycle 24; 2) 2D speed and the magnetic parameters of 22 CME events in this solar cycle have lower values than those of 47 CME events in Solar Cycle 23; 3) all events of group B in Solar Cycle 24 occur only after the beginning of the maximum phase, a trend well consistent with that shown in Solar Cycle 23; 4) the 2D speed and the helicity parameter of group B events continue to increase in the declining phase of Solar Cycle 23, while those of group A events abruptly decrease in the same period. Our results indicate that the two CME groups have a different tendency in the solar cycle variations of CME speed and the helicity parameters. Active regions that show a complex helicity evolution pattern tend to appear in the maximum and declining phases, while active regions with a relatively simple helicity evolution pattern appear throughout the whole solar cycle.

## **Vertical Kink Oscillation of a Magnetic Flux Rope Structure in the Solar Corona**

S. **Kim**<sup>1</sup>, V. M. Nakariakov<sup>2,3,4</sup>, and K.-S. Cho

2014 *ApJ* 797 L22

Vertical transverse oscillations of a coronal magnetic rope, observed simultaneously in the 171 Å and 304 Å bandpasses of the Atmospheric Imaging Assembly on board the *Solar Dynamics Observatory* (SDO), are detected. The oscillation period is about 700 s and the displacement amplitude is about 1 Mm. The oscillation amplitude remains constant during the observation. Simultaneous observation of the rope in the bandpasses corresponding to the coronal and chromospheric temperatures suggests that it has a multi-thermal structure. Oscillatory patterns in 171 Å and 304 Å are coherent, which indicates that the observed kink oscillation is collective, in which the rope moves as a single entity. We interpret the oscillation as a fundamental standing vertically polarized kink mode of the rope, while the interpretation in terms of a perpendicular fast wave could not be entirely ruled out. In addition, the arcade situated above the rope and seen in the 171 Å bandpass shows an oscillatory motion with the period of about 1000 s.

## **Propagation Characteristics of CMEs Associated with Magnetic Clouds and Ejecta**

R.-S. **Kim**, N. Gopalswamy, K.-S. Cho, Y.-J. Moon, S. Yashiro

Solar Phys., Volume 284, Issue 1, pp 77-88, 2013, **File online first**

We have investigated the characteristics of magnetic cloud (MC) and ejecta (EJ) associated coronal mass ejections (CMEs) based on the assumption that all CMEs have a flux rope structure. For this, we used 54 CMEs and their interplanetary counterparts (interplanetary CMEs: ICMEs) that constitute the list of events used by the NASA/LWS Coordinated Data Analysis Workshop (CDAW) on CME flux ropes. We considered the location, angular width, and speed as well as the direction parameter, *D*. The direction parameter quantifies the degree of asymmetry of the CME shape in coronagraph images, and shows how closely the CME propagation is directed to Earth. For the 54 CDAW events, we found the following properties of the CMEs: i) the average value of *D* for the 23 MCs (0.62) is larger than that for the 31 EJs (0.49), which indicates that the MC-associated CMEs propagate more directly toward the Earth than the EJ-associated CMEs; ii) comparison between the direction parameter and the source location shows that the majority of the MC-associated CMEs are ejected along the radial direction, while many of the EJ-associated CMEs are ejected non-radially; iii) the mean speed of MC-associated CMEs (946 km s<sup>-1</sup>) is faster than that of EJ-associated CMEs (771 km s<sup>-1</sup>). For seven very fast CMEs (≥ 1500 km s<sup>-1</sup>), all CMEs with large *D* (≥ 0.4) are associated with MCs and the CMEs with small *D* are associated with EJs. From the statistical analysis of CME parameters, we found

the superiority of the direction parameter. Based on these results, we suggest that the CME trajectory essentially determines the observed ICME structure.

**Table List of shock-driving ICMEs during Solar Cycle 23 ( $E15^\circ \leq l \leq W15^\circ$ ).**

## **MAGNETIC FIELD STRENGTH IN THE UPPER SOLAR CORONA USING WHITE-LIGHT SHOCK STRUCTURES SURROUNDING CORONAL MASS EJECTIONS**

R.-S. **Kim**<sup>1,3</sup>, N. Gopalswamy<sup>1,3</sup>, Y.-J. Moon<sup>2</sup>, K.-S. Cho<sup>1,3,4</sup> and S. Yashiro

2012 ApJ 746 118, **File**

To measure the magnetic field strength in the solar corona, we examined 10 fast ( $\geq 1000$  km s<sup>-1</sup>) limb coronal mass ejections (CMEs) that show clear shock structures in Solar and Heliospheric Observatory/Large Angle and Spectrometric Coronagraph images. By applying the piston-shock relationship to the observed CME's standoff distance and electron density compression ratio, we estimated the Mach number, Alfvén speed, and magnetic field strength in the height range 3-15 solar radii ( $R_s$ ). The main results from this study are as follows: (1) the standoff distance observed in the solar corona is consistent with those from a magnetohydrodynamic model and near-Earth observations; (2) the Mach number as a shock strength is in the range 1.49-3.43 from the standoff distance ratio, but when we use the density compression ratio, the Mach number is in the range 1.47-1.90, implying that the measured density compression ratio is likely to be underestimated owing to observational limits; (3) the Alfvén speed ranges from 259 to 982 km s<sup>-1</sup> and the magnetic field strength is in the range 6-105 mG when the standoff distance is used; (4) if we multiply the density compression ratio by a factor of two, the Alfvén speeds and the magnetic field strengths are consistent in both methods; and (5) the magnetic field strengths derived from the shock parameters are similar to those of empirical models and previous estimates

## **A STUDY OF FLARE-ASSOCIATED X-RAY PLASMA EJECTIONS.**

### **I. ASSOCIATION WITH CORONAL MASS EJECTIONS**

ApJ 622 :1240–1250, 2005 **File**

We have made a comprehensive statistical study of the relationship between flare-associated X-ray plasma ejections and coronal mass ejections (CMEs). For this we considered all flare-mode data in Yohkoh SXT observations from 1999 April to 2001 March and then selected 279 limb flares seen at longitudes greater than 60°. For these events, we identified whether there were associated X-ray plasma ejections or not. We found that about half (137=279) of the flares have X-ray plasma ejections, and we present a comprehensive list of these with their event times and speeds. We then determined whether there was an association between the flares with plasma ejections and CMEs detected by the Solar and Heliospheric Observatory LASCO instrument, on the basis of temporal and spatial proximity. It is found that about 69% (95=137) of the X-ray plasma ejections are associated with CMEs and that about 84% (119=142) of the events without plasma ejections do not have related CMEs. The associations are found to increase with flare strength and duration. We find that X-ray plasma ejections occur nearly simultaneously with the hard X-ray flare peak, supporting the idea that the X-ray plasma ejections are tightly associated with the flaring process. When the CMEs are extrapolated into the Yohkoh field of view for 43 selected, well-observed events, it is found that about 80% of the CMEs preceded X-ray plasma ejections, by approximately 20 minutes on average. Our results show that X-ray plasma ejections usually do not represent the early signature of a CME's leading edge but are closely associated with CMEs. **1999 May 7, 1999 July 25, 2000 October 26, 2001 March 21**

## **Relationships Between Sequential Chromospheric Brightening and the Corona **Review****

Michael S. **Kirk**, K. S. Balasubramaniam, Jason Jackiewicz, Holly R. Gilbert

Proceedings IAU Symposium No. xxx, 2017

<https://arxiv.org/pdf/1704.03835.pdf>

The chromosphere is a complex region that acts as an intermediary between the magnetic flux emergence in the photosphere and the magnetic features seen in the corona. Large eruptions in the chromosphere of flares and filaments are often accompanied by ejections of coronal mass off the sun. Several studies have observed fast-moving progressive trains of compact bright points (called Sequential Chromospheric Brightenings or SCBs) streaming away from chromospheric flares that also produce a coronal mass ejection (CME). In this work, we review studies of SCBs and search for commonalities between them. We place these findings into a larger context with contemporary chromospheric and coronal observations. SCBs are fleeting indicators of the solar atmospheric environment as it existed before their associated eruption. Since they appear at the very outset of a flare eruption, SCBs are good early indication of a CME measured in the chromosphere. **2010-11-06,**

**Table 1. A summary of the events used to investigate the evolution of SCBs.**

## **The Origin of Sequential Chromospheric Brightenings**

Michael S. **Kirk**, K.S. Balasubramaniam, Jason Jackiewicz, Holly R. Gilbert

Solar Phys. 2017

<https://arxiv.org/pdf/1704.03828.pdf>

Sequential chromospheric brightenings (SCBs) are often observed in the immediate vicinity of erupting flares and are associated with coronal mass ejections. Since their initial discovery in 2005, there have been several subsequent investigations of SCBs. These studies have used differing detection and analysis techniques, making it difficult to compare results between studies. This work employs the automated detection algorithm of Kirk et al. (Solar Phys. 283, 97, 2013) to extract the physical characteristics of SCBs in 11 flares of varying size and intensity. We demonstrate that the magnetic substructure within the SCB appears to have a significantly smaller area than the corresponding H-alpha emission. We conclude that SCBs originate in the lower corona around 0.1 R\_sun above the photosphere, propagate away from the flare center at speeds of 35 - 85 km/s, and have peak photosphere magnetic intensities of 148 +/- 2.9 G. In light of these measurements, we infer SCBs to be distinctive chromospheric signatures of erupting coronal mass ejections. 19 December 2002, 6 November 2010

## Combining STEREO SECCHI COR2 and HI1 images for automatic CME front edge tracking

Vladimir [Kirnosov](#)<sup>1\*</sup>, Lin-Ching Chang<sup>1</sup> and Antti Pulkkinen

J. Space Weather Space Clim., 6, A41 (2016)

<http://www.swsc-journal.org/articles/swsc/pdf/2016/01/swsc150079.pdf>

COR2 coronagraph images are the most commonly used data for coronal mass ejection (CME) analysis among the various types of data provided by the STEREO (Solar Terrestrial Relations Observatory) SECCHI (Sun-Earth Connection Coronal and Heliospheric Investigation) suite of instruments. The field of view (FOV) in COR2 images covers 2–15 solar radii (Rs) that allow for tracking the front edge of a CME in its initial stage to forecast the lead-time of a CME and its chances of reaching the Earth. However, estimating the lead-time of a CME using COR2 images gives a larger lead-time, which may be associated with greater uncertainty. To reduce this uncertainty, CME front edge tracking should be continued beyond the FOV of COR2 images. Therefore, heliospheric imager (HI1) data that covers 15–90 Rs FOV must be included. In this paper, we propose a novel automatic method that takes both COR2 and HI1 images into account and combine the results to track the front edges of a CME continuously. The method consists of two modules: pre-processing and tracking. The pre-processing module produces a set of segmented images, which contain the signature of a CME, for both COR2 and HI1 separately. In addition, the HI1 images are resized and padded, so that the center of the Sun is the central coordinate of the resized HI1 images. The resulting COR2 and HI1 image set is then fed into the tracking module to estimate the position angle (PA) and track the front edge of a CME. The detected front edge is then used to produce a height-time profile that is used to estimate the speed of a CME. The method was validated using 15 CME events observed in the period from January 1, 2008 to August 31, 2009. The results demonstrate that the proposed method is effective for CME front edge tracking in both COR2 and HI1 images. Using this method, the CME front edge can now be tracked automatically and continuously in a much larger range, i.e., from 2 to 90 Rs, for the first time. These improvements can greatly help in making the quantitative CME analysis more accurate and have the potential to assist in space weather forecasting. **2008.04.26-27**

Space Weather Volume 13, Issue 8 August 2015 Pages 469–483

The coronagraph images captured by a Solar Terrestrial Relations Observatory (STEREO) Ahead/Behind (A/B) spacecraft allow tracking of a coronal mass ejection (CME) from two different viewpoints and reconstructing its propagation in three-dimensional space. The reconstruction can be done using a triangulation technique that requires a CME front edge location. There are currently no robust automatic CME front edge detection methods that can be integrated with the triangulation technique. In this paper, we propose a novel automatic method to detect the front edge of the CME using STEREO coronagraph 2 red-colored Red, Green, Blue color model images. Our method consists of two modules: preprocessing and classification. The preprocessing module decomposes each coronagraph image into its three channels and uses only the red channel image for CME segmentation. The output of the preprocessing module is a set of segmented running-difference binary images which is fed into the classification module. These images are then transformed into polar coordinates followed by CME front edge detection based on the distance that CME travels in the field of view. The proposed method was validated against a manual method using total 56 CME events, 28 from STEREO A and 28 from STEREO B, captured in the period from 1 January 2008 to 16 August 2009. The results show that the proposed method is effective for CME front edge detection. The proposed method is useful in quantitative CME processing and analysis and will be immediately applicable to assist automatic triangulation method for real-time space weather forecasting.

## Spectro-Polarimetric Properties of Small-Scale Plasma Eruptions Driven by Magnetic Vortex Tubes

Irina N. [Kitiashvili](#)

PASJ, 2014

<http://arxiv.org/pdf/1407.2295v1.pdf>

Highly turbulent nature of convection on the Sun causes strong multi-scale interaction of subsurface layers with the photosphere and chromosphere. According to realistic 3D radiative MHD numerical simulations ubiquitous small-scale vortex tubes are generated by turbulent flows below the visible surface and concentrated in the intergranular lanes. The vortex tubes can capture and amplify magnetic field, penetrate into chromospheric layers and initiate quasi-periodic flow eruptions that generates Alfvénic waves, transport mass and energy into the solar atmosphere. The simulations revealed high-speed flow patterns, and complicated thermodynamic and magnetic structures in the erupting vortex tubes. The spontaneous eruptions are initiated and driven by strong pressure gradients in the near-surface layers, and accelerated by the Lorentz force in the low chromosphere. In this paper, the simulation data are used to further investigate the dynamics of the eruptions, their spectro-polarimetric characteristics for the Fe I 6301.5 and 6302.5 Å spectral lines, and demonstrate expected signatures of the eruptions in the Hinode SP data. We found that the complex dynamical structure of vortex tubes (downflows in the vortex core and upflows on periphery) can be captured by the Stokes I profiles. During an eruption, the ratio of down and upflows can suddenly change, and this effect can be observed in the Stokes V profile. Also, during the eruption the linear polarization signal increases, and this also can be detected with Hinode SP.

#### **4π Models of CMEs and ICMEs** A Review

Jens [Kleimann](#)

E-print, 11 Apr 2012; Solar Phys., November 2012, Volume 281, Issue 1, pp 353-367; **File**

Coronal mass ejections (CMEs), which dynamically connect the solar surface to the far reaches of interplanetary space, represent a major manifestation of solar activity. They are not only of principal interest but also play a pivotal role in the context of space weather predictions. The steady improvement of both numerical methods and computational resources during recent years has allowed for the creation of increasingly realistic models of interplanetary CMEs (ICMEs), which can now be compared to high-quality observational data from various space-bound missions. This review discusses existing models of CMEs, characterizing them by scientific aim and scope, CME initiation method, and physical effects included, thereby stressing the importance of fully 3-D (‘4π’) spatial coverage.

#### **Non-thermal electrons in an eruptive solar event: Magnetic structure, confinement, and escape into the heliosphere**

Karl-Ludwig [Klein](#)<sup>1,2,\*</sup>, Carolina Salas Matamoros<sup>3,\*</sup>, Abdallah Hamini<sup>1,2</sup> and Alexander Kollhoff<sup>4,\*</sup>  
A&A, 690, A382 (2024)

<https://doi.org/10.1051/0004-6361/202450456>

<https://www.aanda.org/articles/aa/pdf/2024/10/aa50456-24.pdf>

Context. Filament eruptions and coronal mass ejections (CMEs) reveal large-scale instabilities of magnetic structures in the solar corona. Some of them are accompanied by radio emission, which at decimetric and longer wavelengths is a signature of electron acceleration that may be different from the acceleration in impulsive flares. The radio emission is part of the broadband continua at decimetre and metre wavelengths called type IV bursts.

Aims. In this article we investigate a particularly well-observed combination of a filament eruption seen in H $\alpha$  and at extreme ultraviolet (EUV) wavelengths and a moving type IV burst on **2021 August 24**. The aim is to shed light on the relationship between the large-scale erupting magnetic structure and the acceleration and transport of non-thermal electrons.

Methods. We used imaging observations of a moving radio source and associated burst groups with the refurbished Nançay Radioheliograph and whole-Sun radio spectrography from different ground-based and space-borne instruments, in combination with X-ray, radio, and in situ electron observations at tens of keV from Solar Orbiter and EUV imaging by SDO/AIA. The radio sources are located with respect to the erupting magnetic structure traced by the filament (EUV 30.4 nm), and the timing of the electrons detected in situ is compared with the timing of the different radio emissions.

Results. We find that the moving radio source is located at the top of the erupting magnetic structure outlined by the filament, which we interpret as a magnetic flux rope. The flux rope erupts in a strongly non-radial direction, guided by the overlying magnetic field of a coronal hole. The electrons detected at Solar Orbiter are found to be released mainly in two episodes, 10–40 minutes after the impulsive phase. The releases coincide with two groups of radio bursts, which originate respectively on the flank and near the top of the erupting flux rope.

Conclusions. The observation allows an unusually clear association between a moving type IV radio burst, an erupting magnetic flux rope as core structure of a CME, and particle releases into the heliosphere. Non-thermal electrons are confined in the flux rope. Electrons escape to the heliosphere mainly in two distinct episodes, which we relate to magnetic reconnection between the flux rope and ambient open field lines.

#### **Eruptive Activity Related to Solar Energetic Particle Events** Review

Karl-Ludwig [Klein](#)

In: O.E. Malandraki, N.B. Crosby (eds.), Solar Particle Radiation Storms Forecasting and Analysis Chapter 2, 2018

<https://link.springer.com/content/pdf/10.1007%2F978-3-319-60051-2.pdf>

**File** Malandraki\_Crosby\_SEPs\_Forecasting and Analysis\_Book.pdf

Solar energetic particle events are associated with solar activity, especially flares and coronal mass ejections (CMEs). In this chapter a basic introduction is presented to the nature of flares and CMEs. Since both are manifestations of evolving magnetic fields in the solar corona, the chapter starts with a qualitative description of the magnetic structuring and electrodynamic coupling of the solar atmosphere. Flares and the radiative manifestations of energetic particles, i.e. bremsstrahlung, gyrosynchrotron and collective plasma emission of electrons, and nuclear gamma-ray emission are briefly presented. Observational evidence on the particle acceleration region in flares is given, as well as a very elementary qualitative overview of acceleration processes. Then CMEs, their origin and their association with shock waves are discussed, and related particle acceleration processes are briefly described.

## **The fast filament eruption leading to the X-flare on March 29, 2014**

Lucia **Kleint**, Marina Battaglia, Kevin Reardon, Alberto Sainz Dalda, Peter R. Young, Säm Krucker

ApJ **806** 9 2015

<http://arxiv.org/pdf/1504.00515v1.pdf>

We investigate the sequence of events leading to the solar X1 flare SOL2014-03-29T17:48. Because of the unprecedented joint observations of an X-flare with the ground-based Dunn Solar Telescope and the spacecraft IRIS, Hinode, RHESSI, STEREO, and SDO, we can sample many solar layers from the photosphere to the corona. A filament eruption was observed above a region of previous flux emergence, which possibly led to a change in magnetic field configuration, causing the X-flare. This was concluded from the timing and location of the hard X-ray emission, which started to increase slightly less than a minute after the filament accelerated. The filament showed Doppler velocities of  $\sim 2\text{--}5\text{ km s}^{-1}$  at chromospheric temperatures for at least one hour before the flare occurred, mostly blueshifts, but also redshifts near its footpoints. 15 minutes before the flare, its chromospheric Doppler shifts increased to  $\sim 6\text{--}10\text{ km s}^{-1}$  and plasma heating could be observed, before it lifted off with at least  $600\text{ km s}^{-1}$ , as seen in IRIS data. Compared to previous studies, this acceleration ( $\sim 3\text{--}5\text{ km s}^{-2}$ ) is very fast, while the velocities are in the common range for coronal mass ejections. An interesting feature was a low-lying twisted second filament near the erupting filament, which did not seem to participate in the eruption. After the flare ribbons started on each of the second filament's sides, it seems to have untangled and vanished during the flare. These observations are some of the highest resolution data of an X-class flare to date and reveal some small-scale features yet to be explained.

## **Flux Ropes as Singularities of the Vector Potential**

M. **Kleman**

Solar Phys. Volume 290, [Issue 3](#), pp 707-725 2015

A flux rope is a domain where a twisted magnetic field  $[B]$  is concentrated; it can be described as the core of a singularity of the outer field or the outer vector potential  $[A]$  (Kleman and Robbins in Solar Phys. 289, 1173, 2014). This latter case, occurring when the outer field is vanishing, is mathematically analysed for a straight infinite rope. Concepts from condensed-matter physics defect theory are used: the flux  $[\Phi]$ , measured as  $\oint C A \cdot ds$  along any loop  $[C]$  surrounding the rope, is a topological constant of the theory. A flux rope with a small outer magnetic field can be treated as a perturbation of the above. This theoretical framework allows for the use of classical configurations inside the core, e.g. the linear force-free field (LFFF) Lundquist model or the nonlinear (NLFFF) Gold-Hoyle model, but restricts the number of stable solutions: they are quantised into strata of increasing energies (an infinite number of strata in the first case, only one stratum in the second case); each stratum is defined by a number  $2\pi\zeta = b/r_0$ , where  $b$  is the periodicity along the axis of the rope and  $r_0$  is its radius, and the rope is made of a continuous set of stable states. We also analyse the merging of identical flux ropes (belonging to the same stratum), with conservation of the relative magnetic helicity: they merge into a unique rope of the first stratum, with a considerable release of energy. These results might apply to ropes that nucleate in the convection zone and the photosphere, where the magnetic field outside the ropes is weak, and less accurately to the magnetic clouds (MCs) into which they evolve after coronal mass ejections (CMEs) are triggered. However, the lowest LFFF stratum and the unique NLFFF stratum, which numerically come close to each other in this analysis, match the spacecraft data remarkably well.

## **Helicity shedding by flux rope ejection**

[B. Kliem](#), [N. Seehafer](#)

A&A 659, A49 2021

<https://arxiv.org/pdf/2112.05833.pdf>

<https://www.aanda.org/articles/aa/pdf/2022/03/aa42422-21.pdf>

We quantitatively address the conjecture that magnetic helicity must be shed from the Sun by eruptions launching coronal mass ejections in order to limit its accumulation in each hemisphere. By varying the ratio of guide and strapping field and the flux rope twist in a parametric simulation study of flux rope ejection from approximately marginally stable force-free equilibria, different ratios of self- and mutual helicity are set and the onset of the torus or helical kink instability is obtained. The helicity shed is found to vary over a broad range from a minor to a major part of the initial

helicity, with self helicity being largely or completely shed and mutual helicity, which makes up the larger part of the initial helicity, being shed only partly. Torus-unstable configurations with subcritical twist and without a guide field shed up to about two-thirds of the initial helicity, while a highly twisted, kink-unstable configuration sheds only about one-quarter. The parametric study also yields stable force-free flux rope equilibria up to a total flux-normalized helicity of 0.25, with a ratio of self- to total helicity of 0.32 and a ratio of flux rope to external poloidal flux of 0.94. These results numerically demonstrate the conjecture of helicity shedding by coronal mass ejections and provide a first account of its parametric dependence. Both self- and mutual helicity are shed significantly; this reduces the total initial helicity by a fraction of  $\sim 0.4$ – $0.65$  for typical source region parameters.

## **Flux Rope Formation by a Confined Solar Flare Preceding a Coronal Mass Ejection**

Bernhard Kliem, Jeongwoo Lee, Stephen M. White, Chang Liu, Satoshi Masuda

ApJ 909 91 2021

<https://arxiv.org/pdf/2101.02181.pdf> File

<https://doi.org/10.3847/1538-4357/abda37>

We present evidence that a magnetic flux rope, observed as an extreme-ultraviolet (EUV) hot channel, was formed before a coronal mass ejection (CME) and its associated long-duration flare during a preceding confined flare in a compound event. EUV images, microwave maps, and the extrapolated field show that the first, impulsive flare, SOL2015-06-21T01:42, results from the eruption of highly sheared low-lying flux and remains confined. Nevertheless, it spawns a vertical current sheet, where magnetic reconnection creates flare ribbons and loops, a nonthermal microwave source, and a sigmoidal hot channel. Until the second flare, SOL2015-06-21T02:36, magnetic reconnection continues at a lower rate and the sigmoid's elbows expand, while its center remains stationary under the erupted, still confined flux. The reconnection during and after the confined flare acts like "tether-cutting reconnection", leading the region to instability. The subsequent full eruption is seen as an accelerated rise of the entire hot channel, a fast halo CME, and the second, long-duration flare. The hot channel can only be interpreted as a magnetic flux rope. This event provides one of the clearest cases so far showing the formation of a flux rope prior to the onset of a CME. It demonstrates that flux ropes are formed or enhanced by confined eruptions that trigger reconnection in a vertical (flare) current sheet. This implies that a flux rope exists prior to a large fraction of all CMEs, those that are preceded by such confined eruptions.

## **II. A Double Flux Rope Model**

Bernhard Kliem, Tibor Török, Viacheslav S. Titov, Roberto Lionello, Jon A. Linker, Rui Liu, Chang Liu, Haimin Wang

ApJ, 792 107 2014

<http://arxiv.org/pdf/1407.2272v1.pdf>

Force-free equilibria containing two vertically arranged magnetic flux ropes of like chirality and current direction are considered as a model for split filaments/prominences and filament-sigmoid systems. Such equilibria are constructed analytically through an extension of the methods developed in Titov & Démoulin (1999) and numerically through an evolutionary sequence including shear flows, flux emergence, and flux cancellation in the photospheric boundary. It is demonstrated that the analytical equilibria are stable if an external toroidal (shear) field component exceeding a threshold value is included. If this component decreases sufficiently, then both flux ropes turn unstable for conditions typical of solar active regions, with the lower rope typically being unstable first. Either both flux ropes erupt upward, or only the upper rope erupts while the lower rope reconnects with the ambient flux low in the corona and is destroyed. However, for shear field strengths staying somewhat above the threshold value, the configuration also admits evolutions which lead to partial eruptions with only the upper flux rope becoming unstable and the lower one remaining in place. This can be triggered by a transfer of flux and current from the lower to the upper rope, as suggested by the observations of a split filament in Paper-I (Liu et al. 2012). It can also result from tether-cutting reconnection with the ambient flux at the X-type structure between the flux ropes, which similarly influences their stability properties in opposite ways. This is demonstrated for the numerically constructed equilibrium.

## **Catastrophe versus instability for the eruption of a toroidal solar magnetic flux rope**

B. Kliem, J. Lin, T. G. Forbes, E. R. Priest, T. Török

ApJ, 789 46, 2014

<http://arxiv.org/pdf/1404.5922v1.pdf>

The onset of a solar eruption is formulated here as either a magnetic catastrophe or as an instability. Both start with the same equation of force balance governing the underlying equilibria. Using a toroidal flux rope in an external bipolar or quadrupolar field as a model for the current-carrying flux, we demonstrate the occurrence of a fold catastrophe by loss of equilibrium for several representative evolutionary sequences in the stable domain of parameter space. We verify that this catastrophe and the torus instability occur at the same point; they are thus equivalent descriptions for the onset condition of solar eruptions.

## **Magnetohydrodynamic Modeling of the Solar Eruption on 2010 April 8**

B. Kliem<sup>1,2,3,4</sup>, Y. N. Su<sup>5</sup>, A. A. van Ballegoijen<sup>5</sup>, and E. E. DeLuca

2013 ApJ 779 129

<http://arxiv.org/abs/1304.6981>

The structure of the coronal magnetic field prior to eruptive processes and the conditions for the onset of eruption are important issues that can be addressed through studying the magnetohydrodynamic (MHD) stability and evolution of nonlinear force-free field (NLFFF) models. This paper uses data-constrained NLFFF models of a solar active region (AR) that erupted on **2010 April 8** as initial conditions in MHD simulations. These models, constructed with the techniques of flux rope insertion and magnetofrictional relaxation (MFR), include a stable, an approximately marginally stable, and an unstable configuration. The simulations confirm previous related results of MFR runs, particularly that stable flux rope equilibria represent key features of the observed pre-eruption coronal structure very well, and that there is a limiting value of the axial flux in the rope for the existence of stable NLFFF equilibria. The specific limiting value is located within a tighter range, due to the sharper discrimination between stability and instability by the MHD description. The MHD treatment of the eruptive configuration yields a very good agreement with a number of observed features, like the strongly inclined initial rise path and the close temporal association between the coronal mass ejection and the onset of flare reconnection. Minor differences occur in the velocity of flare ribbon expansion and in the further evolution of the inclination; these can be eliminated through refined simulations. We suggest that the slingshot effect of horizontally bent flux in the source region of eruptions can contribute significantly to the inclination of the rise direction. Finally, we demonstrate that the onset criterion, formulated in terms of a threshold value for the axial flux in the rope, corresponds very well to the threshold of the torus instability in the considered AR.

### **A Parametric Study of Erupting Flux Rope Rotation**

B. Kliem, T. Török, W. T. Thompson

Solar Physics, November **2012**, Volume 281, Issue 1, pp 137-166

The rotation of erupting filaments in the solar corona is addressed through a parametric simulation study of unstable, rotating flux ropes in bipolar force-free initial equilibrium. The Lorentz force due to the external shear-field component and the relaxation of tension in the twisted field are the major contributors to the rotation in this model, while reconnection with the ambient field is of minor importance, due to the field's simple structure. In the low-beta corona, the rotation is not guided by the changing orientation of the vertical field component's polarity inversion line with height. The model yields strong initial rotations which saturate in the corona and differ qualitatively from the profile of rotation vs. height obtained in a recent simulation of an eruption without preexisting flux rope. Both major mechanisms writhe the flux rope axis, converting part of the initial twist helicity, and produce rotation profiles which, to a large part, are very similar within a range of shear-twist combinations. A difference lies in the tendency of twist-driven rotation to saturate at lower heights than shear-driven rotation. For parameters characteristic of the source regions of erupting filaments and coronal mass ejections, the shear field is found to be the dominant origin of rotations in the corona and to be required if the rotation reaches angles of order 90 degrees and higher; it dominates even if the twist exceeds the threshold of the helical kink instability. The contributions by shear and twist to the total rotation can be disentangled in the analysis of observations if the rotation and rise profiles are simultaneously compared with model calculations. The resulting twist estimate allows one to judge whether the helical kink instability occurred. This is demonstrated for the erupting prominence in the "Cartwheel CME" on **9 April 2008**, which has shown a rotation of  $\approx 115^\circ$  up to a height of  $1.5 R_\odot$  above the photosphere. Out of a range of initial equilibria which include strongly kink-unstable (twist  $\Phi=5\pi$ ), weakly kink-unstable ( $\Phi=3.5\pi$ ), and kink-stable ( $\Phi=2.5\pi$ ) configurations, only the evolution of the weakly kink-unstable flux rope matches the observations in their entirety.

### **Simulations of the CME-Flare Relationship**

Kliem, B.1; Török, T.2

Freiburg ESP Meeting **2008**, Presentation

Observations of coronal mass ejections (CMEs) and solar flares have revealed a high correlation between the acceleration of the ejecta and the plasma heating and particle acceleration signified by the soft and hard X-ray emissions of the associated flare. The latter are generally thought to result from magnetic reconnection. This finding has stimulated the discussion of the CME-flare relationship, but at the same time it has made it difficult to find a conclusive answer as to whether magnetic reconnection or an ideal MHD instability is the prime cause of the eruptions. Numerical simulations of unstable flux ropes will be presented that are in very satisfactory quantitative agreement with erupting filaments, both, confined to the corona and ejective (i.e., developing into a CME). Some of these simulations indeed show a high degree of synchronization between the initial exponential acceleration of the flux rope, due to the ideal MHD instability, and the development of reconnection flows. However, others show a very delayed onset of reconnection, even after the flux rope's acceleration peak. In addition, the reconnection flows generally lag behind the

motions driven by the ideal instability as the flux rope rise velocity nears the saturation phase. Both findings indicate that the ideal MHD process is the primary driver of the coupled CME-flare phenomenon. The strong differences in the degree of synchronization, which the simulated systems show in the main rise phase of the eruption, are related to the magnetic topology prior to the eruption. Given the observational result of a high correlation between CME and flare development (Zhang & Dere 2006), these simulations yield constraints on the topology and lead us to conclude that a seed for a reconnecting current sheet must typically be present already at the onset of the eruption.

## **The Rise and Emergence of Untwisted Toroidal Flux Ropes on the Sun**

K. J. [Knizhnik](#)<sup>1</sup>, J. E. Leake<sup>2</sup>, M. G. Linton<sup>1</sup>, and S. Dacie<sup>3</sup>

2021 ApJ 907 19

<https://doi.org/10.3847/1538-4357/abccc0>

Magnetic flux ropes (MFRs) rising buoyantly through the Sun's convection zone are thought to be subject to viscous forces preventing them from rising coherently. Numerous studies have suggested that MFRs require a minimum twist in order to remain coherent during their rise. Furthermore, even MFRs that get to the photosphere may be unable to successfully emerge into the corona unless they are at least moderately twisted, since the magnetic pressure gradient needs to overcome the weight of the photospheric plasma. To date, however, no lower limit has been placed on the critical minimum twist required for an MFR to rise coherently through the convection zone or emerge through the photosphere. In this paper, we simulate an untwisted toroidal MFR that is able to rise from the convection zone and emerge through the photosphere as an active region that resembles those observed on the Sun. We show that untwisted MFRs can remain coherent during their rise and then pile up near the photosphere, triggering undular instability, allowing the MFR to emerge through the photosphere. We propose that the toroidal geometry of our MFR is critical for its coherent rise. Upon emergence, a pair of lobes rises into the corona. The two lobes then interact and reconnect, resulting in a localized high speed jet. The resulting photospheric magnetogram displays the characteristic salt-and-pepper structure often seen in observations. Our major result is that MFRs need not be twisted to rise coherently through the convection zone and emerge through the photosphere.

## **The Mechanism for the Energy Buildup Driving Solar Eruptive Events**

Kalman J. [Knizhnik](#), [Spiro K. Antiochos](#), [C. Richard DeVore](#), [Peter F. Wyper](#)

ApJL 851 L17 2017

<https://arxiv.org/ftp/arxiv/papers/1711/1711.00166.pdf>

The underlying origin of solar eruptive events (SEEs), ranging from giant coronal mass ejections to small coronal-hole jets, is that the lowest-lying magnetic flux in the Sun's corona undergoes the continual buildup of stress and free energy. This magnetic stress has long been observed as the phenomenon of "filament channels:" strongly sheared magnetic field localized around photospheric polarity inversion lines. However, the mechanism for the stress buildup - the formation of filament channels - is still debated. We present magnetohydrodynamic simulations of a coronal volume that is driven by transient, cellular boundary flows designed to model the processes by which the photosphere drives the corona. The key feature of our simulations is that they accurately preserve magnetic helicity, the topological quantity that is conserved even in the presence of ubiquitous magnetic reconnection. Although small-scale random stress is injected everywhere at the photosphere, driving stochastic reconnection throughout the corona, the net result of the magnetic evolution is a coherent shearing of the lowest-lying field lines. This highly counter-intuitive result - magnetic stress builds up locally rather than spreading out to attain a minimum energy state - explains the formation of filament channels and is the fundamental mechanism underlying SEEs. Furthermore, this mechanism may be relevant to other astrophysical or laboratory plasmas.

## **Modeling UV and X-Ray Emission in a Post-CME Current Sheet**

Yuan-Kuen [Ko](#), John C. Raymond<sup>2</sup>, Bojan Vr̃snak<sup>3</sup>, Eugen Vujić

E-print, 12 Aug 2010, ApJ, 722:625–641, 2010, [File](#)

A post-coronal mass ejection (CME) current sheet (CS) is a common feature developed behind an erupting flux rope in CME models. Observationally, white light observations have recorded many occurrences of a thin ray appearing behind a CME eruption that closely resembles a post-CME CS in its spatial correspondence and morphology. UV and X-ray observations further strengthen this interpretation by the observations of high-temperature emission at locations consistent with model predictions. The next question then becomes whether the properties inside a post-CME CS predicted by a model agree with observed properties. In this work, we assume that the post-CME CS is a consequence of Petschek-like reconnection and that the observed ray-like structure is bounded by a pair of slow mode shocks developed from the reconnection site. We perform time-dependent ionization calculations and model the UV line emission. We find that such a model is consistent with *SOHO*/UVCS observations of the post-CME CS. The change of Fe xviii emission in one event implies an inflow speed of  $\sim 10$  km s<sup>-1</sup> and a corresponding reconnection rate of  $M_A \sim 0.01$ . We calculate the expected X-ray emission for comparison with X-ray observations by *Hinode*/XRT, as well as the ionic charge states as would be measured in situ at 1 AU. We find that the predicted

count rate for *Hinode*/XRT agrees with what was observed in a post-CME CS on **2008 April 9**, and the predicted ionic charge states are consistent with high ionization states commonly measured in the interplanetary CMEs. The model results depend strongly on the physical parameters in the ambient corona, namely the coronal magnetic field, the electron density, and temperature during the CME event. It is crucial to obtain these ambient coronal parameters and as many facets of the CS properties as possible by observational means so that the post-CME CS models can be scrutinized more effectively.

In the present work, we analyze a filament eruption associated with an ICME that arrived at L1 on August 5th, 2011. In multi-wavelength SDO/AIA images, three plasma parcels within the filament were tracked at high-cadence along the solar corona. A novel absorption diagnostic technique was applied to the filament material travelling along the three chosen trajectories to compute the column density and temperature evolution in time. Kinematics of the filamentary material were estimated using STEREO/EUVI and STEREO/COR1 observations. The Michigan Ionization Code used inputs of these density, temperature, and speed profiles for the computation of ionization profiles of the filament plasma. Based on these measurements we conclude the core plasma was in near ionization equilibrium, and the ionization states were not frozen-in at the altitudes where they were visible in absorption in AIA images. Additionally, we report that the filament plasma was heterogeneous, and the filamentary material was continuously heated as it expanded in the low solar corona. **August 4th, 2011**

### **Multiwavelength Study of on-disk Coronal Hole Jets with IRIS and SDO observations**

Solar jets are an important field of study, as they may contribute to the mass and energy transfer from the lower to the upper atmosphere. We use the Interface Region Imaging Spectrograph (IRIS) and Solar Dynamic Observatory (SDO) observations to study two small-scale jets originating in the same on-disk coronal hole observed in October 2013. We combine dopplergrams, intensity maps, and line width maps derived from IRIS Si IV 1393.755 Å spectra along with images from the Atmospheric Imaging Assembly (AIA) on SDO to describe the dynamics of the jets. Images from AIA, with the use of the emission measure loci technique and rectangular differential emission measure (DEM) distributions, provide estimations of the plasma temperatures. We used the O IV 1399.77 Å, 1401.16 Å spectral lines from IRIS to derive electron densities. For jet 1, the SDO images show a small mini-filament 2 minutes before the jet eruption, while jet 2 originates at a pre-existing coronal bright point. The analysis of asymmetric spectral profiles of the Si IV 1393.755 Å and 1402.770 Å lines reveals the existence of two spectral components with inversely dependent 1393.755 Å/1402.770 Å ratios at both regions. One of the components can be related to the background plasma emission originating outside the jet, while the secondary component represents higher-energy plasma flows associated with the jets. Both jets exhibit high densities of the order of 10<sup>11</sup> cm<sup>-3</sup> at their base and 10<sup>10</sup> cm<sup>-3</sup> at the spire, respectively, as well as similar average nonthermal velocities of ~ 50-60 km/s. However, the two jets show differences in their length, duration, and plane-of-sky velocity. Finally, the DEM analysis reveals that both jets exhibit multithermal distributions. **October 9, 2013**

### **Spatial Relationship between CMEs and Prominence Eruptions during SC 24 and SC 25**

2024 *ApJ* 966 22

<https://iopscience.iop.org/article/10.3847/1538-4357/ad2df3/pdf>

During their propagation, coronal mass ejections (CMEs) and prominences sometimes display a nonradial motion. During the years after the solar minimum, the CME central position angle tended to be offset closer to the equator compared to that of the associated prominence eruptions (PE). No such effect was observed during solar maximum. The purpose of this paper is to investigate the latitudinal offsets of CMEs with respect to their source regions. We study 256 events from SC 24 and SC 25, listed in the Coordinate Data Analysis Workshop Data Center. We analyzed the CMES radial offset from the associated PEs by comparing their latitudes in the plane of the sky. This work is an extension of the previous work by Gopalswamy et al., but with an independent data set. We have confirmed the systematic equatorward offset of CME from the solar source region for the rising phase of Solar Cycle 25. Our analysis of the relation between CME linear speed and PE-CME latitudinal offset indicated that the velocities of the deflected CMEs are mainly in the range of 200 and 800 km s<sup>-1</sup>. In this study, we compared the nonradial offsets for the rising and decay phases of SC 24 and our analysis has shown that during the decay phase more events deflected toward the pole can be

observed. The observed variation is attributed to the presence of a substantial number of low-latitude coronal holes during the decay phase and to the influence from nearby active regions. **2010 June 20, 2017 October 18.**

### **Sympathetic Quiet and Active Region Filament Eruptions**

<https://link.springer.com/content/pdf/10.1007/s11207-022-01981-y.pdf>

We present the observations of three sympathetic filament eruptions occurring on **19 July 2015** namely F1, F2, and F3. The events were observed in UV/EUV wavelengths by Atmospheric Imaging Assembly onboard the Solar Dynamics Observatory and by Global Oscillation Network Group telescope in H $\{\alpha\}$  line. As filament F1 starts to erupt, a part of it falls close to the location of the F2 and F3 filaments. This causes the eruption of F2 and F3 during which the two filaments merge together and trigger a medium-class CME and a long-duration GOES C2.1 class flare. We discuss the dynamics and kinematics of these three filament eruptions and related phenomena.

We present analysis of three cases of filament eruptions (FEs) that occurred on **04 Aug 2011, 09 Nov 2011 and 05 Apr 2012** and their associations with flares as sources of solar energetic particles (SEPs) and coronal mass ejections. The associated FEs and SEP-related solar flares were selected by simultaneous observations in X-ray, EUV and radio wavelengths.

### **Kinematics and helicity evolution of a loop-like eruptive prominence \***

K. [Koleva](#)<sup>1</sup>, M. S. [Madjarska](#)<sup>2</sup>, P. [Duchlev](#)<sup>1</sup>, C. J. [Schrijver](#)<sup>5</sup>, J.-C. [Vial](#)<sup>3,4</sup>, E. [Buchlin](#)<sup>3,4</sup> and M. [Dechev](#)

E-print, 14 Feb 2012; A&A 540, A127 (**2012**)

Aims. We aim at investigating the morphology as well as kinematic and helicity evolution of a loop-like prominence during its eruption.

Methods. We used multi-instrument observations from AIA/SDO, EUVI/STEREO and LASCO/SoHO. The kinematic, morphological, geometrical, and helicity evolution of a loop-like eruptive prominence were studied in the context of the magnetic flux rope model of solar prominences.

Results. The prominence eruption evolved as a height-expanding twisted loop with both legs anchored in the chromosphere of a plage area. The eruption process consisted of a prominence activation, acceleration, and a phase of constant velocity. The prominence body was composed of counter-clockwise twisted threads around the main prominence axis. The twist during the eruption was estimated at  $6\pi$  (3 turns). The prominence reached a maximum height of 526 Mm before contracting to its primary location and was partially reformed in the same place two days after the eruption. This ejection, however, triggered a coronal mass ejection (CME) observed in LASCO C2. The prominence was located in the northern periphery of the CME magnetic field configuration and, therefore, the background magnetic field was asymmetric with respect to the filament position. The physical conditions of the falling plasma blobs were analysed with respect to the prominence kinematics.

Conclusions. The same sign of the prominence body twist and writhe, as well as the amount of twisting above the critical value of  $2\pi$  after the activation phase indicate that possibly conditions for kink instability were present. No signature of magnetic reconnection was observed anywhere in the prominence body and its surroundings. The filament/prominence descent following the eruption and its partial reformation at the same place two days later suggest a confined type of eruption. The asymmetric background magnetic field possibly played an important role in the failed eruption. **between 17:30 UT and 19:30 UT on 2010 March 30**

### **Search for flares and associated CMEs on late-type main-sequence stars in optical SDSS spectra**

[Florian Koller](#), [Martin Leitzinger](#), [Manuela Temmer](#), [Petra Odert](#), [Paul G. Beck](#), [Astrid Veronig](#)

A&A **2020**

<https://arxiv.org/pdf/2012.00786.pdf>

This work aims to detect and classify stellar flares and potential stellar coronal mass ejection (CME) signatures in optical spectra provided by the Sloan Digital Sky Survey (SDSS) data release 14. The sample is constrained to all F, G, K, and M main-sequence type stars, resulting in more than 630,000 stars. This work makes use of the individual spectral exposures provided by the SDSS.

An automatic flare search was performed by detecting significant amplitude changes in the H $\alpha$  and H $\beta$  spectral lines after a Gaussian profile was fit to the line core. CMEs were searched for by identifying asymmetries in the Balmer lines caused by the Doppler effect of plasma motions in the line of sight.

We identified 281 flares on late-type stars (spectral types K3 to M9). We identified six possible CME candidates showing excess flux in Balmer line wings. Flare energies in H $\alpha$  were calculated and masses of the CME candidates were estimated. The derived H $\alpha$  flare energies range from  $3 \times 10^{28}$ – $2 \times 10^{33}$  erg. The H $\alpha$  flare energy increases with earlier types, while the fraction of flaring times increases with later types. Mass estimates for the CME candidates are in the range of  $6 \times 10^{16}$ – $6 \times 10^{18}$  g, and the highest projected velocities are  $\sim 300$ – $700$  km/s. The low detection rate of CMEs we obtained agrees with previous studies, suggesting that for late-type main-sequence stars the CME occurrence rate that can be detected with optical spectroscopy is low.

### **Nonlinear oscillations of coalescing magnetic flux ropes**

Dmitrii Y. [Kolotkov](#), Valery M. Nakariakov, and George Rowlands

Phys. Rev. E **2016**

<http://journals.aps.org/pre/accepted/6007fY62C3a1bd4f86428ce58d48609acbd7bf0e8>

An analytical model of highly nonlinear oscillations occurring during a coalescence of two magnetic flux ropes, based upon two-fluid hydrodynamics, is developed. The model accounts for the effect of electric charge separation, and describes perpendicular oscillations of the current sheet formed by the coalescence. The oscillation period is determined by the current sheet thickness, the plasma parameter beta, and the oscillation amplitude. The oscillation periods are typically greater than or about the ion plasma oscillation period. In the nonlinear regime, the oscillations of the ion and electron concentrations have a shape of a narrow symmetric spikes.

### **Splitting and eruption of an active region filament caused by magnetic reconnection**

ApJ **2024** 972 99

<https://arxiv.org/abs/2408.08569>

<https://iopscience.iop.org/article/10.3847/1538-4357/ad66bb/pdf>

To gain a deeper understanding of the intricate process of filament eruption, we present a case study of a filament splitting and eruption by using multi-wavelength data of the Solar Dynamics Observatory (SDO). It is found that the magnetic reconnection between the filament and the surrounding magnetic loops resulted in the formation of two new filaments, which erupted successively. The observational evidences of magnetic reconnection, such as the obvious brightening at the junction of two different magnetic structures, the appearance of a bidirectional jet, and subsequent filament splitting, were clearly observed. Even though the two newly formed filaments experienced failed eruptions, three obvious dimmings were observed at the footpoints of the filaments during their eruptions. Based on these observations, it is suggested that magnetic reconnection is the trigger mechanism for the splitting of the original filament and the subsequent eruption of the newly formed filaments. Furthermore, the process of filament splitting dominated by magnetic reconnection can shed light on the explanation of double-deck filament formation. **March 9, 2019**

### **High-resolution spectroscopy of an erupting minifilament and its impact on the nearby chromosphere**

I. [Kontogiannis](#), [E. Dineva](#), [A. Diercke](#), [M. Verma](#), [C. Kuckein](#), [H. Balthasar](#), [C. Denker](#)

ApJ **898** 144 **2020**

<https://arxiv.org/pdf/2007.01564.pdf>

<https://doi.org/10.3847/1538-4357/aba117>

We study the evolution of a mini-filament eruption in a quiet region at the center of the solar disk and its impact on the ambient atmosphere. We used high-spectral resolution imaging spectroscopy in H $\alpha$  acquired by the echelle spectrograph of the Vacuum Tower Telescope (VTT), Tenerife, Spain, photospheric magnetic field observations from the Helioseismic and Magnetic Imager (HMI), and UV/EUV imaging from the Atmospheric Imaging Assembly (AIA) of the Solar Dynamics Observatory (SDO). The H $\alpha$  line profiles were noise-stripped using Principal Component Analysis (PCA) and then inverted to produce physical and cloud model parameter maps. The minifilament formed between small-scale, opposite-polarity magnetic features through a series of small reconnection events and it erupted within an hour after its appearance in H $\alpha$ . Its development and eruption exhibited similarities with large-scale erupting filaments, indicating the action of common mechanisms. Its eruption took place in two phases, namely a slow rise and a fast expansion, and it produced a coronal dimming, before the minifilament disappeared. During its eruption we detected a complicated velocity pattern, indicative of a twisted, thread-like structure. Part of its material returned to the chromosphere producing observable effects on nearby low-lying magnetic structures. Cloud model analysis showed that the minifilament was initially similar to other chromospheric fine structures, in terms of optical depth, source function and Doppler width, but it resembled a large-scale filament on its course to eruption. High spectral resolution observations of the chromosphere can provide a wealth of information regarding the dynamics and properties of minifilaments and their interactions with the surrounding atmosphere. **May 26, 2019**

### **Which Photospheric Characteristics are Most Relevant to Active-Region Coronal Mass Ejections?**

Ioannis [Kontogiannis](#), [Manolis K. Georgoulis](#), [Jordan A. Guerra](#), [Sung-Hong Park](#), [D. Shaun Bloomfield](#)

Solar Phys. 294:130 2019

<https://arxiv.org/pdf/1909.06088.pdf>

<https://link.springer.com/content/pdf/10.1007%2Fs11207-019-1523-6.pdf>

We investigate the relation between characteristics of coronal mass ejections and parameterizations of the eruptive capability of solar active regions widely used in solar flare prediction schemes. These parameters, some of which are explored for the first time, are properties related to topological features, namely, magnetic polarity inversion lines (MPILs) that indicate large amounts of stored non-potential (i.e. free) magnetic energy. We utilize the Space Weather Database of Notifications, Knowledge, Information (DONKI) and the Large Angle and Spectrometric Coronagraph (LASCO) databases to find flare-associated coronal mass ejections and their kinematic characteristics while properties of MPILs are extracted from Helioseismic and Magnetic Imager (HMI) vector magnetic-field observations of active regions to extract the properties of source-region MPILs. The correlation between all properties and the characteristics of CMEs ranges from moderate to very strong. More significant correlations hold particularly for fast CMEs, which are most important in terms of adverse space-weather manifestations. Non-neutralized currents and the length of the main MPIL exhibit significantly stronger correlations than the rest of the properties. This finding supports a causal relationship between coronal mass ejections and non-neutralized electric currents in highly sheared, conspicuous MPILs. In addition, non-neutralized currents and MPIL length carry distinct, independent information as to the eruptive potential of active regions. The combined total amount of non-neutralized electric currents and the length of the main polarity inversion line, therefore, reflect more efficiently than other parameters the eruptive capacity of solar active regions and the CME kinematic characteristics stemming from these regions.

**Table 1.** Our eruptive flare sample and supporting information (see Section. 2) (2011-2016)

## VLA Measurements of Faraday Rotation Through a Coronal Mass Ejection Using Multiple Lines of Sight

[Jason E. Kooi](#), [Madison L. Ascione](#), [Lianis V. Reyes-Rosa](#), [Sophia K. Rier](#) & [Mohammad Ashas](#)

*Solar Physics* volume 296, Article number: 11 (2021)

<https://link.springer.com/content/pdf/10.1007/s11207-020-01755-4.pdf>

Coronal mass ejections (CMEs) are large eruptions of magnetized plasma from the Sun that play an important role in space weather. The key to understanding the fundamental physics of a CME is measurement of the plasma properties within heliocentric distances of  $<20 R_{\odot}$ . Faraday rotation, a radioastronomical propagation measurement, is an extremely valuable diagnostic for studying CMEs. Faraday rotation measurements [RM] contain information on the magnetic field in the medium causing the Faraday rotation. Recent observations of CME-induced Faraday rotation (e.g., Howard et al. in *Astrophys. J.* 831, 208, 2016; Kooi et al. in *Solar Phys.* 292, 56, 2017; Bisi et al. in EGU General Assembly Conference Abstracts, 13243, 2017) have all been restricted to a single line of sight (LOS) and, therefore, limited to providing estimates of the magnetic field strength. Modeling by Liu et al. (*Astrophys. J.* 665, 1439, 2007) and Jensen and Russell (*Geophys. Res. Lett.* 35, L02103, 2008) demonstrated that multiple LOS are necessary to recover the magnetic field strength and structure of the observed CME. We report the first successful observations of Faraday rotation through a CME using multiple lines of sight: 13 LOS across seven target radio fields. We made these radio observations using the Karl G. Jansky Very Large Array (VLA) at 1–2 GHz frequencies in the triggered operation mode on **31 July 2015**, using a constellation of cosmic radio sources through the solar corona at heliocentric distances of 8.2–19.5  $R_{\odot}$ . For LOS within 10  $R_{\odot}$ , the CME's contribution to the measured RM was  $\approx 0$  to  $-20$  rad  $m^{-2}$ , a significant enhancement over the coronal contribution. We assumed a force-free flux-rope structure for the CME's magnetic field and explored three separate models for the CME's plasma density: constant density, thin shell, and thick shell. The plasma densities and axial magnetic field strengths for the three models ranged over 5.4–6.4  $\times 10^3$   $cm^{-3}$  and 26–35 mG, respectively. Further, using all 13 LOS, we successfully determined the CME's orientation and helicity.

## VLA Measurements of Faraday Rotation through Coronal Mass Ejections

Jason E. [Kooi](#), Patrick D. Fischer, Jacob J. Buffo, Steven R. Spangler

*Solar Physics* April 2017, 292:56

<http://link.springer.com/content/pdf/10.1007%2Fs11207-017-1074-7.pdf>

Coronal mass ejections (CMEs) are large-scale eruptions of plasma from the Sun, which play an important role in space weather. Faraday rotation is the rotation of the plane of polarization that results when a linearly polarized signal passes through a magnetized plasma such as a CME. Faraday rotation is proportional to the path integral through the plasma of the electron density and the line-of-sight component of the magnetic field. Faraday-rotation observations of a source near the Sun can provide information on the plasma structure of a CME shortly after launch. We report on simultaneous white-light and radio observations made of three CMEs in August 2012. We made sensitive Very Large Array (VLA) full-polarization observations using 1–2 GHz frequencies of a constellation of radio sources through the solar corona at heliocentric distances that ranged from 6– $(15 \sim \{R\}_{\odot})$ . Two sources (0842+1835 and 0900+1832) were occulted by a single CME, and one source (0843+1547) was occulted by two CMEs. In addition to our radioastronomical observations, which represent one of the first active hunts for CME Faraday rotation since Bird et al. (*Solar Phys.*, 98, 341, 1985) and the first active hunt using the VLA, we obtained white-light coronagraph images from the Large Angle and Spectrometric Coronagraph (LASCO) C3 instrument to determine the Thomson-scattering brightness [ $\{B\}_{\{T\}}$ ], providing a means to independently estimate the plasma density and determine its contribution to the observed Faraday rotation. A constant-density force-free flux rope embedded in the

background corona was used to model the effects of the CMEs on  $\mathbf{B}_T$  and Faraday rotation. The plasma densities ( $2.2 \times 10^3 \text{ cm}^{-3}$ ) and axial magnetic-field strengths (2–12 mG) inferred from our models are consistent with the modeling work of Liu et al. (Astrophys. J., 665, 1439, 2007) and Jensen and Russell (Geophys. Res. Lett., 35, L02103, 2008), as well as previous CME Faraday-rotation observations by Bird et al. (1985). **2 August 2012, 30 August 2012**  
**CESRA highlight: Nov 2017** <http://cesra.net/?p=1671>

### **On the evolution of pre-flare patterns of a 3-dimensional model of AR 11429**

M. B. [Korsos](#), [S. Poedts](#), [N. Gyenge](#), [M. K. Georgoulis](#), [S. Yu](#), [S. K. Bisoi](#), [Y. Yan](#), [M. S. Ruderman](#), [R. Erdelyi](#)  
**2018**

<https://arxiv.org/pdf/1801.00433.pdf>

We apply a novel pre-flare tracking of sunspot groups towards improving the estimation of flare onset time by focusing on the evolution of the 3D magnetic field construction of AR 11429. The 3D magnetic structure is based on potential field extrapolation encompassing a vertical range from the photosphere through the chromosphere and transition region into the low corona. The basis of our proxy measure of activity prediction is the so-called weighted horizontal gradient of magnetic field (WG\_M) defined between spots of opposite polarities close to the polarity inversion line of an active region. The temporal variation of the distance of the **barycenter** of the opposite polarities is also found to possess potentially important diagnostic information about the flare onset time estimation as function of height similar to its counterpart introduced initially in an application at the photosphere only in Korsos et al. (2015). We apply the photospheric pre-flare behavioural patterns of sunspot groups to the evolution of their associated 3D-constructed AR 11429 as function of height. We found that at a certain height in the lower solar atmosphere the onset time may be estimated much earlier than at the photosphere or at any other heights. Therefore, we present a tool and recipe that may potentially identify the optimum height for flare prognostic in the solar atmosphere allowing to improve our flare prediction capability and capacity. **2012.03.07-10**

### **An application of the weighted horizontal magnetic gradient to solar compact and eruptive events**

M. B. [Korsos](#), [Michael S. Ruderman](#), [R. Erdelyi](#)  
**2017**

<https://arxiv.org/pdf/1801.00281.pdf>

We propose to apply the weighted horizontal magnetic gradient (WGM), introduced in Korsos et al (2015), for analysing the pre-flare and pre-CME behaviour and evolution of Active Regions (ARs) using the SDO/HMI-Debrecen Data catalogue. To demonstrate the power of investigative capabilities of the WGM method, in terms of flare and CME eruptions, we studied two typical ARs, namely, AR 12158 and AR 12192. The choice of ARs represent canonical cases. AR 12158 produced an X1.6 flare with fast "halo" CME ( $v_{\text{linear}}=1267 \text{ km s}^{-1}$ ) while in AR 12192 there occurred a range of powerful X-class eruptions, i.e. X1.1, X1.6, X3.1, X1.0, X2.0 and X2.0-class energetic flares, interestingly, none with an accompanying CME. The value itself and temporal variation of WGM is found to possess potentially important diagnostic information about the intensity of the expected flare class. Furthermore, we have also estimated the flare onset time from the relationship of duration of converging and diverging motions of the area-weighted barycenters of two subgroups of opposite magnetic polarities. This test turns out not only to provide information about the intensity of the expected flare-class and the flare onset time but may also indicate whether a flare will occur with/without fast CME.

We have also found that, in the case when the negative polarity **barycenter** has moved around and the positive one "remained" at the same coordinates preceding eruption, the flare occurred with fast "halo" CME.

Otherwise, when both the negative and the positive polarity barycenters have moved around, the AR produced flares without CME. If these properties found for the movement of the barycenters are generic pre-cursors of CME eruption (or lack of it), identifying them may serve as an excellent pre-condition for refining the forecast of the lift-off of CMEs. **9 September 2014, 22 October 2014**

### **ON THE STATE OF A SOLAR ACTIVE REGION BEFORE FLARES AND CMEs**

M. B. [Korsós](#)<sup>1,2</sup> and R. Erdélyi  
**2016** ApJ 823 153

Several attempts have been made to find reliable diagnostic tools to determine the state prior to flares and related coronal mass ejections (CMEs) in solar active regions (ARs). Characterization of the level of mixed states is carried out using the Debrecen sunspot Data for 116 flaring ARs. Conditional flare probabilities (CFPs) are calculated for different flaring classes. The association with slow/fast CMEs is examined. Two precursor parameters are introduced: (i) the sum of the (daily averaged) horizontal magnetic gradient  $G_S$  ( $G_{DS}$ ) and (ii) the separation parameter  $\rho$ . We found that if for a flaring AR then the CFP of the expected highest-intensity flare being X-class is more than 70%. If the CFP is more than 45% for the highest-intensity flare(s) to be M-class, and if there is larger than 60% CFP that C-class flare(s) may have the strongest intensity within 48 hr. Next, from analyzing  $G_S$  for determining CFP we found: if  $\rho > 6.5$ , then it is very likely that C-class flare(s) may be the most intense; if  $\rho < 6.5$  then there is  $\sim 45\%$  CFP that M-class could have the highest intensity; finally, if  $\rho < 6.5$  then there is at least 70% chance that the strongest energy release will be X-class in the next 48 hr.

ARs are unlikely to produce X-class flare(s) if  $\log(G S) > 5.5$ . Finally, in terms of providing an estimate of an associated slow/fast CME, we found that, if  $0.4$  or  $6.5$ , there is no accompanying fast CME in the following 24 hr.

### **Analysis of a Limb Eruptive Event**

P. [Kotrč](#),<sup>1</sup> Yu. A. Kupryakov,<sup>1,2</sup> M. Barta,<sup>1</sup> L. K. Kashapova,<sup>3</sup> and W. Liu<sup>1</sup>

Ground-based Solar Observations in the Space Instrumentation Era

ASP Conference Series, Vol. 504, p. 51, 2016

<http://aspbooks.org/publications/504/051.pdf>

We present the analysis of an eruptive event that took place on the eastern limb on **April 21, 2015**, which was observed by the Ondřejov horizontal telescope and spectrograph. The eruption of the highly twisted prominence was followed by the onset of soft X-ray sources. We identified the structures observed in  $H\alpha$  spectra with the details on the  $H\alpha$  filtergrams and analyzed the evolution of Doppler component velocities. The timing and observed characteristics of the eruption were compared with the prediction of the model based on the twisting of the flux ropes and the kink/torus instability.

### **Modeling of $H\alpha$ Eruptive Events Observed at the Solar Limb**

P. [Kotrč](#), M. Bárta, P. Schwartz, Y. A. Kupryakov, L. K. Kashapova, M. Karlický

Solar Physics, June 2013, Volume 284, Issue 2, pp 447-466

We present spectra and slit-jaw images of limb and on-disk eruptive events observed with a high temporal resolution by the Ondřejov Observatory optical spectrograph. Analysis of the time series of full width at half-maximum (FWHM) in  $H\alpha$ ,  $H\beta$ , and radio and soft X-ray (SXR) fluxes indicates two phenomenologically distinct types of observations which differ significantly in the timing of FWHM and SXR/radio fluxes. We investigated one such unusual case of a limb eruptive event in more detail. Synthesis of all observed data supports the interpretation of the  $H\alpha$  broadening in the sense of regular macroscopic plasma motions, contrary to the traditional view (emission from warm dense plasma). The timing and observed characteristics indicate that we may have actually observed the initiation of a prominence eruption. We test this scenario via modeling of the initial phase of the flux rope eruption in a magnetohydrodynamic (MHD) simulation, calculating subsequently – under some simplifying assumptions – the modeled  $H\alpha$  emission and spectrum. The modeled and observed data correspond well. Nevertheless, the following question arises: To what extent is the resulting emission sensitive to the underlying model of plasma dynamics? To address this issue, we have computed a grid of kinematic models with various arbitrary plasma flow patterns and then calculated their resulting emission. Finally, we suggest a diagnostics based on the model and demonstrate that it can be used to estimate the Alfvén velocity and plasma beta in the prominence, which are otherwise hard to obtain.

### **CME Expansion as the Driver of Metric Type II Shock Emission as Revealed by Self-Consistent Analysis of High Cadence EUV Images and Radio Spectrograms**

[Kouloumvakos](#), A.; [Patsourakos](#), S.; [Hillaris](#), A.; [Vourlidis](#), A.; [Preka-Papadema](#), P.; [Moussas](#), X.; [Caroubalos](#), C.; [Tsitsipis](#), P.; [Kontogeorgos](#), A.

E-print, Dec 2013, **File**; Solar Phys. June 2014, Volume 289, Issue 6, pp 2123-2139

On **13 June 2010**, an eruptive event occurred near the solar limb. It included a small filament eruption and the onset of a relatively narrow coronal mass ejection (CME) surrounded by an extreme ultraviolet wave front recorded by the Solar Dynamics Observatory's (SDO) Atmospheric Imaging Assembly (AIA) at high cadence. The ejection was accompanied by a GOES M1.0 soft X-ray flare and a Type-II radio burst; high-resolution dynamic spectra of the latter were obtained by the ARTEMIS IV radio spectrograph. The combined observations enabled a study of the evolution of the ejecta and the EUV wavefront and its relationship with the coronal shock manifesting itself as metric Type-II burst. By introducing a novel technique, which deduces a proxy of the EUV compression ratio from AIA imaging data and compares it with the compression ratio deduced from the band-split of the Type-II metric radio burst, we are able to infer the potential source locations of the radio emission of the shock on that AIA images. Our results indicate that the expansion of the CME ejecta is the source for both EUV and radio shock emissions. Early in the CME expansion phase, the Type-II burst seems to originate in the sheath region between the EUV bubble and the EUV shock front in both radial and lateral directions. This suggests that both the nose and the flanks of the expanding bubble could have driven the shock.

### **Observation of galactic cosmic ray spallation events from the SoHO mission 20-Year operation of LASCO**

S. [Koutchmy](#), [E. Tavabi](#), [O. Urtado](#)

MNRAS 2018

<https://arxiv.org/ftp/arxiv/papers/1805/1805.04930.pdf>

A shower of secondary Cosmic Ray (CR) particles is produced at high altitudes in the Earth's atmosphere, so the primordial Galactic Cosmic Rays (GCRs) are never directly measured outside the Earth magnetosphere and atmosphere. They approach the Earth and other planets in the complex pattern of rigidity's dependence, generally excluded by the magnetosphere. GCRs revealed by images of single nuclear reactions also called spallation events are described here. Such an event was seen on **Nov. 29, 2015** using a unique LASCO C3 space coronagraph routine image taken during the

Solar and Heliospheric Observatory (SoHO) mission observing uninterruptedly at the Lagrangian L1 point. The spallation signature of a GCR identified well outside the Earth's magnetosphere is obtained for the 1st time. The resulting image includes different diverging linear "tracks" of varying intensity, leading to a single pixel, this frame identifies the site on the silicon CCD chip of the coronagraph camera. There was no solar flare reported at that time, nor Coronal Mass Ejection (CME) and no evidence of optical debris around the spacecraft. More examples of smaller CR events have been discovered through the 20 years of continuous observations from SoHO. This is the first spallation event from a CR, recorded outside the Earth's magnetosphere. We evaluate the probable energy of these events suggesting a plausible galactic source. **14th July 2000**

## **Analysis and interpretation of a fast limb CME with eruptive prominence, C-flare, and EUV dimming**

S. [Koutchmy](#)<sup>1</sup>, V. Slemzin<sup>2</sup>, B. Filippov<sup>3</sup>, J.-C. Noens<sup>4</sup>, D. Romeuf<sup>5</sup>, and L. Golub<sup>6</sup>  
A&A 483, 599-608 (2008)

DOI: 10.1051/0004-6361:20078311

*Aims.* Coronal mass ejections or CMEs are large dynamical solar-corona events. The mass balance and kinematics of a fast limb CME, including its prominence progenitor and the associated flare, will be compared with computed magnetic structures to look for their origin and effect.

*Methods.* Multi-wavelength ground-based and spaceborne observations are used to study a fast W-limb CME event of **December 2, 2003**, taking into account both on and off disk observations. Its erupting prominence is measured at high cadence with the Pic du Midi full H  $\alpha$  line-flux imaging coronagraph. EUV images from SOHO/EIT and CORONAS-F/SPIRIT space instruments are processed including difference imaging. SOHO/LASCO images are used to study the mass excess and motions. Computed coronal structures from extrapolated surface magnetic fields are compared to observations.

*Results.* A fast bright expanding coronal loop is identified in the region recorded slightly later by GOES as a C7.2 flare, followed by a brightening and an acceleration phase of the erupting material with both cool and hot components. The total coronal radiative flux dropped by ~7% in the 19.5 nm channel and by 4% in the 17.5 nm channel, revealing a large dimming effect at and above the limb over a 2 h interval. The typical 3-part structure observed 1 h later by the Lasco C2 and C3 coronagraphs shows a core shaped similarly to the eruptive filament/prominence. The total measured mass of the escaping CME (~1.5x10<sup>16</sup> g from C2 LASCO observations) definitely exceeds the estimated mass of the escaping cool prominence material although assumptions made to analyze the H  $\alpha$  erupting prominence, as well as the corresponding EUV darkening of the filament observed several days before, made this evaluation uncertain by a factor of 2. This mass budget suggests that the event is not confined to the eruption region alone. From the current free extrapolation we discuss the shape of the magnetic neutral surface and a possible scenario leading to an instability, including the small scale dynamics inside and around the filament.

## **Connecting the Properties of Coronal Shock Waves with those of Solar Energetic Particles**

<https://iopscience.iop.org/article/10.3847/1538-4357/ab15d7/pdf>

We develop and exploit a new catalog of coronal pressure waves modeled in 3D to study the potential role of these waves in accelerating solar energetic particles (SEPs) measured in situ. Our sample comprises modeled shocks and SEP events detected during solar cycle 24 observed over a broad range of longitudes. From the 3D reconstruction of shock waves using coronagraphic observations we derived the 3D velocity along the entire front as a function of time. Combining new reconstruction techniques with global models of the solar corona, we derive the 3D distribution of basic shock parameters such as Mach numbers, compression ratios, and shock geometry. We then model in a time-dependent manner how the shock wave connects magnetically with spacecraft making in situ measurements of SEPs. This allows us to compare modeled shock parameters deduced at the magnetically well-connected regions, with different key parameters of SEPs such as their maximum intensity. This approach accounts for projection effects associated with remote-sensing observations and constitutes the most extensive study to date of shock waves in the corona and their relation to SEPs. We find a high correlation between the maximum flux of SEPs and the strength of coronal shock waves quantified, for instance, by the Mach number. We discuss the implications of that work for understanding particle acceleration in the corona. **13 Dec 2006, 2012 July 23**

Proceedings of IAUS 388 **2024**

<https://arxiv.org/pdf/2411.10110>

We present the observations of a quiescent filament eruption and its deflection from the radial direction. The event occurred in the southern solar hemisphere on **2021 May 9** and was observed by the Atmospheric Imaging Assembly (AIA) on board the Solar Dynamics Observatory (SDO), by the STEREO A Observatory and GONG. Part of the filament erupted in the west direction, while major part of the filament deviated towards east direction. LASCO

observed a very weak CME towards the west direction where it faded quickly. Moreover, the eruption was associated with CME observed by STEREO A COR1 and COR2. Our observations provide the evidence that the filament eruption was highly non-radial in nature

### **The Coronal Analysis of SHocks and Waves (CASHeW) Framework**

Coronal Bright Fronts (CBF) are large-scale wavelike disturbances in the solar corona, related to solar eruptions. They are observed in extreme ultraviolet (EUV) light as transient bright fronts of finite width, propagating away from the eruption source. Recent studies of individual solar eruptive events have used EUV observations of CBFs and metric radio type II burst observations to show the intimate connection between low coronal waves and coronal mass ejection (CME)-driven shocks. EUV imaging with the Atmospheric Imaging Assembly (AIA) instrument on the Solar Dynamics Observatory (SDO) has proven particularly useful for detecting CBFs, which, combined with radio and in situ observations, holds great promise for early CME-driven shock characterization capability. This characterization can further be automated, and related to models of particle acceleration to produce estimates of particle fluxes in the corona and in the near Earth environment early in events. We present a framework for the Coronal Analysis of SHocks and Waves (CASHeW). It combines analysis of NASA Heliophysics System Observatory data products and relevant data-driven models, into an automated system for the characterization of off-limb coronal waves and shocks and the evaluation of their capability to accelerate solar energetic particles (SEPs). The system utilizes EUV observations and models written in the Interactive Data Language (IDL). In addition, it leverages analysis tools from the SolarSoft package of libraries, as well as third party libraries. We have tested the CASHeW framework on a representative list of coronal bright front events. Here we present its features, as well as initial results. With this framework, we hope to contribute to the overall understanding of coronal shock waves, their importance for energetic particle acceleration, as well as to the better ability to forecast SEP events fluxes.

[http://www.astro.bas.bg/SES2017/Kozarevetal\\_SES2017.pdf](http://www.astro.bas.bg/SES2017/Kozarevetal_SES2017.pdf)

Coronal mass ejections (CMEs), one of the most energetic manifestations of solar activity, are complex events, which combine multiple related phenomena occurring on the solar surface, in the extended solar atmosphere (corona), as well as in interplanetary space. We present here an outline of a new collaborative project between scientists from the Bulgarian Academy of Sciences (BAS), Bulgaria and the University of Graz, Austria. The goal of this research project is to answer the following questions: 1) What are the properties of erupting filaments, CMEs, and CME-driven shock waves near the Sun, and of associated solar energetic particle (SEP) fluxes in interplanetary space? 2) How are these properties related to the coronal acceleration of SEPs? To achieve the scientific goals of this project, we will use remote solar observations with high spatial and temporal resolution to characterize the early stages of coronal eruption events in a systematic way - studying the pre-eruptive behavior of filaments and flares during energy build-up, the kinematics and morphology of CMEs and compressive shock waves, and the signatures of high energy non-thermal particles in both remote and in situ observations.

### **Properties of a Coronal Shock Wave as A Driver of Early SEP Acceleration**

Kamen A. [Kozarev](#), John C. Raymond, Vasili V. Lobzin, Michael Hammer

ApJ 799 167 2015

<http://arxiv.org/pdf/1406.2363v1.pdf>

Coronal mass ejections (CMEs) are thought to drive collisionless shocks in the solar corona, which in turn have been shown capable of accelerating solar energetic particles (SEPs) in minutes. It has been notoriously difficult to extract information about energetic particle spectra in the corona, due to lack of in-situ measurements. It is possible, however, to combine remote observations with data-driven models in order to deduce coronal shock properties relevant to the local acceleration of SEPs and their heliospheric connectivity to near-Earth space. We present such novel analysis applied to the **May 11, 2011** CME event on the western solar limb, focusing on the evolution of the eruption-driven, dome-like shock wave observed by the Atmospheric Imaging Assembly (AIA) EUV telescopes on board the Solar Dynamics Observatory spacecraft. We analyze the shock evolution and estimate its strength using emission measure modeling. We apply a new method combining a geometric model of the shock front with a potential field source surface model to estimate time-dependent field-to-shock angles and heliospheric connectivity during shock passage in the low corona. We find that the shock was weak, with an initial speed of ~450 km/s. It was initially mostly quasi-parallel, but significant portion of it turned quasi-perpendicular later in the event. There was good magnetic connectivity to near-

Earth space towards the end of the event as observed by the AIA instrument. The methods used in this analysis hold a significant potential for early characterization of coronal shock waves and forecasting of SEP spectra based on remote observations.

<http://arxiv.org/pdf/1406.2377v1.pdf>

The acceleration of protons and electrons to high (sometimes GeV/nucleon) energies by solar phenomena is a key component of space weather. These solar energetic particle (SEP) events can damage spacecraft and communications, as well as present radiation hazards to humans. In-depth particle acceleration simulations have been performed for idealized magnetic fields for diffusive acceleration and particle propagation, and at the same time the quality of MHD simulations of coronal mass ejections (CMEs) has improved significantly. However, to date these two pieces of the same puzzle have remained largely decoupled. Such structures may contain not just a shock but also sizable sheath and pileup compression regions behind it, and may vary considerably with longitude and latitude based on the underlying coronal conditions. In this work, we have coupled results from a detailed global three-dimensional MHD time-dependent CME simulation to a global proton acceleration and transport model, in order to study time-dependent effects of SEP acceleration between 1.8 and 8 solar radii in the **2005 May 13** CME. We find that the source population is accelerated to at least 100 MeV, with distributions enhanced up to six orders of magnitude. Acceleration efficiency varies strongly along field lines probing different regions of the dynamically evolving CME, whose dynamics is influenced by the large-scale coronal magnetic field structure. We observe strong acceleration in sheath regions immediately behind the shock.

In order to analyze the influence of a Coronal Mass Ejection (CME) on the coronal streamer belt, we made 3-D reconstructions of the electron density in the corona at heliospheric distances from 1.5 to 4 R<sub>☉</sub>; for periods before and after a CME occurred. The reconstructions were performed using a tomography technique. We studied two CME cases: (i) a slow CME on **1 June 2008**; (ii) two fast CMEs on **31 December 2007** and **2 January 2008**. For the first case of slow CME, it was found: (i) the potential magnetic field configuration in the CME initiation region before the CME does not agree with the coronal density structure while after the CME the agreement between the field and density is much better. This could be manifestation of that the field was non-potential before the CME and after the CME the field relaxes towards a more potential state. (ii) It was shown that the dimming caused by the slow CME is not due to rotation of the corona and a line-of-sight (LOS) effect but a streamer blow out effect took place

### **Are CMEs capable of producing Moreton waves? A case study: the 2006 December 6 event**

G. [Krause](#); [M. Cécere](#); [E. Zurbriggen](#); [A. Costa](#); [C. Francile](#) ...

*Monthly Notices of the Royal Astronomical Society*, Volume 474, Issue 1, 11 February **2018**, Pages 770–778, <https://doi.org/10.1093/mnras/stx2817>

<https://academic.oup.com/mnras/article/474/1/770/4688933>

Considering the chromosphere and a stratified corona, we examine, by performing 2D compressible magnetohydrodynamics simulations, the capability of a coronal mass ejection (CME) scenario to drive a Moreton wave. We find that given a typical flux rope (FR) magnetic configuration, in initial pseudo-equilibrium, the larger the magnetic field and the lighter (and hotter) the FR, the larger the amplitude and the speed of the chromospheric disturbance, which eventually becomes a Moreton wave. We present arguments to explain why Moreton waves are much rarer than CME occurrences. In the frame of the present model, we explicitly exclude the action of flares that could be associated with the CME. Analysing the Mach number, we find that only fast magnetosonic shock waves will be able to produce Moreton events. In these cases an overexpansion of the FR is always present and it is the main factor responsible for the Moreton generation. Finally, we show that this scenario can account for the Moreton wave of the **2006 December 6** event (Francile et al. 2013).

This paper investigates the solar source region of supra-thermal (few keV up to the MeV range) electron beams observed near Earth by combining in situ measurements of the three-dimensional Plasma and Energetic Particles experiment on the WIND spacecraft with remote-sensing hard X-ray observations by the Reuven Ramaty High Energy Solar Spectroscopic Imager. The in situ observations are used to identify events, and the hard X-ray observations are then searched for signatures of supra-thermal electrons radiating bremsstrahlung emission in the solar atmosphere. Only prompt events detected above 50 keV with a close temporal correlation between the flare hard X-ray emission and the electrons seen near Earth are selected, limiting the number of events to 16. We show that for 7 of these 16 events, hard X-ray imaging shows three chromospheric sources: two at the footpoints of the post-flare loop and one related to an apparently open field line. The remaining events show two footpoints (seven events, four of which show elongated sources possibly hiding a third source) or are spatially unresolved (two events). Out of the 16 events, 6 have a solar source region within the field of view of the Transition Region and Corona Explorer (TRACE). All events with TRACE data show EUV jets that have the same onset as the hard X-ray emission (within the cadence of tens of seconds). After the hard X-ray burst ends, the jets decay. These results suggest that escaping prompt supra-thermal electron events observed near Earth are accelerated in flares associated with reconnection between open and closed magnetic field lines, the so-called interchange reconnection scenario.

<http://arxiv.org/pdf/1606.04301v1.pdf>

Coronal mass ejections (CMEs) are large-scale eruptions of magnetized plasma that may cause severe geomagnetic storms if Earth-directed. Here we report a rare instance with comprehensive in situ and remote sensing observations of a CME combining white-light, radio, and plasma measurements from four different vantage points. For the first time, we have successfully applied a radio direction-finding technique to an interplanetary type II burst detected by two identical widely separated radio receivers. The derived locations of the type II and type III bursts are in general agreement with the white light CME reconstruction. We find that the radio emission arises from the flanks of the CME, and are most likely associated with the CME-driven shock. Our work demonstrates the complementarity between radio triangulation and 3D reconstruction techniques for space weather applications. **2013 November 29**

## **Determining the dynamics and magnetic fields in He I 10830 Å during a solar filament eruption**

<https://arxiv.org/pdf/2006.10473.pdf>

<https://www.aanda.org/articles/aa/pdf/2020/08/aa38408-20.pdf>

We investigate the dynamics and magnetic properties of the plasma, such as line-of-sight velocity (LOS), optical depth, vertical and horizontal magnetic fields, belonging to an erupted solar filament. The filament eruption was observed with the GREGOR Infrared Spectrograph (GRIS) at the 1.5-meter GREGOR telescope on **2016 July 3**. Three consecutive full-Stokes slit-spectropolarimetric scans in the He I 10830 Å spectral range were acquired. The Stokes I profiles were classified using the machine learning k-means algorithm and then inverted with different initial conditions using the HAZEL code. The erupting-filament material presents the following physical conditions: (1) ubiquitous upward motions with peak LOS velocities of ~73 km/s; (2) predominant large horizontal components of the magnetic field, on average, in the range of 173-254 G, whereas the vertical components of the fields are much lower, on average between 39-58 G; (3) optical depths in the range of 0.7-1.1. The average azimuth orientation of the field lines between two consecutive raster scans (<2.5 minutes) remained constant. The analyzed filament eruption belonged to the fast rising phase, with total velocities of about 124 km/s. The orientation of the magnetic field lines does not change from one raster scan to the other, indicating that the untwisting phase has not started yet. The untwisting seems to start about 15 min after the beginning of the filament eruption.

## **Direct Imaging of a Prolonged Plasma/Current Sheet and Quasiperiodic Magnetic Reconnection on the Sun**

ApJ **2024**

<https://arxiv.org/pdf/2407.07687>

Magnetic reconnection is widely believed to be the fundamental process in the solar atmosphere that underlies magnetic energy release and particle acceleration. This process is responsible for the onset of solar flares, coronal mass ejections, and other explosive events (e.g., jets). Here, we report direct imaging of a prolonged plasma/current sheet along with quasiperiodic magnetic reconnection in the solar corona using ultra-high-resolution observations from the 1.6-meter Goode Solar Telescope (GST) at BBSO and Solar Dynamics Observatory/Atmospheric Imaging Assembly (SDO/AIA). The current sheet appeared near a null point in the fan-spine topology and persisted over an extended period (~20 hours). The length and apparent width of the current sheet were about 6 arcsec and 2 arcsec respectively, and the plasma temperature was ~10-20 MK. We observed quasiperiodic plasma inflows and outflows (bidirectional jets with plasmoids) at the reconnection site/current sheet. Furthermore, quasiperiodic reconnection at the long-lasting current sheet produced recurrent eruptions (small flares and jets) and contributed significantly to the recurrent impulsive heating of the active region. Direct imaging of a plasma/current sheet and recurrent null-point reconnection for such an extended period has not been reported previously. These unprecedented observations provide compelling evidence that supports the universal model for solar eruptions (i.e., the breakout model) and have implications for impulsive heating of active regions by recurrent reconnection near null points. The prolonged and sustained reconnection for about 20 hours at the breakout current sheet provides new insights into the dynamics and energy release processes in the solar corona. **August 22, 2022**

## **Magnetohydrodynamics simulation of magnetic flux rope formation in a quadrupolar magnetic field configuration**

[Sanjay Kumar](#), [Avijeet Prasad](#), [Sushree S. Nayak](#), [Satyam Agarwal](#), [R. Bhattacharyya](#)  
**2023**

<https://arxiv.org/pdf/2307.06025.pdf>

Magnetic flux ropes (MFRs) play an important role in high-energetic events like solar flares and coronal mass ejections in the solar atmosphere. Importantly, solar observations suggest an association of some flaring events with quadrupolar magnetic configurations. However, the formation and subsequent evolution of MFRs in such magnetic configurations still need to be fully understood. In this paper, we present idealized magnetohydrodynamics (MHD) simulations of MFR formation in a quadrupolar magnetic configuration. A suitable initial magnetic field having a quadrupolar configuration is constructed by modifying a three-dimensional (3D) linear force-free magnetic field. The initial magnetic field contains neutral lines, which consist of X-type null points. The simulated dynamics initially demonstrate the oppositely directed magnetic field lines located across the polarity inversion lines (PILs) moving towards each other, resulting in magnetic reconnections. Due to these reconnections, four highly twisted MFRs form over the PILs. With time, the foot points of the MFRs move towards the X-type neutral lines and reconnect, generating complex magnetic structures around the neutral lines, thus making the MFR topology more complex in the quadrupolar configuration than those formed in bipolar loop systems. Further evolution reveals the non-uniform rise of the MFRs. Importantly, the simulations indicate that the pre-existing X-type null points in magnetic configurations can be crucial to the evolution of the MFRs and may lead to the observed brightenings during the onset of some flaring events in the quadrupolar configurations.

## **Plasmoids, Flows, and Jets During Magnetic Reconnection in a Failed Solar Eruption**

ApJ **943** 156 **2023**

<https://arxiv.org/pdf/2212.11159.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/acaea4/pdf>

We report a detailed analysis of a failed eruption and flare in active region 12018 on **2014 April 3** using multiwavelength observations from SDO/AIA, IRIS, STEREO, and Hinode/SOT. At least four jets were observed to

emanate from the cusp of this small active region (large bright point) with a null-point topology during the two hours prior to the slow rise of a filament. During the filament slow rise multiple plasma blobs were seen, most likely formed in a null-point current sheet near the cusp. The subsequent filament eruption, which was outside the IRIS field of view, was accompanied by a flare but remained confined. During the explosive flare reconnection phase, additional blobs appeared repetitively and moved bidirectionally within the flaring region below the erupting filament. The filament kinked, rotated, and underwent leg-leg reconnection as it rose, yet it failed to produce a coronal mass ejection. Tiny jet-like features in the fan loops were detected during the filament slow-rise/pre-flare phase. We interpret them as signatures of reconnection between the ambient magnetic field and the plasmoids leaving the null-point sheet and streaming along the fan loops. We contrast our interpretation of these tiny jets, which occur within the large-scale context of a failed filament eruption, with the local nanoflare-heating scenario proposed by Antolin et al. (2021).

### **Kink Oscillation of a Flux Rope During a Failed Solar Eruption**

[Pankaj Kumar](#), [Valery M. Nakariakov](#), [Judith T. Karpen](#), [C. Richard DeVore](#), [Kyung-Suk Cho](#)

ApJL **932** L9 **2022**

<https://arxiv.org/pdf/2205.03480.pdf>

<https://iopscience.iop.org/article/10.3847/2041-8213/ac6e3e/pdf>

We report a decaying kink oscillation of a flux rope during a confined eruptive flare, observed off the solar limb by SDO/AIA, that lacked a detectable white-light coronal mass ejection. The erupting flux rope underwent kinking, rotation, and apparent leg-leg interaction during the event. The oscillations were observed simultaneously in multiple AIA channels at 304, 171, and 193 Å, indicating that multithermal plasma was entrained in the rope. After reaching the overlying loops in the active region, the flux rope exhibited large-amplitude, decaying kink oscillations with an apparent initial amplitude of 30 Mm, period of about 16 min, and decay time of about 17 min. We interpret these oscillations as a fundamental standing kink mode of the flux rope. The oscillation polarization has a clear vertical component, while the departure of the detected waveform from a sinusoidal signal suggests that the oscillation could be circularly or elliptically polarized. The estimated kink speed is 1080 km/s, corresponding to an Alfvén speed of about 760 km/s. This speed, together with the estimated electron density in the rope from our DEM analysis,  $n_e \approx (1.5\text{--}2.0) \times 10^9 \text{ cm}^{-3}$ , yields a magnetic field strength of about 15 G. To the best of our knowledge, decaying kink oscillations of a flux rope with non-horizontal polarization during a confined eruptive flare have not been reported before. These oscillations provide unique opportunities for indirect measurements of the magnetic-field strength in low-coronal flux ropes during failed eruptions. **2014 April 3**

### **Quasiperiodic Energy Release and Jets at the Base of Solar Coronal Plumes**

ApJ **933** 21 **2022**

<https://arxiv.org/pdf/2204.13871.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac6c24/pdf>

Coronal plumes are long, ray-like, open structures, which have been considered as possible sources for the solar wind. Their origin in the largely unipolar coronal holes has long been a mystery. Earlier spectroscopic and imaging observations revealed blue-shifted plasma and propagating disturbances (PDs) in plumes that are widely interpreted in terms of flows and/or propagating slow-mode waves, but these interpretations (flows vs waves) remain under debate. Recently we discovered an important clue about plume internal structure: dynamic filamentary features called plumelets, which account for most of the plume emission. Here we present high-resolution observations from the Solar Dynamics Observatory/Atmospheric Imaging Assembly (SDO/AIA) and the Interface Region Imaging Spectrograph (IRIS) that revealed numerous, quasiperiodic, tiny jets (so-called jetlets) associated with transient brightening, flows, and plasma heating at the chromospheric footpoints of the plumelets. By analogy to larger coronal jets, these jetlets are most likely produced within the plume base by magnetic reconnection between closed and open flux at stressed 3D null points. The jetlet-associated brightenings are in phase with plumelet-associated PDs, and vary with a period of about 3 to 5 minutes, which is remarkably consistent with the photospheric/chromospheric p-mode oscillation. This reconnection at the open-closed boundary in the chromosphere/transition region is likely modulated or driven by local manifestations of the global p-mode waves. The jetlets extend upward to become plumelets, contribute mass to the solar wind, and may be sources of the switchbacks recently detected by the Parker Solar Probe. **19 Mar 2016**

### **From Pseudostreamer Jets to CMEs: Observations of the Breakout Continuum**

[Pankaj Kumar](#), [Judith T. Karpen](#), [Spiro K. Antiochos](#), [Peter F. Wyper](#), [C. Richard DeVore](#), [Benjamin J. Lynch](#)

**2021 ApJ 907** 41

<https://arxiv.org/pdf/2011.07029.pdf> File

<https://iopscience.iop.org/article/10.3847/1538-4357/abca8b/pdf>

The magnetic breakout model, in which reconnection in the corona leads to destabilization of a filament channel, explains numerous features of eruptive solar events, from small-scale jets to global-scale coronal mass ejections (CMEs). The underlying multipolar topology, pre-eruption activities, and sequence of magnetic reconnection onsets (first breakout, then flare) of many observed fast CMEs/eruptive flares are fully consistent with the model. Recently, we have demonstrated that most observed coronal-hole jets in fan/spine topologies also are induced by breakout reconnection at the null point above a filament channel (with or without a filament). For these two types of eruptions

occurring in similar topologies, the key question is, why do some events generate jets while others form CMEs? We focused on the initiation of eruptions in large bright points/small active regions that were located in coronal holes and clearly exhibited null-point (fan/spine) topologies: such configurations are referred to as pseudostreamers. We analyzed and compared SDO/AIA, SOHO/LASCO, and RHESSI observations of three events. Our analysis of the events revealed two new observable signatures of breakout reconnection prior to the explosive jet/CME outflows and flare onset: coronal dimming and the opening-up of field lines above the breakout current sheet. Most key properties were similar among the selected erupting structures, thereby eliminating region size, photospheric field strength, magnetic configuration, and pre-eruptive evolution as discriminating factors between jets and CMEs. We consider the factors that contribute to the different types of dynamic behavior, and conclude that the main determining factor is the ratio of the magnetic free energy associated with the filament channel compared to the energy associated with the overlying flux inside and outside the pseudostreamer dome. **2015 Jan 12, 2015 April 20, 2015 April 21**

### **First Detection of Plasmoids from Breakout Reconnection on the Sun**

APJL **885** L15 **2019**

<https://arxiv.org/pdf/1909.06637.pdf>

[sci-hub.se/10.3847/2041-8213/ab45f9](https://sci-hub.se/10.3847/2041-8213/ab45f9)

Transient collimated plasma ejections (jets) occur frequently throughout the solar corona, in active regions, quiet Sun, and coronal holes. Although magnetic reconnection is generally agreed to be the mechanism of energy release in jets, the factors that dictate the location and rate of reconnection remain unclear. Our previous studies demonstrated that the magnetic breakout model explains the triggering and evolution of most jets over a wide range of scales, through detailed comparisons between our numerical simulations and high-resolution observations. An alternative explanation, the resistive-kink model, invokes breakout reconnection without forming and explosively expelling a flux rope. Here we report direct observations of breakout reconnection and plasmoid formation during two jets in the fan-spine topology of an embedded bipole. For the first time, we observed the formation and evolution of multiple small plasmoids with bidirectional flows associated with fast reconnection in 3D breakout current sheets in the solar corona. The first narrow jet was launched by reconnection at the breakout current sheet originating at the deformed 3D null, without significant flare reconnection or a filament eruption. In contrast, the second jet and release of cool filament plasma were triggered by explosive breakout reconnection when the leading edge of the rising flux rope formed by flare reconnection beneath the filament encountered the preexisting breakout current sheet. These observations solidly support both reconnection-driven jet models: the resistive kink for the first jet, and the breakout model for the second explosive jet with a filament eruption. **2014 May 1**

### **Multiwavelength Study of Equatorial Coronal-Hole Jets**

Pankaj [Kumar](#), [Judith T. Karpen](#), [Spiro K. Antiochos](#), [Peter F. Wyper](#), [C. Richard DeVore](#), [Craig E. DeForest](#)

ApJ **873** 93 **2019**

<https://arxiv.org/pdf/1902.00922.pdf>

[sci-hub.se/10.3847/1538-4357/ab04af](https://sci-hub.se/10.3847/1538-4357/ab04af)

Jets (transient/collimated plasma ejections) occur frequently throughout the solar corona and contribute mass/energy to the corona and solar wind. By combining numerical simulations and high-resolution observations, we have made substantial progress recently on determining the energy buildup and release processes in these jets. Here we describe a study of 27 equatorial coronal-hole jets using Solar Dynamics Observatory/AIA and HMI observations on **2013 June 27-28 and 2014 January 8-10**. Out of 27 jets, 18 (67%) are associated with mini-filament ejections; the other 9 (33%) do not show mini-filament eruptions but do exhibit mini-flare arcades and other eruptive signatures. This indicates that every jet in our sample involved a filament-channel eruption. From the complete set of events, 6 jets (22%) are apparently associated with tiny flux-cancellation events at the polarity inversion line, and 2 jets (7%) are associated with sympathetic eruptions of filaments from neighboring bright points. Potential-field extrapolations of the source-region photospheric magnetic fields reveal that all jets originated in the fan-spine topology of an embedded bipole associated with an extreme ultraviolet coronal bright point. Hence, all our jets are in agreement with the breakout model of solar eruptions. We present selected examples and discuss the implications for the jet energy build-up and initiation mechanisms.

### **Evidence For The Magnetic Breakout Model in an Equatorial Coronal-Hole Jet**

Pankaj [Kumar](#), [Judith T. Karpen](#), [Spiro K. Antiochos](#), [Peter F. Wyper](#), [C. Richard DeVore](#), [Craig E. DeForest](#)

ApJ **854** 155 **2018**

<https://arxiv.org/pdf/1801.08582.pdf>

<http://sci-hub.tw/http://iopscience.iop.org/0004-637X/854/2/155/>

Small, impulsive jets commonly occur throughout the solar corona, but are especially visible in coronal holes. Evidence is mounting that jets are part of a continuum of eruptions that extends to much larger coronal mass ejections and eruptive flares. Because coronal-hole jets originate in relatively simple magnetic structures, they offer an ideal testbed for theories of energy buildup and release in the full range of solar eruptions. We analyzed an equatorial coronal-hole jet observed by SDO/AIA on **09 January 2014**, in which the magnetic-field structure was consistent with the embedded-bipole topology that we identified and modeled previously as an origin of coronal jets. In addition, this event

contained a mini-filament, which led to important insights into the energy storage and release mechanisms. SDO/HMI magnetograms revealed footpoint motions in the primary minority-polarity region at the eruption site, but show negligible flux emergence or cancellation for at least 16 hours before the eruption. Therefore, the free energy powering this jet probably came from magnetic shear concentrated at the polarity inversion line within the embedded bipole. We find that the observed activity sequence and its interpretation closely match the predictions of the breakout jet model, strongly supporting the hypothesis that the breakout model can explain solar eruptions on a wide range of scales.

### **Characteristics of Radio-Loud CMEs**

Pankaj **Kumar**, P.K. Manoharan, K.S. Cho

2017

[https://www.researchgate.net/publication/315637846\\_Characteristics\\_of\\_radio-loud\\_CMEs](https://www.researchgate.net/publication/315637846_Characteristics_of_radio-loud_CMEs)

In this paper, we study the characteristics of 46 radio-loud (RL) Coronal Mass Ejections (CMEs), which occurred during 1997-2006. All these RL CMEs were associated with M- and X-class flares. We selected 46 RL CMEs, out of which 26 events (57%) were associated with Solar Energetic Particle (SEP) events detected at 1 AU. Furthermore, we study the link between the flare accelerated electrons in the low corona and protons at 1 AU and found a positive correlation (30%). It suggests the link between the injection sites for electrons and protons, which are most likely accelerated at the flare current sheet. We also study the relation between the CME speed and peak proton flux ( $>10$  MeV) at 1 AU and found a good correlation ( $\sim 60\%$ ), which suggests the proton acceleration by CME driven shocks. In addition, we found two branches (lower and upper) of SEP events with different characteristics. The lower branch SEP events are associated with impulsive rise along with more proton flux whereas the upper branch SEP events exhibit gradual rise and less proton flux. We suggest that flares (current sheet) and CMEs (shocks) both are involved in the particle acceleration for the lower branch, whereas in the upper branch mostly CME driven shocks play an important role in the particle acceleration. **2 May 1998, 29 March, 2001**

### **Multiwavelength Observations of a Flux Rope Formation by Series of Magnetic Reconnection in the Chromosphere**

Pankaj **Kumar**, Vasylyur Yurchyshyn, Kyung-Suk Cho, Haimin Wang

A&A 603, A36 2017

<https://arxiv.org/pdf/1703.09871.pdf>

Using high-resolution observations from the 1.6 m New Solar Telescope (NST) operating at the Big Bear Solar Observatory (BBSO), we report direct evidence of merging/reconnection of cool H $\alpha$  loops in the chromosphere during two homologous flares (B- and C-class) caused by a shear motion at the footpoint of two loops. The reconnection between these loops caused the formation of an unstable flux rope which showed counterclockwise rotation. The flux rope could not reach the height of torus instability and failed to form a coronal mass ejection. The HMI magnetograms revealed rotation of the negative/positive (N1/P2) polarity sunspots in the opposite directions, which increased the right and left-handed twist in the magnetic structures rooted at N1/P2. Rapid photospheric flux cancellation (duration  $\sim 20$ -30 min, rate  $\sim 3.44 \times 10^{20}$  Mx h $^{-1}$ ) was observed during and even after the first B6.0 flare and continued until the end of the second C2.3 flare. The RHESSI X-ray sources were located at the site of the loop's coalescence. To the best of our knowledge, such a clear interaction of chromospheric loops along with rapid flux cancellation has not been reported before. These high-resolution observations suggest the formation of a small flux rope by a series of magnetic reconnection within chromospheric loops associated with very rapid flux cancellation. **23 May 2015**

### **On the role of repetitive magnetic reconnections in evolution of magnetic flux-ropes in solar corona**

Sanjay **Kumar**, R. Bhattacharyya, Bhuwan Joshi, P. K. Smolarkiewicz

2016

<http://arxiv.org/pdf/1609.08260v1.pdf>

Parker's magnetostatic theorem extended to astrophysical magnetofluids with large magnetic Reynolds number supports *ceaseless regeneration of current sheets and hence, spontaneous magnetic reconnections recurring in time*.

Consequently, a scenario is possible where the repeated reconnections provide an autonomous mechanism governing emergence of coherent structures in astrophysical magnetofluids. In this work, such a scenario is explored by performing numerical computations commensurate with the magnetostatic theorem. In particular, the computations explore the evolution of a flux-rope governed by repeated reconnections in a magnetic geometry resembling bipolar loops of solar corona. The revealed morphology of the evolution process, including onset and ascent of the rope, reconnection locations and the associated topology of the magnetic field lines, agrees with observations, and thus substantiates physical realisability of the advocated mechanism.

### **ON THE ROLE OF REPETITIVE MAGNETIC RECONNECTIONS IN EVOLUTION OF MAGNETIC FLUX ROPES IN SOLAR CORONA**

Sanjay **Kumar**<sup>1</sup>, R. Bhattacharyya<sup>1</sup>, Bhuwan Joshi<sup>1</sup>, and P. K. Smolarkiewicz

2016 ApJ 830 80

Parker's magnetostatic theorem, extended to astrophysical magnetofluids with large magnetic Reynolds number, supports ceaseless regeneration of current sheets and, hence, spontaneous magnetic reconnections recurring in time. Consequently, a scenario is possible where the repeated reconnections provide an autonomous mechanism governing emergence of coherent structures in astrophysical magnetofluids. In this work, such a scenario is explored by performing numerical computations commensurate with the magnetostatic theorem. In particular, the computations explore the evolution of a flux rope governed by repeated reconnections in a magnetic geometry resembling bipolar loops of solar corona. The revealed morphology of the evolution process—including onset and ascent of the rope, reconnection locations, and the associated topology of the magnetic field lines—agrees with observations, and thus substantiates physical realizability of the advocated mechanism.

## **Formation and Eruption of a Small Flux Rope in the Chromosphere Observed by NST, IRIS, and SDO**

Pankaj **Kumar**, Vasyl Yurchyshyn, Haimin Wang, Kyung-Suk Cho

ApJ 809 83 2015

<http://arxiv.org/pdf/1507.01761v1.pdf>

Using high-resolution images from 1.6 m New Solar Telescope (NST) at Big Bear Solar Observatory (BBSO), we report the direct evidence of chromospheric reconnection at the polarity inversion line (PIL) between two small opposite polarity sunspots. Small jet-like structures (with velocities of  $\sim 20$ - $55$  km/s) were observed at the reconnection site before the onset of the first M1.0 flare. The slow rise of untwisting jets was followed by the onset of cool plasma inflow ( $\sim 10$  km/s) at the reconnection site, causing the onset of a two-ribbon flare. The reconnection between two sheared J-shaped cool H $\alpha$  loops causes the formation of a small twisted flux rope (S shaped) in the chromosphere. In addition, Helioseismic and Magnetic Imager (HMI) magnetograms show the flux cancellation (both positive and negative) during the first M1.0 flare. The emergence of negative flux and cancellation of positive flux (with shear flows) continue until the successful eruption of the flux rope. The newly formed chromospheric flux rope becomes unstable and rises slowly with the speed of  $\sim 108$  km/s during a second C8.5 flare that occurred after  $\sim 3$  hours of the first M1.0 flare. The flux rope was destroyed by repeated magnetic reconnection induced by its interaction with the ambient field (fan-spine topology) and looks like an untwisting surge ( $\sim 170$  km/s) in the coronal images recorded by Solar Dynamic Observatory/Atmospheric Imaging Assembly (SDO/AIA). These observations suggest the formation of a chromospheric flux rope (by magnetic reconnection associated with flux cancellation) during the first M1.0 flare and its subsequent eruption/disruption during the second C8.5 flare. **12 June 2014**

## **Multiwavelength observation of a large-scale flux rope eruption above kinked mini-filament**

Pankaj **Kumar**, Kyung-Suk Cho

A&A, 572, A83 2014

<http://.org/pdf/1409.7213v1.pdf>

We analyse multiwavelength observations of a western limb flare (C3.9) occurred in AR NOAA 111465 on **30 April 2012**. The high resolution images recorded by SDO/AIA 304, 1600 \AA and Hinode/SOT H $\alpha$  show the activation of a mini-filament (rising speed  $\sim 40$  km s $^{-1}$ ) associated with kink instability and the onset of a C-class flare near the southern leg of the filament. The first magnetic reconnection occurred at one of the footpoints of the filament causing the breaking of its southern leg. The filament shows unwinding motion of the northern leg and apex in the counterclockwise direction and failed to erupt. A flux-rope (visible only in hot channels, i.e., AIA 131 and 94 \AA channels and Hinode/SXT) structure was appeared along the neutral line during the second magnetic reconnection taking place above the kinked filament. Formation of the RHESSI hard X-ray source (12-25 keV) above the kinked filament and simultaneous appearance of the hot 131 \AA loops associated with photospheric brightenings (AIA 1700 \AA) suggest the particle acceleration along these loops from the top of the filament. In addition, EUV disturbances/waves observed above the filament in 171 \AA also show a close association with magnetic reconnection. The flux rope rises slowly ( $\sim 100$  km s $^{-1}$ ) producing a rather big twisted structure possibly by reconnection with the surrounding sheared magnetic fields within  $\sim 15$ - $20$  minutes, and showed an impulsive acceleration reaching a height of about 80--100 Mm. AIA 171 and SWAP 174 \AA images reveal a cool compression front (or CME frontal loop) surrounding the hot flux rope structure.

## **Simultaneous EUV and radio observations of bidirectional plasmoids ejection during magnetic reconnection\***

Pankaj **Kumar** and Kyung-Suk Cho

A&A 557, A115 (2013)

We present a multiwavelength study of the X-class flare, which occurred in active region (AR) NOAA 11339 on **3 November 2011**. The extreme ultraviolet (EUV) images recorded by SDO/AIA show the activation of a remote filament (located north of the AR) with footpoint brightenings about 50 min prior to the flare's occurrence. The kinked filament rises up slowly, and after reaching a projected height of  $\sim 49$  Mm, it bends and falls freely near the AR, where the X-class flare was triggered. Dynamic radio spectrum from the Green Bank Solar Radio Burst Spectrometer

(GBSRBS) shows simultaneous detection of both positive and negative drifting pulsating structures (DPSs) in the decimetric radio frequencies (500–1200 MHz) during the impulsive phase of the flare. The global negative DPSs in solar flares are generally interpreted as a signature of electron acceleration related to the upward-moving plasmoids in the solar corona. The EUV images from AIA 94 Å reveal the ejection of multiple plasmoids, which move simultaneously upward and downward in the corona during the magnetic reconnection. The estimated speeds of the upward- and downward-moving plasmoids are  $\sim 152$ – $362$  and  $\sim 83$ – $254$  km s<sup>-1</sup>, respectively. These observations strongly support the recent numerical simulations of the formation and interaction of multiple plasmoids due to tearing of the current-sheet structure. On the basis of our analysis, we suggest that the simultaneous detection of both the negative and positive DPSs is most likely generated by the interaction or coalescence of the multiple plasmoids moving upward and downward along the current-sheet structure during the magnetic reconnection process. Moreover, the differential emission measure (DEM) analysis of the active region reveals a hot flux-rope structure (visible in AIA 131 and 94 Å) prior to the flare initiation and ejection of the multitemperature plasmoids during the flare impulsive phase.

## **Multiwavelength Study of a Solar Eruption from AR NOAA 11112:**

### **II. Large-Scale Coronal Wave and Loop Oscillation**

Pankaj [Kumar](#)<sup>1</sup>, K.-S. Cho<sup>1, 2, 3</sup>, P. F. Chen<sup>4</sup>, S.-C. Bong<sup>1</sup> and Sung-Hong Park

Solar Physics, February **2013**, Volume 282, Issue 2, pp 523-541, [File](#)

We analyze multiwavelength observations of an M2.9/1N flare that occurred in AR NOAA 11112 on **16 October 2010**. AIA 211 Å EUV images reveal the presence of a faster coronal wave (decelerating from  $\approx 1390$  to  $\approx 830$  km s<sup>-1</sup>) propagating ahead of a slower wave (decelerating from  $\approx 416$  to  $\approx 166$  km s<sup>-1</sup>) towards the western limb. The dynamic radio spectrum from Sagamore Hill radio telescope shows the presence of a metric type II radio burst, which reveals the presence of a coronal shock wave (speed  $\approx 800$  km s<sup>-1</sup>). The speed of the faster coronal wave, derived from AIA 211 Å images, is found to be comparable to the coronal shock speed. AIA 171 Å high-cadence observations showed that a coronal loop, which was located at a distance of  $\approx 0.32R_{\odot}$  to the west of the flaring region, started to oscillate by the end of the impulsive phase of the flare. The results indicate that the faster coronal wave may be the first driver of the transversal oscillations of coronal loop. As the slower wave passed through the coronal loop, the oscillations became even stronger. There was a plasmoid eruption observed in EUV and a white-light CME was recorded, having velocity of  $\approx 340$ – $350$  km s<sup>-1</sup>. STEREO 195 Å images show an EIT wave, propagating in the same direction as the lower-speed coronal wave observed in AIA, but decelerating from  $\approx 320$  to  $\approx 254$  km s<sup>-1</sup>. These observations reveal the co-existence of both waves (i.e. coronal Moreton and EIT waves), and the type II radio burst seems to be associated with the coronal Moreton wave.

## **Multiwavelength Study of a Solar Eruption from AR NOAA 11112**

### **I. Flux Emergence, Sunspot Rotation and Triggering of a Solar Flare**

Pankaj [Kumar](#), Sung-Hong Park, K.-S. Cho, S.-C. Bong

Solar Physics, February **2013**, Volume 282, Issue 2, pp 503-521

We analyze the multiwavelength observations of an M2.9/1N flare that occurred in the active region (AR) NOAA 11112 in the vicinity of a huge filament system on **16 October 2010**. SDO/HMI magnetograms reveal the emergence of a bipole (within the existing AR) 50 hours prior to the flare event. During the emergence, both the positive and negative sunspots in the bipole show translational as well as rotational motion. The positive-polarity sunspot shows significant motion/rotation in the south-westward/clockwise direction, and we see continuously pushing/sliding of the surrounding opposite-polarity field region. On the other hand, the negative-polarity sunspot moves/rotates in the westward/anticlockwise direction. The positive-polarity sunspot rotates  $\approx 70^\circ$  within 30 hours, whereas the one with negative polarity rotates  $\approx 20^\circ$  within 10 hours. SDO/AIA 94 Å EUV images show the emergence of a flux tube in the corona, consistent with the emergence of the bipole in HMI. The footpoints of the flux tube were anchored in the emerging bipole. The initial brightening starts at one of the footpoints (western) of the emerging loop system, where the positive-polarity sunspot pushes/slides towards a nearby negative-polarity field region. A high speed plasmoid ejection (speed  $\approx 1197$  km s<sup>-1</sup>) was observed during the impulsive phase of the flare, which suggests magnetic reconnection of the emerging positive-polarity sunspot with the surrounding opposite-polarity field region. The entire AR shows positive-helicity injection before the flare event. Moreover, the newly emerging bipole reveals the signature of a negative (left-handed) helicity. These observations provide unique evidence of the emergence of twisted flux tubes from below the photosphere to coronal heights, triggering a flare mainly due to the interaction between the emerging positive-polarity sunspot and a nearby negative-polarity sunspot by the shearing motion of the emerging positive sunspot towards the negative one. Our observations also strongly support the idea that the rotation can most likely be attributed to the emergence of twisted magnetic fields, as proposed by recent models.

## **INITIATION OF CORONAL MASS EJECTION AND ASSOCIATED FLARE CAUSED BY HELICAL KINK INSTABILITY OBSERVED BY SDO/AIA**

Pankaj [Kumar](#), K.-S. Cho<sup>1,2,3</sup>, S.-C. Bong<sup>1</sup>, Sung-Hong Park<sup>1</sup> and Y. H. Kim

2012 ApJ 746 67, [File](#)

In this paper, we present multiwavelength observations of helical kink instability as a trigger of a coronal mass ejection (CME) which occurred in active region NOAA 11163 on **2011 February 24**. The CME was associated with an M3.5 limb flare. High-resolution observations from the Solar Dynamics Observatory/Atmospheric Imaging Assembly suggest the development of helical kink instability in the erupting prominence, which implies a flux rope structure of the magnetic field. A brightening starts below the apex of the prominence with its slow rising motion ( $\sim 100 \text{ km s}^{-1}$ ) during the activation phase. A bright structure, indicative of a helix with  $\sim 3$ -4 turns, was transiently formed at this position. The corresponding twist of  $\sim 6\pi$ - $8\pi$  is sufficient to generate the helical kink instability in a flux rope according to recently developed models. A slowly rising blob structure was subsequently formed at the apex of the prominence, and a flaring loop was observed near the footpoints. Within 2 minutes, a second blob was formed in the northern prominence leg. The second blob erupts (like a plasmoid ejection) with the detachment of the northern prominence leg, and flare intensity maximizes. The first blob at the prominence apex shows rotational motion in the counterclockwise direction in the plane of sky, interpreted as the unwinding motion of a helix, and it also erupts to give the CME. RHESSI hard X-ray (HXR) sources show the two footpoint sources and a loop-top source during the flare. We found RHESSI HXR flux, soft X-ray flux derivative, and CME acceleration in the low corona correlate well, which is in agreement with the standard flare model (CSHKP). We also discuss the possible role of ballooning as well as torus instabilities in driving the CME. We conclude that the CME and flare were triggered by the helical kink instability in a flux rope and accelerated mainly by the torus instability.

### **Multi-Wavelength Observations of a Flux Rope Failed in the Eruption and Associated M-Class Flare from NOAA AR 11045**

Pankaj [Kumar](#)<sup>1;2</sup> \_ A.K. Srivastava<sup>1;4</sup> \_ B. Filippov<sup>3</sup> \_ R. Erdelyi<sup>4</sup> \_ Wahab Uddin<sup>1</sup>  
E-print, July 2011, [File](#);

We present the multi-wavelength observations of a flux rope that was trying to erupt from NOAA AR 11045 and the associated M-class solar flare on **12 February 2010** using space and ground based observations from TRACE, STEREO, SOHO/MDI, Hinode/XRT and BBSO. While the flux rope was rising from the active region, an M1.1/2F class flare was triggered nearby one of its footpoints. We suggest that the flare triggering was due to the reconnection of a rising flux rope with the surrounding low-lying magnetic loops. The flux rope reached a projected height of  $\sim 0.15R_{\odot}$  with a speed of  $\sim 90 \text{ km s}^{-1}$  while the soft X-ray flux enhanced gradually during its rise. The flux rope was suppressed by an overlying field and the field plasma moved towards the negative polarity field to the west of its activation site. We find the first observational evidence of the initial suppression of a flux rope due to a remnant filament visible both at chromospheric and coronal temperatures that evolved couple of days before at the same location in the active region. SOHO/MDI magnetograms show the emergence of a bipole  $\sim 12$  h prior to the flare initiation. The emerged negative polarity moved towards the flux rope activation site, and flare triggering near the photospheric polarity inversion line (PIL) took place. The motion of the negative polarity region towards PIL helped in the build-up of magnetic energy at the flare and flux rope activation site. This study provides a unique observational

### **Effects of optimisation parameters on data-driven magnetofrictional modelling of active regions**

[A. Kumari](#), [D. J. Price](#), [F. Daei](#), [J. Pomoell](#), [E. K. J. Kilpua](#)

A&A 2023

<https://arxiv.org/pdf/2305.16080.pdf>

Data-driven time-dependent magnetofrictional modelling (TMFM) of active region magnetic fields has been proven to be a useful tool to study the corona. The input to the model is the photospheric electric field that is inverted from a time series of the photospheric magnetic field. Constraining the complete electric field, that is, including the non-inductive component, is critical for capturing the eruption dynamics. We present a detailed study of the effects of optimisation of the non-inductive electric field on the TMFM of AR12473. We aim to study the effects of varying the non-inductive electric field on the data-driven coronal simulations, for two alternative parametrisations. By varying parameters controlling the strength of the non-inductive electric field, we wish to explore the changes in flux rope formation and their early evolution and other parameters, for instance, axial flux and magnetic field magnitude. The non-inductive electric field component in the photosphere is critical for energising and introducing twist to the coronal magnetic field, thereby allowing unstable configurations to be formed. We estimated this component using an approach based on optimising the injection of magnetic energy. However, the flux rope formation, evolution and eruption time varies depending on the values of the optimisation parameters. The flux rope is formed and has overall similar evolution and properties with a large range of non-inductive electric fields needed to determine the non-inductive electric field component that is critical for energising and introducing twist to the coronal magnetic field. This study shows that irrespective of non-inductive electric field values, flux ropes are formed and erupted, which indicates that data-driven TMFM can be used to estimate flux rope properties early in their evolution without employing a lengthy optimisation process. **December 22, 2015 to January 02, 2016**

### **On the occurrence of type IV solar radio bursts in the solar cycle 24 and their association with coronal mass ejections**

[Anshu Kumari](#), [D. E. Morosan](#), [E. K. J. Kilpua](#)

2021 ApJ 906 79

<https://arxiv.org/pdf/2011.03509.pdf>  
<https://doi.org/10.3847/1538-4357/abc878>

Solar activity, in particular coronal mass ejections (CMEs), are often accompanied by bursts of radiation at metre wavelengths. Some of these bursts have a long duration and extend over a wide frequency band, namely, type IV radio bursts. However, the association of type IV bursts with coronal mass ejections is still not well understood. In this article, we perform the first statistical study of type IV solar radio bursts in the solar cycle 24. Our study includes a total of 446 type IV radio bursts that occurred during this cycle. Our results show that a clear majority, ~81% of type IV bursts, were accompanied by CMEs, based on a temporal association with white-light CME observations. However, we found that only ~2.2% of the CMEs are accompanied by type IV radio bursts. We categorised the type IV bursts as moving or stationary based on their spectral characteristics and found that only ~18% of the total type IV bursts in this study were moving type IV bursts. Our study suggests that type IV bursts can occur with both 'Fast' ( $\geq 500$  km/s) and 'Slow' ( $< 500$  km/s), and also both 'Wide' ( $\geq 60^\circ$ ) and 'Narrow' ( $< 60^\circ$ ) CMEs. However, the moving type IV bursts in our study were mostly associated with 'Fast' and 'Wide' CMEs (~52%), similar to type II radio bursts. Contrary to type II bursts, stationary type IV bursts have a more uniform association with all CME types. **October 03, 2011, October 18, 2017**

## Strength of the Solar Coronal Magnetic Field – A Comparison of Independent Estimates Using Contemporaneous Radio and White-Light Observations

Anshu [Kumari](#), R. Ramesh, C. Kathiravan, T. J. Wang

[Solar Physics](#) November 2017, 292:161

<https://arxiv.org/pdf/1711.02307.pdf>

We estimated the coronal magnetic field strength (BB) during the **23 July 2016** coronal mass ejection (CME) event using i) the flux rope structure of the CME in the white-light coronagraph images and ii) the band-splitting in the associated type II burst. No models were assumed for the coronal electron density ( $N(r)N(r)$ ) we used in the estimation. The results obtained with these two independent methods correspond to different heliocentric distances ( $r$ ) in the range  $\approx 2.5$ – $4.5 R_\odot$ – $\approx 2.5$ – $4.5 R_\odot$ , but they show excellent consistency and could be fit with a single power-law distribution of the type  $B(r)=5.7r^{-2.6}$  GB( $r)=5.7r^{-2.6}$  G, which is applicable in that distance range. The power-law index (i.e.  $-2.6$ ) is in good agreement with the results obtained in previous studies by different methods.

## New Evidence for a Coronal Mass Ejection-driven High Frequency Type II Burst near the Sun

Anshu [Kumari](#)<sup>1</sup>, R. Ramesh<sup>1</sup>, C. Kathiravan<sup>1</sup>, and N. Gopalswamy

**2017** ApJ 843 10

<http://sci-hub.cc/10.3847/1538-4357/aa72e7>

We report observations of the high frequency type II radio burst ( $\approx 430$ – $30$  MHz) that occurred in the solar corona on **2015 November 4**. The drift rate of the burst, estimated close to the start frequency of its fundamental component ( $\approx 215$  MHz), is unusually high ( $\approx 2$  MHz  $s^{-1}$ ). Our analysis shows that the estimated speed of the magnetohydrodynamic shock driver of the burst varies with time. The peak speed and acceleration are very large,  $\approx 2450$  km  $s^{-1}$  and  $\approx 17$  km  $s^{-2}$ , respectively. There is spatio-temporal correlation between the type II burst and the associated coronal mass ejection (CME) in the whitelight and extreme-ultraviolet images. The time profile of the shock speed and the light curve of the associated soft X-ray flare correlate well. These results indicate that in the present case, (i) the magnetohydrodynamic shock responsible for the high frequency coronal type II burst is driven by the CME and (ii) the time profile of the type II burst shock speed represents the near-Sun kinematics of the CME.

## Simulation of Spectral Observations of an Eruptive Prominence.

[Kupryakov](#), Y.A., Bychkov, K.V., Belova, O.M. et al.

Geomagn. Aeron. 64, 19–23 (**2024**).

<https://doi.org/10.1134/S0016793223600881>

The paper presents the results of an analysis of observations of an eruptive prominence on the MFS and HSFA2 spectrographs of the Ondřejov Observatory (Astronomical Institute, Czech Republic) in the hydrogen, helium, and calcium lines. After spectral processing, the integral radiation fluxes in the lines were determined and the physical parameters of the plasma were calculated theoretically using a model in the absence of local thermodynamic equilibrium. Comparison of the observed and calculated values showed that the observed radiation fluxes in the lines can be explained in a model of stationary gas radiation taking into account the opacity in the spectral lines. To calculate the theoretical fluxes, in some cases, it was necessary to introduce radiation from several layers with different

temperatures and heights. The calculated radiation fluxes agree with the observed ones to within 10%. As a result of the simulation, the main parameters of the plasma of the prominence were obtained: temperature, concentration, etc. The values of the radiation fluxes in the spectral lines are evidence of inhomogeneity of the emitting gas, and there may be regions next to each other with temperatures differing by an order of magnitude.

## **KELVIN–HELMHOLTZ INSTABILITY IN SOLAR CHROMOSPHERIC JETS: THEORY AND OBSERVATION**

D. Kuridze<sup>1,5</sup>, T. V. Zaqarashvili<sup>2,3,4</sup>, V. Henriques<sup>1</sup>, M. Mathioudakis<sup>1</sup>, F. P. Keenan<sup>1</sup>, and A. Hanslmeier<sup>2</sup>

2016 ApJ 830 133

Using data obtained by the high-resolution CRisp Imaging SpectroPolarimeter instrument on the Swedish 1 m Solar Telescope, we investigate the dynamics and stability of quiet-Sun chromospheric jets observed at the disk center. Small-scale features, such as rapid redshifted and blueshifted excursions, appearing as high-speed jets in the wings of the H $\alpha$  line, are characterized by short lifetimes and rapid fading without any descending behavior. To study the theoretical aspects of their stability without considering their formation mechanism, we model chromospheric jets as twisted magnetic flux tubes moving along their axis, and use the ideal linear incompressible magnetohydrodynamic approximation to derive the governing dispersion equation. Analytical solutions of the dispersion equation indicate that this type of jet is unstable to Kelvin–Helmholtz instability (KHI), with a very short (few seconds) instability growth time at high upflow speeds. The generated vortices and unresolved turbulent flows associated with the KHI could be observed as a broadening of chromospheric spectral lines. Analysis of the H $\alpha$  line profiles shows that the detected structures have enhanced line widths with respect to the background. We also investigate the stability of a larger-scale H $\alpha$  jet that was ejected along the line of sight. Vortex-like features, rapidly developing around the jet's boundary, are considered as evidence of the KHI. The analysis of the energy equation in the partially ionized plasma shows that ion–neutral collisions may lead to fast heating of the KH vortices over timescales comparable to the lifetime of chromospheric jets.

## **Failed filament eruption inside a coronal mass ejection in active region 11121\***

D. Kuridze<sup>1,4</sup>, M. Mathioudakis<sup>1</sup>, A. F. Kowalski<sup>2</sup>, P. H. Keys<sup>1</sup>, D. B. Jess<sup>1,5</sup>, K. S. Balasubramaniam<sup>3</sup> and F. P. Keenan

A&A 552, A55 (2013)

**Aims.** We study the formation and evolution of a failed filament eruption observed in NOAA active region 11121 near the southeast limb on **November 6, 2010**.

**Methods.** We used a time series of SDO/AIA 304, 171, 131, 193, 335, and 94 Å images, SDO/HMI magnetograms, as well as ROSA and ISOON H $\alpha$  images to study the erupting active region.

**Results.** We identify coronal loop arcades associated with a quadrupolar magnetic configuration, and show that the expansion and cancellation of the central loop arcade system over the filament is followed by the eruption of the filament. The erupting filament reveals a clear helical twist and develops the same sign of writhe in the form of inverse  $\gamma$ -shape.

**Conclusions.** The observations support the “magnetic breakout” process in which the eruption is triggered by quadrupolar reconnection in the corona. We propose that the formation mechanism of the inverse  $\gamma$ -shape flux rope is the magnetohydrodynamic helical kink instability. The eruption has failed because of the large-scale, closed, overlying magnetic loop arcade that encloses the active region.

## **MAGNETIC FIELD STRUCTURES TRIGGERING SOLAR FLARES AND CORONAL MASS EJECTIONS**

K. Kusano<sup>1,4</sup>, Y. Bamba<sup>1</sup>, T. T. Yamamoto<sup>1</sup>, Y. Iida<sup>2,5</sup>, S. Toriumi<sup>2,5</sup>, and A. Asai

2012 ApJ 760 31

Solar flares and coronal mass ejections, the most catastrophic eruptions in our solar system, have been known to affect terrestrial environments and infrastructure. However, because their triggering mechanism is still not sufficiently understood, our capacity to predict the occurrence of solar eruptions and to forecast space weather is substantially hindered. Even though various models have been proposed to determine the onset of solar eruptions, the types of magnetic structures capable of triggering these eruptions are still unclear. In this study, we solved this problem by systematically surveying the nonlinear dynamics caused by a wide variety of magnetic structures in terms of three-dimensional magnetohydrodynamic simulations. As a result, we determined that two different types of small magnetic structures favor the onset of solar eruptions. These structures, which should appear near the magnetic polarity inversion line (PIL), include magnetic fluxes reversed to the potential component or the nonpotential component of major field on the PIL. In addition, we analyzed two large flares, the X-class flare on **2006 December 13** and the M-class flare on **2011 February 13**, using imaging data provided by the Hinode satellite, and we demonstrated that they conform to the simulation predictions. These results suggest that forecasting of solar eruptions is possible with sophisticated observation of a solar magnetic field, although the lead time must be limited by the timescale of changes in the small magnetic structures.

## Development and Parameters of a Non-Self-Similar CME Caused by Eruption of a Quiescent Prominence

I.V. [Kuzmenko](#) (1), [V.V. Grechnev](#)

Solar Phys. 292:143 2017

<https://arxiv.org/pdf/1709.01226.pdf> File

<https://link.springer.com/content/pdf/10.1007%2Fs11207-017-1167-3.pdf>

The eruption of a large quiescent prominence on **17 August 2013** and associated coronal mass ejection (CME) were observed from different vantage points by Solar Dynamics Observatory (SDO), Solar-Terrestrial Relations Observatory (STEREO), and Solar and Heliospheric Observatory (SOHO). Screening of the quiet Sun by the prominence produced an isolated negative microwave burst. We estimated parameters of the erupting prominence from a model of radio absorption and measured from 304 Å images. Their variations obtained by both methods are similar and agree within a factor of two. The CME development was studied from the kinematics of the front and different components of the core and their structural changes. The results are verified using movies in which the CME expansion was compensated according to the measured kinematics. We found that the CME mass ( $3.6 \times 10^{15}$  g) was mainly supplied by the prominence ( $\approx 6 \times 10^{15}$  g), while a considerable part drained back. The mass of the coronal-temperature component did not exceed  $10^{15}$  g. The CME was initiated by the erupting prominence, which constituted its core and remained active. The structural and kinematical changes started in the core and propagated outward. The CME structures continued to form during expansion, which did not become self-similar up to  $25R_{\odot}$ . The aerodynamic drag was insignificant. The core formed until  $4R_{\odot}$ . Some of its components were observed to straighten and stretch forward, indicating the transformation of tangled structures of the core into a simpler flux rope, which grew and filled the cavity as the CME expanded.

## Synthetic radio views on simulated solar flux ropes

Alexey [Kuznetsov](#), Rony Keppens, Chun Xia

Solar Phys. 2016

<http://arxiv.org/pdf/1601.02370v1.pdf>

In this paper, we produce synthetic radio views on simulated flux ropes in the solar corona, where finite-beta magnetohydrodynamic (MHD) simulations serve to mimic the flux rope formation stages, as well as their stable endstates. These endstates represent twisted flux ropes where balancing Lorentz forces, gravity and pressure gradients determine the full thermodynamic variation throughout the flux rope. The obtained models are needed to quantify radiative transfer in radio bands, and allow us to contrast weak to strong magnetic field conditions. Field strengths of up to 100 G in the flux rope yield the radio views dominated by optically thin free-free emission. The forming flux rope shows clear morphological changes in its emission structure as it deforms from an arcade to a flux rope, both on disk and at the limb. For an active region filament channel with a field strength of up to 680 G in the flux rope, gyroresonance emission (from the third-fourth gyrolayers) can be detected and even dominates over free-free emission at the frequencies of up to 7 GHz. Finally, we also show synthetic views on a simulated filament embedded within a (weak-field) flux rope, resulting from an energetically consistent MHD simulation. For this filament, synthetic views at the limb show clear similarities with actual observations, and the transition from optically thick (below 10 GHz) to optically thin emission can be reproduced. On the disk, its dimension and temperature conditions are as yet not realistic enough to yield the observed radio brightness depressions.

## The density compression ratio of shock fronts associated with coronal mass ejections

Ryun-Young [Kwon](#), [Angelos Vourlidis](#)

Journal of Space Weather and Space Climate 8, A08 2018

<https://arxiv.org/pdf/1801.04355.pdf>

<https://www.swsc-journal.org/articles/swsc/pdf/2018/01/swsc170031.pdf>

We present a new method to extract the three-dimensional electron density profile and density compression ratio of shock fronts associated with Coronal Mass Ejections (CMEs) observed in white light coronagraph images. We demonstrate the method with two examples of fast halo CMEs ( $\sim 2000 \text{ km s}^{-1}$ ) observed on **2011 March 7** and **2014 February 25**. Our method uses the ellipsoid model to derive the three-dimensional (3D) geometry and kinematics of the fronts. The density profiles of the sheaths are modeled with double-Gaussian functions with four free parameters and the electrons are distributed within thin shells behind the front. The modeled densities are integrated along the lines of sight to be compared with the observed brightness in COR2-A, and a  $\chi^2$  approach is used to obtain the optimal parameters for the Gaussian profiles. The upstream densities are obtained from both the inversion of the brightness in a pre-event image and an empirical model. Then the density ratio and Alfvénic Mach number are derived. We find that the density compression peaks around the CME nose, and decreases at larger position angles. The behavior is consistent with a driven shock at the nose and a freely-propagating shock wave at the CME flanks. Interestingly, we find that the supercritical region extends over a large area of the shock and last longer (several tens of minutes) than past reports. *It follows that CME shocks are capable of accelerating energetic particles in the corona over extended spatial and temporal scales and are likely responsible for the wide longitudinal distribution of these particles in the inner heliosphere.* Our results also demonstrate the power of multi-viewpoint coronagraphic observations and forward modeling in remotely deriving key shock properties in an otherwise inaccessible regime.

## Investigating the Wave Nature of the Outer Envelope of Halo Coronal Mass Ejections

Ryun-Young [Kwon](#)<sup>1,3</sup> and Angelos Vourlidas<sup>2</sup>

2017 ApJ 836 246

<http://sci-hub.cc/doi/10.3847/1538-4357/aa5b92>

We investigate the nature of the outer envelope of halo coronal mass ejections (H-CMEs) using multi-viewpoint observations from the Solar Terrestrial Relations Observatory-A, -B, and Solar and Heliospheric Observatory coronagraphs. The 3D structure and kinematics of the halo envelopes and the driving CMEs are derived separately using a forward modeling method. We analyze three H-CMEs with peak speeds from 1355 to 2157 km s<sup>-1</sup>; sufficiently fast to drive shocks in the corona. We find that the angular widths of the halos range from 192° to 252°, while those of the flux ropes range between only 58° and 91°, indicating that the halos are waves propagating away from the CMEs. The halo widths are in agreement with widths of Extreme Ultraviolet (EUV) waves in the low corona further demonstrating the common origin of these structures. To further investigate the wave nature of the halos, we model their 3D kinematic properties with a linear fast magnetosonic wave model. The model is able to reproduce the position of the halo flanks with realistic coronal medium assumptions but fails closer to the CME nose. The CME halo envelope seems to arise from a driven wave (or shock) close to the CME nose, but it is gradually becoming a freely propagating fast magnetosonic wave at the flanks. This interpretation provides a simple unifying picture for CME halos, EUV waves, and the large longitudinal spread of solar energetic particles. **2011 March 7, 2013 April 11, and 2014 February 25**

## THREE-DIMENSIONAL GEOMETRY OF A CURRENT SHEET IN THE HIGH SOLAR CORONA: EVIDENCE FOR RECONNECTION IN THE LATE STAGE OF THE CORONAL MASS EJECTIONS

Ryun-Young [Kwon](#)<sup>1,2</sup>, Angelos Vourlidas<sup>2</sup>, and David Webb

2016 ApJ 826 94

Motivated by the standard flare model, ray-like structures in the wake of coronal mass ejections (CMEs) have been often interpreted as proxies of the reconnecting current sheet connecting the CME with the postflare arcade. We present the three-dimensional properties of a post-CME ray derived from white light images taken from three different viewing perspectives on **2013 September 21**. By using a forward modeling method, the direction, cross section, and electron density are determined within the heliocentric distance range of 5–9 R<sub>☉</sub>. The width and depth of the ray are  $0.42 \pm 0.08 R_{\odot}$  and  $1.24 \pm 0.35 R_{\odot}$ , respectively, and the electron density is  $(2.0 \pm 0.5) \times 10^4 \text{ cm}^{-3}$ , which seems to be constant with height. Successive blobs moving outward along the ray are observed around 13 hr after the parent CME onset. We model the three-dimensional geometry of the parent CME with the Gradual Cylindrical Shell model and find that the CME and ray are coaxial. We suggest that coaxial post-CME rays, seen in coronagraph images, with successive formation of blobs could be associated with current sheets undergoing magnetic reconnection in the late stage of CMEs.

## Are Halo-like Solar Coronal Mass Ejections Merely a Matter of Geometric Projection Effects?

Ryun-Young [Kwon](#), Jie Zhang, and Angelos Vourlidas

2015 ApJ 799 L29

[http://spaceweather.gmu.edu/public/rkwon/manuscript\\_halo\\_CMEs/manuscript.pdf](http://spaceweather.gmu.edu/public/rkwon/manuscript_halo_CMEs/manuscript.pdf)

We investigated the physical nature of halo coronal mass ejections (CMEs) based on the stereoscopic observations from the two STEREO spacecraft, Ahead and Behind (hereafter A and B), and the SOHO spacecraft. Sixty-two halo CMEs occurred as observed by SOHO LASCO C2 for the three-year period from 2010 to 2012 during which the separation angles between SOHO and STEREO were nearly 90°. In such quadrature configuration, the coronagraphs of STEREO, COR2-A and -B, showed the side view of those halo CMEs seen by C2. It has been widely believed that the halo appearance of a CME is caused by the geometric projection effect, i.e., a CME moves along the Sun-observer line. In other words, it would appear as a non-halo CME if viewed from the side. However, to our surprise, we found that 41 out of 62 events (66%) were observed as halo CMEs by all coronagraphs. This result suggests that a halo CME is not just a matter of the propagating direction. In addition, we show that a CME propagating normal to the line of sight can be observed as a halo CME due to the associated fast magnetosonic wave or shock front. We conclude that the apparent width of CMEs, especially halos or partial halos is driven by the existence and the extent of the associated waves or shocks and does not represent an accurate measure of the CME ejecta size. This effect needs to be taken into careful consideration in space weather predictions and modeling efforts. **2012 March 18**

## NEW INSIGHTS INTO THE PHYSICAL NATURE OF CORONAL MASS EJECTIONS AND ASSOCIATED WAVES/SOCKS WITHIN THE FRAMEWORK OF THREE-DIMENSIONAL STRUCTURE

Ryun-Young [Kwon](#), Jie Zhang, and Oscar Olmedo

ApJ, 794 148 **2014**

<http://spaceweather.gmu.edu/public/rkwon/> **File**

We present new insights into the physical nature of coronal mass ejections (CMEs) and associated shock waves within the framework of the three-dimensional (3D) structure. We have developed a compound model in order to determine the 3D structure of multiple fronts composing a CME, using data sets taken from STEREO, SDO, and SOHO. We applied the method to time series observations of a CME on **2012 March 7**. From the analyses, we revealed that a CME could

consist of two different fronts: one is represented well with the ellipsoid model, implying that CMEs are bubble-shaped structures and the other is reproduced well with the graduated cylindrical shell model, indicating that CMEs are flux rope-shaped structures. The bubble-shaped structure is seen as the outermost front of the CME, and the flux rope-shaped structure is seen as the bright frontal loop or three-part morphology. From our results, we conclude that (1) a CME could consist of two distinct structures, a bubble shaped structure and a flux rope-shaped structure, (2) the bubble-shaped structure is a fast magnetosonic shock wave while the flux rope-shaped structure is the mass carried outward by the underlying magnetic structure, (3) the driven shock front could be either a piston-shock type or a bow-shock type, (4) the observed EUV wave in the low corona is the footprint of the bubble-shaped wave, and (5) the halo CME is primarily the projection of the bubble-shaped shock wave but not the underlying flux rope.

## **Global Coronal Seismology in the Extended Solar Corona through Fast Magnetosonic Waves Observed by STEREO SECCHI COR1**

Ryun-Young [Kwon](#)<sup>1,2,3</sup>, Maxim Kramar<sup>1,2</sup>, Tongjiang Wang<sup>1,2</sup>, Leon Ofman<sup>1,2,4</sup>, Joseph M. Davila<sup>2</sup>, Jongchul Chae<sup>5</sup>, and Jie Zhang

2013 ApJ 776 55

We present global coronal seismology for the first time, which allows us to determine inhomogeneous magnetic field strength in the extended corona. From the measurements of the propagation speed of a fast magnetosonic wave associated with a **coronal mass ejection (CME)** and the coronal background density distribution derived from the polarized radiances observed by the STEREO SECCHI COR1, we determined the **magnetic field strengths** along the trajectories of the wave at different heliocentric distances. We found that the results have an uncertainty less than 40%, and are consistent with values determined with a potential field model and reported in previous works. The characteristics of the coronal medium we found are that (1) the density, magnetic field strength, and plasma  $\beta$  are lower in the **coronal hole** region than in streamers; (2) the magnetic field strength decreases slowly with height but the electron density decreases rapidly so that the local fast magnetosonic speed increases while plasma  $\beta$  falls off with height; and (3) the variations of the local fast magnetosonic speed and plasma  $\beta$  are dominated by variations in the electron density rather than the magnetic field strength. These results imply that **Moreton and EIT waves** are downward-reflected fast magnetosonic waves from the upper solar corona, rather than freely propagating fast magnetosonic waves in a certain atmospheric layer. In addition, the azimuthal components of CMEs and the driven waves may play an important role in various manifestations of shocks, such as **type II radio bursts and solar energetic particle events**.

## **Survey of Magnetic Helicity Injection in Regions Producing X-Class Flares**

[LaBonte](#), B. J., [Georgoulis](#), M. K., & [Rust](#), D. M.

E-print, Aug. 2007

we surveyed magnetic helicity injection into 48 X-flare producing active regions recorded by the MDI between 1996 July and 2005 July.

Most of the X-flare regions generated the helicity needed for a CME in a few days to a few hours.

## **The Evolution of Ion Charge States in Coronal Mass Ejections**

[J. Martin Laming](#), [Elena Provornikova](#), [Yuan-Kuen Ko](#)

ApJ 954 145 2023

<https://arxiv.org/pdf/2307.15762.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/acebc2/pdf>

We model the observed charge states of the elements C, O, Mg, Si, and Fe in the coronal mass ejections (CMEs) ejecta. We concentrate on "halo" CMEs observed in situ by ACE/SWICS to measure ion charge states, and also remotely by STEREO when in near quadrature with Earth, so that the CME expansion can be accurately specified. Within this observed expansion, we integrate equations for the CME ejecta ionization balance, including electron heating parameterized as a fraction of the kinetic and gravitational energy gain of the CME. We also include the effects of non-Maxwellian electron distributions, characterized as a kappa function. Focusing first on the **2010 April 3** CME, we find a somewhat better match to observed charge states with kappa in the range 2-4, close to the theoretical minimum value of kappa = 3/2, implying a hard spectrum of non-thermal electrons. Similar, but more significant results come from the **2011 February 15** event, although it is quite different in terms of its evolution. We discuss the implications of these values, and of the heating required, in terms of the magnetic reconnection Lundquist number and anomalous resistivity associated with CME evolution close to the Sun.

## **Observing Solar Coronal Mass Ejections from Space**

[Philippe Lamy](#)

Proceedings of the IAU Symposium 388, 2024

<https://arxiv.org/pdf/2407.08354>

**Review**

In this contribution to the panel discussion of the IAU Symposium 388 "Solar and Stellar Coronal Mass Ejections", I concentrate on white-light observations of solar coronal mass ejections (CMEs) from space and specifically address the following aspects: i) history of observations, ii) available catalogs of CMEs, iii) achievements of space observations of CMEs, iv) future of CME observation, and v) challenges and future directions.

## **The State of the White-Light Corona over the Minimum and Ascending Phases of Solar Cycle 25 -- Comparison with Past Cycles**

Philippe **Lamy** (1), [Hugo Gilardy](#) (1)

Solar Phys. **297**, Article number: 140 **2022**

<https://arxiv.org/pdf/2205.06462.pdf>

<https://doi.org/10.1007/s11207-022-02057-7>

We report on the state of the corona over the minimum and ascending phases of Solar Cycle (SC) 25 on the basis of the temporal evolutions of its radiance and of the properties of coronal mass ejections (CMEs) as determined from white-light observations performed by the SOHO/LASCO-C2 coronagraph. These evolutions are further compared with those determined during the past two SC. The integrated radiance of the K-corona and the occurrence rate of CMEs closely track the indices/proxies of solar activity, prominently the total magnetic field for the radiance and the radio flux for the CMEs, all undergoing a steep increase during the ascending phase of SC 25. This increase is much steeper than anticipated on the basis of the predicted quasi similarity between SC 25 and 24, and is confirmed by the recent evolution of the sunspot number. The radiance reached the same base level during the minima of SC 24 and 25, but the latitudinal extent of the streamer belt differed, being flatter during the latter minimum and in fact more similar to that of the minimum of SC 23. Phasing the descending branches of SC 23 and 24 led to a duration of SC 24 of 11.0 years, similar to that given by the sunspot number. In contrast, the base level of the occurrence rate of CMEs during the minimum of SC 25 was significantly larger than during the two previous minima. The southern hemisphere is conspicuously more active than the northern one in agreement with several predictions and the current evolution of the hemispheric sunspot numbers. The mean apparent width of CMEs and the number of halo CMEs remains at relatively large, constant levels throughout the early phase of SC 25 implying the persistence of weak total pressure in the heliosphere. These results and the perspective of a corona more active than anticipated are extremely promising for the forthcoming observations by Solar Orbiter and Parker Solar Probe.

## **Coronal Mass Ejections over Solar Cycles 23 and 24**

**Review**

P. L. **Lamy**, [O. Floyd](#), [B. Boclet](#), [J. Wojak](#), [H. Gilardy](#)...

*Space Science Reviews* August **2019**, 215:39

<https://link.springer.com/content/pdf/10.1007%2Fs11214-019-0605-y.pdf>

We present a statistical analysis of solar coronal mass ejections (CMEs) based on 23 years of quasi-continuous observations with the LASCO coronagraph, thus covering two complete Solar Cycles (23 and 24). We make use of five catalogs, one manual (CDAW) and four automated (ARTEMIS, CACTus, SEEDS, and CORIMP), to characterize the temporal evolutions and distributions of their properties: occurrence and mass rates, waiting times, periodicities, angular width, latitude, speed, acceleration and kinetic energy. Our analysis points to inevitable discrepancies between catalogs due to the complex nature of CMEs and to the different techniques implemented to detect them, but also to large areas of convergence that are critically important to ascertain the reliability of the results. The temporal variations of these properties are compared to four indices/proxies of solar activity: the radio flux at 10.7 cm (F10.7), the international sunspot number (SSN), the sunspot area (SSA), and the total magnetic field (TMF), either globally or separately in the northern and southern hemispheres in the case of the last three. We investigate the association of CMEs with flares, erupting prominences, active regions and streamers. We find that the CME occurrence and mass rates globally track the indices/proxies of solar activity with no time lag, prominently the radio flux F10.7, but the linear relationships were different during the two solar cycles, implying that the CME rates were relatively larger during SC 24 than during SC 23. However, there exists a pronounced divergence of the CME rates in the northern hemisphere during SC 24 as these rates were substantially larger than predicted by the temporal variation of the sunspot number. The distribution of kinetic energy follows a log-normal law and that of angular width follows an exponential law implying that they are random and independent. The distribution of waiting time (WTD) has a long power-law tail extending from 3 to 100 hr with a power-law index which varies with the solar cycle, thus reflecting the temporal variability of the process of CME formation. There is very limited evidence for periodicities in the occurrence and mass rates of CMEs, a striking feature being the dichotomy between the two hemispheres. Rather weak correlations are present among the various CME parameters and particularly none between speed and acceleration. The association of CMEs with flares and erupting prominences involves only a few percents of the overall population of CMEs but the associated CMEs have distinctly larger mass, speed, kinetic energy and angular width. A more pronounced association is found with active regions but the overwhelming one is with streamers further confirmed by the similarity between the heliolatitudinal distribution of CMEs and that of the electron density reconstructed from time-dependent tomographic inversion. We find no evidence of bimodality in the distributions of physical parameters that would support the existence of two classes, particularly that based on speed and acceleration, the distributions thus favoring a continuum of properties. There exists an excess of narrow CMEs which however does not define a special class. These narrow CMEs are likely associated with the ubiquitous mini-filaments eruptions and with mini flux ropes originating from small magnetic bipoles, the disruption mechanisms being similar to those launching larger CMEs. This supports the concept that CMEs at large arise from closed-field coronal regions at both large and small scales.

## **Anomalous Surge of the White-Light Corona at the Onset of the Declining Phase of Solar Cycle 24**

P. Lamy, B. Boclet, J. Wojak, D. Vibert

Solar Physics April 2017, 292:60

<http://link.springer.com/content/pdf/10.1007%2Fs11207-017-1085-4.pdf>

In late 2014, when the current Solar Cycle 24 entered its declining phase, the white-light corona as observed by the LASCO-C2 coronagraph underwent an unexpected surge that increased its global radiance by 60%, reaching a peak value comparable to the peak values of the more active Solar Cycle 23. A comparison of the temporal variation of the white-light corona with the variations of several indices and proxies of solar activity indicate that it best matches the variation of the total magnetic field. The daily variations point to a localized enhancement or bulge in the electron density that persisted for several months. Carrington maps of the radiance and of the HMI photospheric field allow connecting this bulge to the emergence of the large sunspot complex AR 12192 in October 2014, the largest since AR 6368 observed in November 1990. The resulting unusually high increase of the magnetic field and the distortion of the neutral sheet in a characteristic inverse S-shape caused the coronal plasma to be trapped along a similar pattern. A 3D reconstruction of the electron density based on time-dependent solar rotational tomography supplemented by 2D inversion of the coronal radiance confirms the morphology of the bulge and reveals that its level was well above the standard models of a corona of the maximum type, by typically a factor of 3. A rather satisfactory agreement is found with the results of the thermodynamic MHD model produced by Predictive Sciences, although discrepancies are noted. The specific configuration of the magnetic field that led to the coronal surge resulted from the interplay of various factors prevailing at the onset of the declining phase of the solar cycles, which was particularly efficient in the case of Solar Cycle 24. **18-28 November 2014.**

## **Density Diagnostics of Coronal Mass Ejection Cores with the Solar Dynamics Observatory/Atmospheric Imaging Assembly**

E. Landi<sup>1</sup> and M. P. Miralles

2014 ApJ 780 L7

In this Letter, we investigate the application of the intensity ratio from pairs of narrow-band images from the Atmospheric Imaging Assembly (AIA) on the Solar Dynamics Observatory, the Extreme Ultraviolet (EUV) Imager (EUVI) on board the Sun Earth Connection Coronal and Heliospheric Investigation, and the EUV Imaging Telescope (EIT) on board the Solar and Heliospheric Observatory, to density diagnostics of optically thin plasmas. By inspecting the filtered spectra allowed by each instrument's effective area, we find that ratios between AIA images in the 171 Å and 193 Å channels can be used to determine the plasma electron density at transition region temperatures. This diagnostic potential is due to a pair of O V transitions which dominate the effective spectra of these two channels at temperatures around  $2.5\text{-}3.0 \times 10^5$  K. The temperature and electron density ranges where the 171/193 ratio is density sensitive are relevant for the cores of accelerating coronal mass ejections (CMEs) in the inner solar corona. We discuss how AIA series of images can be used for simultaneous temperature and density diagnostics of CME cores.

## **Hot Plasma Associated with a Coronal Mass Ejection**

E. Landi<sup>1</sup>, M. P. Miralles<sup>2</sup>, J. C. Raymond<sup>2</sup>, and H. Hara

2013 ApJ 778 29

We analyze coordinated observations from the EUV Imaging Spectrometer (EIS) and X-Ray Telescope (XRT) on board Hinode of an X-ray Plasma Ejection (XPE) that occurred during the coronal mass ejection (CME) event of **2008 April 9**. The XPE was trailing the CME core from behind, following the same trajectory, and could be identified both in EIS and XRT observations. Using the EIS spectrometer, we have determined the XPE plasma parameters, measuring the electron density, thermal distribution, and elemental composition. We have found that the XPE composition and electron density were very similar to those of the pre-event active region plasma. The XPE temperature was higher, and its thermal distribution peaked at around 3 MK; also, typical flare lines were absent from EIS spectra, indicating that any XPE component with temperatures in excess of 5 MK was likely either faint or absent. We used XRT data to investigate the presence of hotter plasma components in the XPE that could have gone undetected by EIS and found that—if at all present—these components have small emission measure values and their temperature is in the 8-12.5 MK range. The very hot plasma found in earlier XPE observations obtained by Yohkoh seems to be largely absent in this CME, although plasma ionization timescales may lead to non-equilibrium ionization effects that could make bright lines from ions formed in a 10 MK plasma not detectable by EIS. Our results supersede the XPE findings of Landi et al., who studied the same event with older response functions for the XRT Al-poly filter; the differences in the results stress the importance of using accurate filter response functions.

## **POST-CORONAL MASS EJECTION PLASMA OBSERVED BY HINODE**

E. Landi<sup>1</sup>, J. C. Raymond<sup>2</sup>, M. P. Miralles<sup>2</sup>, and H. Hara

2012 ApJ 751 21

In the present work we study the evolution of an active region after the eruption of a coronal mass ejection (CME) using observations from the EIS and XRT instruments on board Hinode. The field of view includes a post-eruption arcade, a current sheet, and a coronal dimming. The goal of this paper is to provide a comprehensive set of measurements for all these aspects of the CME phenomenon made on the same CME event. The main physical properties of the plasma along the line of sight—electron density, thermal structure, plasma composition, size, and, when possible, mass—are measured and monitored with time for the first three hours following the CME event of **2008 April 9**. We find that the loop arcade observed by EIS and XRT may not be related to the post-eruption arcade. Post-CME plasma is hotter than the surrounding corona, but its temperature never exceeds 3 MK. Both the electron density and thermal structure do not show significant evolution with time, while we found that the size of the loop arcade in the Hinode plane of the sky decreased with time. The plasma composition is the same in the current sheet, in the loop arcade, and in the ambient plasma, so all these plasmas are likely of coronal origin. No significant plasma flows were detected.

## PHYSICAL CONDITIONS IN A CORONAL MASS EJECTION FROM *HINODE*, *STEREO*, AND *SOHO* OBSERVATIONS

E. [Landi1](#), J. C. Raymond<sup>2</sup>, M. P. Miralles<sup>2</sup>, and H. Hara<sup>3</sup>

*Astrophysical Journal*, 711:75–98, **2010** March; **File**

In the present work, we analyze multiwavelength observations from *Hinode*, *Solar and Heliospheric Observatory (SOHO)*, and *STEREO* of the early phases of a coronal mass ejection (CME). We use *Hinode*/EIS and *SOHO*/UVCS high-resolution spectra to measure the physical properties of the CME ejecta as a function of time at 1.1 and 1.9 solar radii. *Hinode*/XRT images are used in combination with EIS spectra to constrain the high temperature plasma properties of the ejecta. SECCHI/EUVI, SECCHI/COR 1, *SOHO*/EIT, and *SOHO*/LASCO images are used to measure the CME trajectory, velocity, and acceleration. The combination of measurements of plane of the sky velocities from two different directions allows us to determine the total velocity of the CME plasma up to 5 solar radii. Plasma properties, dynamical status, thermal structure, and brightness distributions are used to constrain the energy content of the CME plasma and to determine the heating rate. We find that the heating is larger than the kinetic energy, and compare it to theoretical predictions from models of CME plasma heating and acceleration.

## Space, time and velocity association of successive coronal mass ejections

Alejandro [Lara](#). Nat Gopalswamy, [Tatiana Niembro](#), [Román Pérez-Enríquez](#), [Seiji Yashiro](#)

*A&A* 635, A112 **2020**

<https://arxiv.org/pdf/2002.03998.pdf>

<https://doi.org/10.1051/0004-6361/201936016>

Our aim is to investigate the possible physical association between consecutive coronal mass ejections (CMEs). Through a statistical study of the main characteristics of 27761 CMEs observed by SOHO/LASCO during the past 20 years. We found the waiting time (WT) or time elapsed between two consecutive CMEs is <5 hrs for 59% and <25 hrs for 97% of the events, and the CME WTs follow a Pareto Type IV statistical distribution. The difference of the position-angle of a considerable population of consecutive CME pairs is less than 30°, indicating the possibility that their source locations are in the same region. The difference between the speed of trailing and leading consecutive CMEs follows a generalized Student t-distribution. The fact that the WT and the speed difference have heavy-tailed distributions along with a detrended fluctuation analysis shows that the CME process has a long-range dependence. As a consequence of the long-range dependence, we found a small but significant difference between the speed of consecutive CMEs, with the speed of the trailing CME being higher than the speed of the leading CME. The difference is largest for WTs < 2 hrs and tends to be zero for WTs > 10 hrs, and it is more evident during the ascending and descending phases of the solar cycle. We suggest that this difference may be caused by a drag force acting over CMEs closely related in space and time.

## The Source Region of Coronal Mass Ejections

Alejandro [Lara](#)

*The Astrophysical Journal*, Vol. 688, No. 1: 647-655, **2008**.

<http://www.journals.uchicago.edu/doi/abs/10.1086/591725>

We use the large database of coronal mass ejections (CMEs) observed by SOHO LASCO during solar cycle 23 to statistically obtain information about the source regions of CMEs. By determining the functional form of the position angle (P.A.) distribution, we are able to construct a random set of CME direction vectors (DVCME) under the following conditions: (1) assume a radial movement of the CME center of mass and (2) propose a latitude and longitude ( $\lambda$ ,  $\phi$ ) photospheric position for the DVCME in such a way that (3) the distribution of the projected (on the plane of the sky) DVCME must be equal to the observed distribution of position angles. We iteratively adjust the proposed positions ( $\lambda$ ,  $\phi$ ) until both distributions are equal, based on the Kolmogorov-Smirnov statistics. In this way, we obtain a set of DVCME that we use to study the relation between the CME source region and the overall coronal and photospheric magnetic field structures. We found that the CME activity has a small “preference” for the northern hemisphere during the first part of solar cycle, and for the southern hemisphere during the second part. This P.A. asymmetry is related to the overall magnetic field north-south asymmetry. We found also that most CME source regions are situated between high magnetic field regions, and are not necessarily associated to any one such region. For instance, during the

minimum and ascending phase of the cycle, ~85% and ~60%, respectively, of the CME source regions are confined to the equatorial plane ( $\lambda = 0^\circ$ ), between the two active region belts ( $\lambda = \pm 40^\circ$ ). We conclude from this study that CME sources are in general high-altitude magnetic loops, or more precisely, transequatorial loops, occurring during the minimum and ascending phases of the cycle.

### **Short-Period Fluctuations in Coronal Mass Ejection Activity during Solar Cycle 23**

Alejandro [Lara](#) · Andrea Borgazzi · Odim Mendes Jr. · Reinaldo R. Rosa · Margarete Oliveira Domingues  
Solar Phys (2008) 248: 155–166

<http://www.springerlink.com/content/44k0w353n6445633/fulltext.pdf>

We have constructed a time series of the number of coronal mass ejections (CMEs) observed by SOHO/LASCO during solar cycle 23. Using spectral analysis techniques (the maximum entropy method and wavelet analysis) we found short-period (<one year) semiperiodic activity. Among others, we found interesting periodicities at 193, 36, 28, and 25 days. We discuss the implications of such short-period activity in terms of the emergence and escape of magnetic flux from the convection zone, through the low solar atmosphere (where these periodicities have been found for numerous activity parameters), toward interplanetary space. This analysis shows that CMEs remove the magnetic flux in a quasiperiodic process in a way similar to that of magnetic flux emergence and other solar eruptive activity.

### **A statistical study of CMEs associated with metric type II bursts**

A. [Lara](#), N. Gopalswamy, S. Nunes, G. Muñ' oz, and S. Yashiro  
GEOPHYSICAL RESEARCH LETTERS, VOL. 30, NO. 12, 8016, 2003

[sci-hub.se/10.1029/2002GL016481](http://sci-hub.se/10.1029/2002GL016481)

We present a statistical study of the characteristics of CMEs which show temporal association with type II bursts in the metric domain but not in the decameter/hectometric (DH) domain. This study is based on a set of 80 metric (m) type II bursts associated with surface events in the solar western hemisphere. It was found that in general, the distribution of the widths and speeds of the CMEs associated with metric (but not DH) type II bursts are shifted towards higher values compared to those of all CMEs observed by LASCO in the 1996 – 2001 period. We also found that these distributions have lower values than the same distributions of the CMEs associated with DH type II bursts. In terms of energy, this means that the CMEs associated only with metric type II bursts are more energetic (wider and faster) than regular CMEs but less energetic than the CMEs associated with DH type II bursts.

### **Evolution of coronal mass ejections with and without sheaths from the inner to the outer heliosphere: Statistical investigation for 1975 to 2022**

C. [Larrodera](#)<sup>1,2</sup> and M. Temmer<sup>2</sup>

A&A, 685, A89 (2024)

<https://arxiv.org/pdf/2402.16653.pdf>

<https://www.aanda.org/articles/aa/pdf/2024/05/aa48641-23.pdf>

**Aims.** This study covers a thorough statistical investigation of the evolution of interplanetary coronal mass ejections (ICMEs) with and without sheaths through a broad heliocentric distance and temporal range. The analysis treats the sheath and magnetic obstacle (MO) separately in order to gain more insight on their physical properties. In detail, we aim to unravel different characteristics of these structures occurring over the inner and outer heliosphere.

**Methods.** The method is based on a large statistical sample of ICMEs probed over different distances in the heliosphere. For this, information about detection times for the sheath and MO from 13 individual ICME catalogs was collected and crosschecked. The time information was then combined into a main catalog that was used as the basis for the statistical investigation. The data analysis based on this catalog covers a large number of spacecraft missions, enabling in situ solar wind measurements from 1975 to 2022. This allowed us to study the differences between solar cycles.

**Results.** All the structures under study (sheath, MO with and without sheath) show the biggest increase in size together with the largest decrease in density at a distance of ~0.75 AU. At 1 AU, we found different sizes for MOs with and without a sheath, with the former being larger. Up to 1 AU, the upstream solar wind shows the strongest pileup close to the interface with the sheath. For larger distances, the pileup region seems to shift, and it recedes from that interface further into the upstream solar wind. This might refer to a change in the sheath formation mechanism (driven versus non-driven) with heliocentric distance, suggesting the relevance of the CME propagation and the expansion behavior in the outer heliosphere. A comparison to previous studies showed inconsistencies over the solar cycle, which makes more detailed studies necessary in order to fully understand the evolution of ICME structures.

**Appendix A: Description of catalogs** **Table A.1.** References of the individual catalogs used.

## Multiwavelength Stereoscopic Observation of the 2013 May 1 Solar Flare and CME

Erica [Lastufka](#)<sup>1,2</sup>, Säm Krucker<sup>1,3</sup>, Ivan Zimovets<sup>4</sup>, Bulat Nizamov<sup>5</sup>, Stephen White<sup>6</sup>, Satoshi Masuda<sup>7</sup>, Dmitriy Golovin<sup>4</sup>, Maxim Litvak<sup>4</sup>, Igor Mitrofanov<sup>4</sup>, and Anton Sanin<sup>4</sup>

2019 ApJ 886 9

[sci-hub.se/10.3847/1538-4357/ab4a0a](https://sci-hub.se/10.3847/1538-4357/ab4a0a)

A M-class behind-the-limb solar flare on **2013 May 1** (SOL2013-05-01T02:32), accompanied by a ( $\sim 400$  km s<sup>-1</sup>) coronal mass ejection (CME), was observed by several space-based observatories with different viewing angles. We investigated the RHESSI-observed occulted hard X-ray (HXR) emissions that originated at least  $0.1 R_s$  above the flare site. Emissions below  $\sim 10$  keV revealed a hot, extended (11 MK,  $>60''$ ) thermal source from the escaping CME core, with densities around  $10^9$  cm<sup>-3</sup>. In such a tenuous hot plasma, ionization times scales are several minutes, consistent with the nondetection of the hot CME core in SDO/AIA's 131 Å filter. The nonthermal RHESSI source originated from an even larger area ( $\sim 100''$ ) at lower densities ( $10^8$  cm<sup>-3</sup>) located above the hot core, but still behind the CME front. This indicates that the observed part of the nonthermal electrons are not responsible for heating the CME core. Possibly the hot core was heated by nonthermal electrons before it became visible from Earth, meaning that the unocculted part of the nonthermal emission likely originates from a more tenuous part of the CME core, where nonthermal electrons survive long enough to become visible from Earth. Simultaneous HXR spectra from the Mars Odyssey mission, which viewed the flare on disk, indicated that the number of nonthermal electrons  $>20$  keV within the high coronal source is  $\sim 0.1\% - 0.5\%$  compared with the number within the chromospheric flare ribbons. The detection of high coronal HXR sources in this moderate size event suggests that such sources are likely a common feature within solar eruptive events.

## Coronal Mass Ejections with and without DH Type II Radio Bursts

Solar Phys. Volume 290, [Issue 11](#), pp 3365-3377 2015

A statistical analysis of 135 out of 141 X-class flares observed during 1997 – 2012 with and without deca-hectometric (DH) type II radio bursts has been performed. It was found that 79 events (X-class flares and coronal mass ejections – Group I) were associated with DH type II radio bursts and 62 X-class flare events were not. Out of these 62 events without DH type IIs, 56 events (Group II) have location information, and they were selected for this study. Of these 56 events, only 32 were associated with CMEs. Most of the DH-associated X-class events ( $\sim 79\%$ ) were halo CMEs, in contrast to 14% in Group II. The average CME speed of the X-class flares associated with DH type IIs is 1555 km s<sup>-1</sup>, which is nearly twice that of the X-class flare-associated CMEs without DH event (744 km s<sup>-1</sup>). The X-class flares associated with DH radio bursts have a mean flare intensity ( $3.63 \times 10^{-4}$  W m<sup>-2</sup>) that is 38% greater than that of X-class flares without DH radio bursts ( $2.23 \times 10^{-4}$  W m<sup>-2</sup>). In addition to the greater intensity, it is also found that the duration and rise time of flares associated with DH radio emission (DH flares) is more than twice than that of the flares without DH radio emission. When the events were further divided into two categories with respect to their source locations in eastern and western regions, 65% of the events in the radio-loud category (with DH radio bursts) are from the western hemisphere and the remaining 35% are from the eastern hemisphere. On the other hand, in the radio-quiet category (without DH radio bursts), nearly 60% of the events are from the eastern hemisphere in contrast to those of the radio-loud category. It is found that 81% of the events from eastern regions have flare durations  $> 30$  min in the DH-flare category, in contrast to a nearly equal number from the western side for flare durations longer/shorter than 30 min. Similarly, the eastern events in the DH-flare category have a longer average rise-time of 34 min, while the western events have an average flare rise-time of 26 min. On the other hand, the CME speed and flare strength are found to be nearly equal among east and west side events, except that both these parameters are greater for events with DH type IIs.

## The Role of Reconnection in the Onset of Solar Eruptions

[James Leake](#), [Mark Linton](#), [Spiro Antiochos](#)

ApJ 934 10 2022

<https://arxiv.org/pdf/2205.12957.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac74b7/pdf>

Solar eruptive events such as coronal mass ejections and eruptive flares are frequently associated with the emergence of magnetic flux from the convection zone into the corona. We use three dimensional magnetohydrodynamic numerical simulations to study the interaction of coronal magnetic fields with emerging flux and determine the conditions that lead to eruptive activity. A simple parameter study is performed, varying the relative angle between emerging magnetic flux and a pre-existing coronal dipole field. We find that in all cases, the emergence results in a sheared magnetic arcade that transitions to a twisted coronal flux rope via low-lying magnetic reconnection. This structure, however, is constrained by its own outer field, and so is non-eruptive in the absence of reconnection with the overlying coronal field. The amount of this overlying reconnection is determined by the relative angle between the emerged and pre-existing fields. The reconnection between emerging and pre-existing fields is necessary to generate sufficient expansion of the emerging structure so that flare-like reconnection below the coronal flux rope becomes strong enough to trigger its release. Our results imply that the relative angle is the key parameter in determining whether the resultant active regions exhibit eruptive behavior, and is thus a potentially useful candidate for predicting eruptions in newly emerging active regions. More generally, our results demonstrate that the detailed interaction between the convection zone/photosphere and the corona must be calculated self-consistently in order to model solar eruptions accurately.

## **Simulations of Emerging Magnetic Flux. II. The Formation of Unstable Coronal Flux Ropes and the Initiation of Coronal Mass Ejections**

James E. [Leake](#)<sup>1</sup>, Mark G. Linton<sup>2</sup>, and Spiro K. Antiochos

2014 ApJ 787 46

<http://arxiv.org/pdf/1402.2645v2.pdf>

We present results from three-dimensional magnetohydrodynamic simulations of the emergence of a twisted convection zone flux tube into a pre-existing coronal dipole field. As in previous simulations, following the partial emergence of the sub-surface flux into the corona, a combination of vortical motions and internal magnetic reconnection forms a coronal flux rope. Then, in the simulations presented here, external reconnection between the emerging field and the pre-existing dipole coronal field allows further expansion of the coronal flux rope into the corona. After sufficient expansion, internal reconnection occurs beneath the coronal flux rope axis, and the flux rope erupts up to the top boundary of the simulation domain (~36 Mm above the surface). We find that the presence of a pre-existing field, orientated in a direction to facilitate reconnection with the emerging field, is vital to the fast rise of the coronal flux rope. The simulations shown in this paper are able to self-consistently create many of the surface and coronal signatures used by coronal mass ejection (CME) models. These signatures include surface shearing and rotational motions, quadrupolar geometry above the surface, central sheared arcades reconnecting with oppositely orientated overlying dipole fields, the formation of coronal flux ropes underlying potential coronal field, and internal reconnection which resembles the classical flare reconnection scenario. This suggests that proposed mechanisms for the initiation of a CME, such as "magnetic breakout," are operating during the emergence of new active regions.

## **Simulations of Emerging Magnetic Flux. I. The Formation of Stable Coronal Flux Ropes**

James E. [Leake](#)<sup>1</sup>, Mark G. Linton<sup>2</sup>, and Tibor Török

2013 ApJ 778 99

<http://arxiv.org/pdf/1308.6204v1.pdf>

We present results from three-dimensional visco-resistive magnetohydrodynamic simulations of the emergence of a convection zone magnetic flux tube into a solar atmosphere containing a pre-existing dipole coronal field, which is orientated to minimize reconnection with the emerging field. We observe that the emergence process is capable of producing a coronal flux rope by the transfer of twist from the convection zone, as found in previous simulations. We find that this flux rope is stable, with no evidence of a fast rise, and that its ultimate height in the corona is determined by the strength of the pre-existing dipole field. We also find that although the electric currents in the initial convection zone flux tube are almost perfectly neutralized, the resultant coronal flux rope carries a significant net current. These results suggest that flux tube emergence is capable of creating non-current-neutralized stable flux ropes in the corona, tethered by overlying potential fields, a magnetic configuration that is believed to be the source of coronal mass ejections.

## **Tests of Dynamical Flux Emergence as a Mechanism for CME Initiation**

James E. [Leake](#), Mark G. Linton, Spiro K. Antiochos

E-print, 30 July 2010, ApJ, 722:550–565, 2010, [File](#)

Current coronal mass ejection (CME) models set their lower boundary to be in the lower corona. They do not calculate accurately the transfer of free magnetic energy from the convection zone to the magnetically dominated corona because they model the effects of flux emergence using kinematic boundary conditions or simply assume the appearance of flux at these heights. We test the importance of including dynamical flux emergence in CME modeling by simulating, in 2.5D, the emergence of sub-surface flux tubes into different coronal magnetic field configurations. We investigate how much free magnetic energy, in the form of shear magnetic field, is transported from the convection zone to the corona, and whether dynamical flux emergence can drive CMEs. We find that multiple coronal flux ropes can be formed during flux emergence, and although they carry some shear field into the corona, the majority of shear field is confined to the lower atmosphere. Less than 10% of the magnetic energy in the corona is in the shear field, and this, combined with the fact that the coronal flux ropes bring up significant dense material, means that they do not erupt. Our results have significant implications for all CME models which rely on the transfer of free magnetic energy from the lower atmosphere into the corona but which do not explicitly model this transfer. Such studies of flux emergence and CMEs are timely, as we have new capabilities to observe this with Hinode and SDO, and therefore to test the models against observations.

## **Modeling CME encounters at Parker Solar Probe with OSPREI: Dependence on photospheric and coronal conditions**

[Vincent E. Ledvina](#), [Erika Palmerio](#), [Christina Kay](#), [Nada Al-Haddad](#), [Pete Riley](#)

A&A 2023

<https://arxiv.org/pdf/2303.10793.pdf>

Context: Coronal mass ejections (CMEs) are eruptions of plasma from the Sun that travel through interplanetary space and may encounter Earth. CMEs often enclose a magnetic flux rope (MFR), the orientation of which largely determines the CME's geoeffectiveness. Current operational CME models do not model MFRs, but a number of research ones do, including the Open Solar Physics Rapid Ensemble Information (OSPREDI) model. Aims: We report the sensitivity of OSPREDI to a range of user-selected photospheric and coronal conditions. Methods: We model four separate CMEs observed in situ by Parker Solar Probe (PSP). We vary the input photospheric conditions using four input magnetograms (HMI Synchronic, HMI Synoptic, GONG Synoptic Zero-Point Corrected, and GONG ADAPT). To vary the coronal field reconstruction, we employ the Potential-Field Source-Surface (PFSS) model and we vary its source-surface height in the range 1.5--3.0  $R_{\odot}$  with 0.1  $R_{\odot}$  increments. Results: We find that both the input magnetogram and PFSS source surface often affect the evolution of the CME as it propagates through the Sun's corona into interplanetary space, and therefore the accuracy of the MFR prediction compared to in-situ data at PSP. There is no obvious best combination of input magnetogram and PFSS source surface height. Conclusions: The OSPREDI model is moderately sensitive to the input photospheric and coronal conditions. Based on where the source region of the CME is located on the Sun, there may be best practices when selecting an input magnetogram to use. **21 June 2020, 9 June 2021, 7 November 2021, 26 January 2022**

## Microwave Perspective on Magnetic Breakout Eruption

Jeongwoo Lee

Front. Astron. Space Sci., 9:855737. 2022

<https://www.frontiersin.org/articles/10.3389/fspas.2022.855737/full>

<https://www.frontiersin.org/articles/10.3389/fspas.2022.855737/pdf>

<https://doi.org/10.3389/fspas.2022.855737>

Microwave maps may provide critical information on the flux rope interaction and the breakout eruption if their polarization is measured with high precision. We demonstrate this diagnostic capability using the 17 GHz maps from the Nobeyama Radioheliograph (NoRH) of a circular ribbon flare SOL2014-12-17T04:51. The EUV images from SDO/AIA and the coronal magnetic field extrapolated from the HMI magnetogram are also used to support the interpretation of the microwave data. The most obvious evidence for the breakout eruption comes from the sign change of the microwave polarization over the AR at heliographic coordinates S20E09, indicating change of the overlying fields from a closed fan structure to a spine-like structure. Another important piece of evidence comes from the spatial and temporal variations of quasi-periodic pulsations (QPP) detected at the 17 GHz. The QPP was more obvious in one loop leg before the eruption and later moved to the spine field region on and after the flare. This indicates that the oscillatory power is transferred from an interacting flux rope to the outer spine, along which the reconnection launches torsional Alfvén waves, in good agreement with MHD model predictions for breakout eruption. In the practical viewpoint, these two diagnostics work because microwave observations are free of saturation even in strong flaring regions.

## Rapid Evolution of Bald Patches in a Major Solar Eruption

[Jonathan H. Lee](#), [Xudong Sun](#), [Maria D. Kazachenko](#)

ApJL 2021

<https://arxiv.org/pdf/2111.00336.pdf>

Bald patch (BP) is a magnetic topological feature where U-shaped field lines turn tangent to the photosphere. Field lines threading the BP trace a separatrix surface where reconnection preferentially occurs. Here we study the evolution of multiple, strong-field BPs in active region 12673 during the most intense, X9.3 flare of solar cycle 24. The central BP, located between the initial flare ribbons, largely "disintegrated" within 35 minutes. The more remote, southern BP survived. The disintegration manifested as a 9-degree rotation of the median shear angle; the perpendicular component of the horizontal field (with respect to the polarity inversion line) changed sign. The parallel component exhibited a step-wise, permanent increase of 1 kG, consistent with previous observations of the flare-related "magnetic imprint". The observations suggest that magnetic reconnection during a major eruption may involve entire BP separatrices, leading to a change of magnetic topology from BPs to sheared arcades. **6 Sep 2017**

## Heating and Eruption of a Solar Circular-ribbon Flare

Jeongwoo Lee<sup>1,2,3</sup>, Judith T. Karpen<sup>4</sup>, Chang Liu<sup>1,2,3</sup>, and Haimin Wang<sup>1,2,3</sup>

2020 ApJ 893 158

<https://doi.org/10.3847/1538-4357/ab80c4>

We studied a circular-ribbon flare, SOL2014-12-17T04:51, with emphasis on its thermal evolution as determined by the differential emission measure (DEM) inversion analysis of the extreme ultraviolet (EUV) images of the Atmospheric Imaging Assembly instrument on board the Solar Dynamics Observatory. Both temperature and emission measure start to rise much earlier than the flare, along with an eruption and formation of a hot halo over the fan structure. In the main flare phase, another set of ribbons forms inside the circular ribbon, and expands as expected for ribbons at the footpoints of a postflare arcade. An additional heating event further extends the decay phase, which is also characteristic of some

eruptive flares. The basic magnetic configuration appears to be a fan–spine topology, rooted in a minority-polarity patch surrounded by majority-polarity flux. We suggest that reconnection at the null point begins well before the impulsive phase, when the null is distorted into a breakout current sheet, and that both flare and breakout reconnection are necessary in order to explain the subsequent local thermal evolution and the eruptive activities in this confined magnetic structure. Using local DEMs, we found a postflare temperature increase inside the fan surface, indicating that the so-called EUV late phase is due to continued heating in the flare loops.

### **Formation of Post-CME Blobs Observed by LASCO-C2 and K-Cor on 2017 September 10**

Jae-Ok Lee<sup>1</sup>, Kyung-Suk Cho<sup>1,2</sup>, Kyoung-Sun Lee<sup>3</sup>, Il-Hyun Cho<sup>4</sup>, Junggi Lee<sup>5</sup>, Yukinaga Miyashita<sup>1</sup>, Yeon-Han Kim<sup>1</sup>, Rok-Soon Kim<sup>1</sup>, and Soojeong Jang<sup>1</sup>

<https://doi.org/10.3847/1538-4357/ab799a>

<https://doi.org/10.3847/1538-4357/ab799a>

Understanding the formation of post-CME blobs, we investigate 2 blobs in the outer corona observed by LASCO-C2 and 34 blobs in the inner corona by K-Cor on **2017 September 10** from 17:11 to 18:58 UT. By visual inspection of the structure of a post-CME current sheet (CS) and its associated blobs, we find that the CS is well identified in the K-Cor and its radial lengths are nine times longer than lateral widths, indicating the CS is unstable to the linear tearing mode. The inner corona blobs can be classified into two groups: 27 blobs generated in the middle of the CS (Group 1) and 7 blobs occurred above the tips of it (Group 2). Their lateral widths are  $\langle 0.02R_{\odot} \rangle$  and  $\langle 0.05R_{\odot} \rangle$ , which is smaller than, or similar to, those  $\langle 0.06R_{\odot} \rangle$  of the CS. They have elongated shapes: ratios of lateral to radial widths are  $\langle 0.53 \rangle$  and  $\langle 0.40 \rangle$ , respectively. In the first group, only three blobs propagate above the tip of the CS while the others are located in the CS. In the second group, only two blobs have associations with those of outer corona in their temporal and spatial relationship and their initial heights are 1.81 and 1.95  $R_{\odot}$ , measured from the center of the Sun. The others cannot be identified in the outer corona. Our results first demonstrate that LASCO-C2 blobs could be generated by the tearing mode instability near the tips of post-CME CSs, similar to the magnetic reconnection process in the tail CS of Earth's magnetosphere.

### **Non-equilibrium ionization effects on solar EUV and X-ray imaging observations**

Jin-Yi Lee, John C. Raymond, Katharine K. Reeves, Chengcai Shen, Yong-Jae Moon, Yeon-Han Kim  
ApJ 879 111 2019

<https://arxiv.org/pdf/1905.11632.pdf>

[sci-hub.se/10.3847/1538-4357/ab24bb](https://doi.org/10.3847/1538-4357/ab24bb)

During transient events such as major solar eruptions, the plasma can be far from the equilibrium ionization state because of rapid heating or cooling. Non-equilibrium ionization (NEI) is important in rapidly evolving systems where the thermodynamical timescale is shorter than the ionization or recombination time scales. We investigate the effects of NEI on EUV and X-ray observations by the Atmospheric Imaging Assembly (AIA) on board Solar Dynamic Observatory and X-ray Telescope (XRT) on board Hinode. Our model assumes that the plasma is initially in ionization equilibrium at low temperature, and it is heated rapidly by a shock or magnetic reconnection. We tabulate the responses of the AIA and XRT passbands as functions of temperature and a characteristic timescale,  $\tau$ . We find that most of the ions reach equilibrium at  $\tau \leq 1012 \text{ cm}^{-3}\text{s}$ . Comparing ratios of the responses between different passbands allows us to determine whether a combination of plasmas at temperatures in ionization equilibrium can account for a given AIA and XRT observation. It also expresses how far the observed plasma is from equilibrium ionization. We apply the ratios to a supra-arcade plasma sheet on **2012 January 27**. We find that the closer the plasma is to the arcade, the closer it is to a single-temperature plasma in ionization equilibrium. We also utilize the set of responses to estimate the temperature and density for shocked plasma associated with a coronal mass ejection on **2010 June 13**. The temperature and density ranges we obtain are in reasonable agreement with previous works.

### **Three-dimensional Oscillations of 21 Halo Coronal Mass Ejections Using Multi-spacecraft Data**

Harim Lee<sup>1</sup>, Y.-J. Moon<sup>1,2</sup>, V. M. Nakariakov<sup>1,3</sup>, Hyeonock Na<sup>1</sup>, Il-Hyun Cho<sup>2</sup>, and Eunsu Park  
2018 ApJ 868 18

[sci-hub.tw/10.3847/1538-4357/aae5f6](https://doi.org/10.3847/1538-4357/aae5f6)

We investigate the 3D structure of kinematic oscillations of full halo coronal mass ejections (FHCMEs) using multi-spacecraft coronagraph data from two non-parallel lines of sight. For this, we consider 21 FHCMEs which are simultaneously observed by the Solar and Heliospheric Observatory and the Solar Terrestrial Relations Observatory A or B, from *2010 June to 2012 August* when the spacecraft were roughly in quadrature. Using sequences of running difference images, we estimate the instantaneous projected speeds of the FHCMEs at 24 different azimuthal angles in the planes of the sky of those coronagraphs. We find that all these FHCMEs have experienced kinematic oscillations characterized by quasi-periodic variations of the instantaneous projected radial velocity with periods ranging from 24 to 48 min. The oscillations detected in the analyzed events are found to show distinct azimuthal wave modes. Thirteen events (about 62%) are found to oscillate with the azimuthal wave number  $m = 1$ . The oscillating directions of the nodes of the  $m = 1$  mode for these FHCMEs are consistent with those of their position angles (or the direction of eruption),

with a mean difference of about  $23^\circ$ . The oscillation amplitude is found to correlate well with the projected radial speed of the CME. An estimation of Lorentz accelerations shows that they are dominant over other forces, implying that the magnetic force is responsible for the kinematic oscillations of CMEs. However, we cannot rule out other possibilities: a global layer of enhanced current around the CMEs or the nonlinear nature of its driver, for example the effect of vortex shedding. **2011 September 22, 2011 September 24, 2012 January 27, 2012 March 10**

## **MHD Simulation for Investigating the Dynamic State Transition Responsible for a Solar Eruption in Active Region 12158**

Hwanhee Lee<sup>1</sup> and Tetsuya Magara

2018 ApJ 859 132 DOI [10.3847/1538-4357/aabfe6](https://doi.org/10.3847/1538-4357/aabfe6)

We present a magnetohydrodynamic model of solar eruption based on the dynamic state transition from the quasi-static state to the eruptive state of an active region (AR) magnetic field. For the quasi-static state before an eruption, we consider the existence of a slow solar wind originating from an AR, which may continuously make the AR magnetic field deviate from mechanical equilibrium. In this model, we perform a three-dimensional magnetohydrodynamic simulation of AR 12158 producing a coronal mass ejection, where the initial magnetic structure of the simulation is given by a nonlinear force-free field derived from an observed photospheric vector magnetic field. We then apply a pressure-driven outflow to the upper part of the magnetic structure to achieve a quasi-static pre-eruptive state. The simulation shows that the eruptive process observed in this AR may be caused by the dynamic state transition of an AR magnetic field, which is essentially different from the destabilization of a static magnetic field. The dynamic state transition is determined from the shape evolution of the magnetic field line according to the [κH-mechanism](#). This work demonstrates how the mechanism works to produce a solar eruption in the dynamic solar corona governed by the gravitational field and the continuous outflows of solar wind.

## **Heating of an erupting prominence associated with a solar coronal mass ejection on 2012 January 27**

Jin-Yi Lee, John C. Raymond, Katharine K. Reeves, [Yong-Jae Moon](#), [Kap-Sung Kim](#)

ApJ 844 3 2017

<https://arxiv.org/pdf/1706.09116.pdf>

<http://sci-hub.cc/10.3847/1538-4357/aa79a4>

We investigate the heating of an erupting prominence and loops associated with a coronal mass ejection and X-class flare. The prominence is seen in absorption in EUV at the beginning of its eruption. Later the prominence changes to emission, which indicates heating of the erupting plasma. We find the densities of the erupting prominence using the absorption properties of hydrogen and helium in different passbands. We estimate the temperatures and densities of the erupting prominence and loops seen as emission features using the differential emission measure method, which uses both EUV and X-ray observations from the Atmospheric Imaging Assembly on board Solar Dynamics Observatory and the X-ray Telescope on board Hinode. We consider synthetic spectra using both photospheric and coronal abundances in these calculations. We verify the methods for the estimation of temperatures and densities for the erupting plasmas. Then we estimate the thermal, kinetic, radiative loss, thermal conduction, and heating energies of the erupting prominence and loops. We find that the heating of the erupting prominence and loop occurs strongly at early times in the eruption. This event shows a writhing motion of the erupting prominence, which may indicate a hot flux rope heated by thermal energy release during magnetic reconnection.

## **Which Bow Shock Theory, Gasdynamic or Magnetohydrodynamic, Better Explains CME Stand-off Distance Ratios from LASCO-C2 Observations ?**

Jae-Ok Lee<sup>1,2</sup>, Y.-J. Moon<sup>1</sup>, Jin-Yi Lee<sup>3</sup>, R.-S. Kim<sup>2</sup>, and K.-S. Cho<sup>2</sup>

2017 ApJ 838 70

<http://sci-hub.cc/10.3847/1538-4357/aa656f>

It is generally believed that fast coronal mass ejections (CMEs) can generate their associated shocks, which are characterized by faint structures ahead of CMEs in white-light coronagraph images. In this study, we examine whether the observational stand-off distance ratio, defined as the CME stand-off distance divided by its radius, can be explained by bow shock theories. Of 535 SOHO/LASCO CMEs (from 1996 to 2015) with speeds greater than  $1000 \text{ km s}^{-1}$  and angular widths wider than  $60^\circ$ , we select 18 limb CMEs with the following conditions: (1) their Alfvénic Mach numbers are greater than one under Mann's magnetic field and Saito's density distributions; and (2) the shock structures ahead of the CMEs are well identified. We determine observational CME stand-off distance ratios by using brightness profiles from LASCO-C2 observations. We compare our estimates with theoretical stand-off distance ratios from gasdynamic (GD) and magnetohydrodynamic (MHD) theories. The main results are as follows. Under the GD theory, 39% (7/18) of the CMEs are explained in the acceptable ranges of adiabatic gamma ( $\gamma$ ) and CME geometry. Under the MHD theory, all the events are well explained when we consider quasi-parallel MHD shocks with  $\gamma = 5/3$ . When we use polarized brightness (pB) measurements for coronal density distributions, we also find similar results: 8% (1/12) under GD theory and 100% (12/12) under MHD theory. Our results demonstrate that the bow shock relationships based on MHD theory are more suitable than those based on GD theory for analyzing CME-driven shock signatures. **1997 Nov 14, 1999 July 25, 1999 Nov 16, 2000 May 05, 2002 Jan 14,**

## SOLAR ERUPTION AND LOCAL MAGNETIC PARAMETERS

Jeongwoo Lee<sup>1,2</sup>, Chang Liu<sup>3</sup>, Ju Jing<sup>3</sup>, and Jongchul Chae

2016 *ApJL* 831 L18 DOI 10.3847/2041-8205/831/2/L18

<http://sci-hub.cc/doi/10.3847/2041-8205/831/2/L18>

<https://arxiv.org/pdf/1708.04055.pdf>

It is now a common practice to use local magnetic parameters such as magnetic decay index for explaining solar eruptions from active regions, but there can be an alternative view that the global properties of the source region should be counted as a more important factor. We discuss this issue based on *Solar Dynamics Observatory* observations of the **three successive eruptions within 1.5 hr from the NOAA active region 11444** and the magnetic parameters calculated using the nonlinear force-free field model. Two violent eruptions occurred in the regions with relatively high magnetic twist number (0.5–1.5) and high decay index (0.9–1.1) at the nominal height of the filament (12") and otherwise a mild eruption occurred, which supports the local-parameter paradigm. Our main point is that the time sequence of the eruptions did not go with these parameters. It is argued that an additional factor, in the form of stabilizing force, should operate to determine the onset of the first eruption and temporal behaviors of subsequent eruptions. As supporting evidence, we report that the heating and fast plasma flow continuing for a timescale of an hour was the direct cause for the first eruption and that the unidirectional propagation of the disturbance determined the timing of subsequent eruptions. Both of these factors are associated with the overall magnetic structure rather than local magnetic properties of the active region. **2012 March 27**

## DEPENDENCE OF OCCURRENCE RATES OF SOLAR FLARES AND CORONAL MASS EJECTIONS ON THE SOLAR CYCLE PHASE AND THE IMPORTANCE OF LARGE-SCALE CONNECTIVITY

Kangjin Lee<sup>1</sup>, Y.-J. Moon<sup>1</sup>, and V. M. Nakariakov<sup>1,2</sup>

2016 *ApJ* 831 131 DOI 10.3847/0004-637X/831/2/131

We investigate the dependence of the occurrence rates of major solar flares (M- and X-class) and front-side halo coronal mass ejections (FHCMEs), observed from 1996 to 2013, on the solar cycle (SC) phase for six active McIntosh sunspot group classes: Fkc, Ekc, Dkc, Fki, Eki, and Dki. We classify SC phases as follows: (1) ascending phase of SC 23 (1996–1999), (2) maximum phase of SC 23 (2000–2002), (3) descending phase of SC 23 (2003–2008), and (4) ascending phase of SC 24 (2009–2013). We find that the occurrence rates of major flares and FHCMEs during the descending phase are noticeably higher than those during the other phases for most sunspot group classes. For the most active sunspot group class, Fkc, the occurrence rate of FHCMEs during the descending phase of SC 23 is three times as high as that during the ascending phase of SC 23. The potential of each McIntosh sunspot group class to produce major flares or FHCMEs is found to depend on the SC phase. The occurrence rates (R) of major flares and FHCMEs are strongly anti-correlated with the annual average latitude of the sunspot groups (L): for major flares and for FHCMEs. This finding indicates the possible role of large-scale coronal connectivity, e.g., trans-equatorial loops, in powerful energy releases. Interestingly, this relationship is very similar to that between the volumetric coronal heating rate and X-ray loop lengths, indicating common energy release mechanisms.

## SOLAR MULTIPLE ERUPTIONS FROM A CONFINED MAGNETIC STRUCTURE

Jeongwoo Lee<sup>1</sup>, Chang Liu<sup>2</sup>, Ju Jing<sup>2</sup>, and Jongchul Chae

2016 *ApJ* 829 L1 File

<https://arxiv.org/pdf/1708.04056.pdf>

How eruption can recur from a confined magnetic structure is discussed based on the Solar Dynamics Observatory observations of the NOAA active region 11444, which produced three eruptions within 1.5 hr on **2012 March 27**. The active region (AR) had the positive-polarity magnetic fields in the center surrounded by the negative-polarity fields around. Since such a distribution of magnetic polarity tends to form a dome-like magnetic fan structure confined over the AR, the multiple eruptions were puzzling. Our investigation reveals that this event exhibits several properties distinct from other eruptions associated with magnetic fan structures: (i) a long filament encircling the AR was present before the eruptions; (ii) expansion of the open–closed boundary (OCB) of the field lines after each eruption was suggestive of the growing fan-dome structure, and (iii) the ribbons inside the closed magnetic polarity inversion line evolved in response to the expanding OCB. It thus appears that in spite of multiple eruptions the fan-dome structure remained undamaged, and the closing back field lines after each eruption rather reinforced the fan-dome structure. We argue that the multiple eruptions could occur in this AR in spite of its confined magnetic structure because the filament encircling the AR was adequate for slipping through the magnetic separatrix to minimize the damage to its overlying fan-dome structure. The result of this study provides a new insight into the productivity of eruptions from a confined magnetic structure.

## Photospheric Abundances of Polar Jets on the Sun Observed by Hinode

Kyoung-Sun Lee<sup>1</sup>, David H. Brooks<sup>2</sup>, and Shinsuke Imada

2015 ApJ 809 114

Many jets are detected at X-ray wavelengths in the Sun's polar regions, and the ejected plasma along the jets has been suggested to contribute mass to the fast solar wind. From in situ measurements in the magnetosphere, it has been found that the fast solar wind has photospheric abundances while the slow solar wind has coronal abundances. Therefore, we investigated the abundances of polar jets to determine whether they are the same as that of the fast solar wind. For this study, we selected 22 jets in the polar region observed by Hinode/EUV Imaging Spectroscopy (EIS) and X-ray Telescope (XRT) simultaneously on **2007 November 1–3**. We calculated the First Ionization Potential (FIP) bias factor from the ratio of the intensity between high (S) and low (Si, Fe) FIP elements using the EIS spectra. The values of the FIP bias factors for the polar jets are around 0.7–1.9, and 75% of the values are in the range of 0.7–1.5, which indicates that they have photospheric abundances similar to the fast solar wind. The results are consistent with the reconnection jet model where photospheric plasma emerges and is rapidly ejected into the fast wind.

[http://solarb.mssl.ucl.ac.uk/SolarB/nuggets/nugget\\_2016jan.jsp](http://solarb.mssl.ucl.ac.uk/SolarB/nuggets/nugget_2016jan.jsp)

## Forecast of a Daily Halo CME Occurrence Probability Depending on Class and Area Change of the Associated Sunspot

Kangjin Lee, Yong-Jae Moon, Jin-Yi Lee

Solar Phys. Volume 290, Issue 6, pp 1661-1669 2015

We investigate the halo (partial and full) coronal mass ejection (CME) occurrence probability depending on class and area change of the associated sunspot using front-side halo CMEs from 1996 to 2011. We select the most halo CME-productive 14 sunspot classifications: Cao, Cko, Dai, Dao, Dko, Dki, Dkc, Eao, Eai, Eko, Eki, Ekc, Fki, and Fkc. For each class, we assign three subgroups according to sunspot class area change: “Decrease”, “Steady”, or “Increase”. As a result, in the case of asymmetric (k) and compact (c) groups, their CME occurrence probabilities increase. We also find that the halo-CME occurrence probabilities for the “Increase” subgroups are noticeably higher than those for the other subgroups. Our results demonstrate statistically that magnetic-flux emergence or cancellation enhances CME occurrence. We expect that this model can be routinely operated to forecast the halo-CME occurrence probability.

## Radial and Azimuthal Oscillations of Halo Coronal Mass Ejections in the Sun

Harim Lee<sup>1</sup>, Y.-J. Moon<sup>1</sup>, and V. M. Nakariakov

2015 ApJ 803 L7

[http://www2.warwick.ac.uk/fac/sci/physics/research/cfsa/people/valery/research/eprints/2041-8205\\_803\\_1\\_L7.pdf](http://www2.warwick.ac.uk/fac/sci/physics/research/cfsa/people/valery/research/eprints/2041-8205_803_1_L7.pdf)

We present the first observational detection of radial and azimuthal oscillations in full halo coronal mass ejections (HCMEs). We analyze nine HCMEs well-observed by the Large Angle and Spectrometric Coronagraph (LASCO) from 2011 February to June. Using the LASCO C3 running difference images, we estimated the instantaneous apparent speeds of the HCMEs in different radial directions from the solar disk center. We find that the development of all these HCMEs is accompanied by quasi-periodic variations of the instantaneous radial velocity with the periods ranging from 24 to 48 minutes. The amplitudes of the instant speed variations reach about a half of the projected speeds. The amplitudes are found to anti-correlate with the periods and correlate with the HCME speed, indicating the nonlinear nature of the process. The oscillations have a clear azimuthal structure in the heliocentric polar coordinate system. The oscillations in seven events are found to be associated with distinct azimuthal wave modes with the azimuthal wave number  $m = 1$  for six events and  $m = 2$  for one event. The polarization of the oscillations in these seven HCMEs is broadly consistent with those of their position angles with the mean difference of  $43^\circ$ . The oscillations may be connected with natural oscillations of the plasmoids around a dynamical equilibrium, or self-oscillatory processes, e.g., the periodic shedding of Alfvénic vortices. Our results indicate the need for an advanced theory of oscillatory processes in coronal mass ejections.

## Ensemble Modeling of Successive Halo CMEs: A Case Study

C. O. Lee, C. N. Arge, D. Odstrcil, G. Millward, V. Pizzo, N. Lugaz

Solar Phys., 2015

The Wang–Sheeley–Arge (WSA)–Enlil cone modeling system is used for making routine arrival-time forecasts of Earth-directed halo coronal mass ejections (CMEs), since they typically produce the most geoeffective events. A major objective of this work is to better understand the sensitivity of the WSA–Enlil modeling results to input model parameters and how these parameters contribute to the overall model uncertainty and performance. In this study, ensemble-modeling results for a succession of three halo CME events that occurred on **2–4 August 2011** are presented. We investigate the sensitivity of the modeled CME arrival times to small variations in the input-cone properties by creating ensemble sets of numerical simulations for each CME event, based on multiple sets of cone parameters. We find that the accuracy of the modeled CME arrival times not only depends on the small variations to the initial input geometry, but also on the reliable specification of the background solar wind, which is driven by the input maps of the photospheric magnetic field. The accuracy in the arrival-time predictions also depends on whether the cone parameters for all three CMEs are specified in a single WSA–Enlil simulation. The inclusion or exclusion of one or two of the preceding CMEs affects the solar-wind conditions through which the succeeding CME propagates. Although the accuracy of the modeled arrival times is sensitive to the input maps that are used to drive the background solar wind, the spread in the modeling ensemble remains mostly unchanged when different input maps are used.

## **Helical Blowout Jets in the Sun: Untwisting and Propagation of Waves**

E. J. Lee, V. Archontis, A. W. Hood

ApJL, **798** L10 **2015**

<http://arxiv.org/pdf/1412.4853v1.pdf>

We report on numerical experiment of the recurrent onset of helical "blowout" jets in an emerging flux region (EFR). We find that these jets are running with velocities of  $\sim 100\text{--}250\text{ km s}^{-1}$  and they transfer a vast amount of heavy plasma into the outer solar atmosphere. During their emission, they undergo an untwisting motion as a result of reconnection between the twisted emerging and the non-twisted pre-existing magnetic field in the solar atmosphere. For the first time in the context of blowout jets, we provide a direct evidence that their untwisting motion is associated with the propagation of torsional Alfvén waves in the corona.

## **Are 3-D coronal mass ejection parameters from single-view observations consistent with multiview ones?**

Harim Lee, Y.-J. Moon, Hyeonock Na, Soojeong Jang, Jae-Ok Lee

JGR Volume 120, Issue 12 December **2015** Pages 10,237–10,249

To prepare for when only single-view observations are available, we have made a test whether the 3-D parameters (radial velocity, angular width, and source location) of halo coronal mass ejections (HCMEs) from single-view observations are consistent with those from multiview observations. For this test, we select 44 HCMEs from December 2010 to June 2011 with the following conditions: partial and full HCMEs by SOHO and limb CMEs by twin STEREO spacecraft when they were approximately in quadrature. In this study, we compare the 3-D parameters of the HCMEs from three different methods: (1) a geometrical triangulation method, the STEREO CAT tool developed by NASA/CCMC, for multiview observations using STEREO/SECCHI and SOHO/LASCO data, (2) the graduated cylindrical shell (GCS) flux rope model for multiview observations using STEREO/SECCHI data, and (3) an ice cream cone model for single-view observations using SOHO/LASCO data. We find that the radial velocities and the source locations of the HCMEs from three methods are well consistent with one another with high correlation coefficients ( $\geq 0.9$ ). However, the angular widths by the ice cream cone model are noticeably underestimated for broad CMEs larger than  $100^\circ$  and several partial HCMEs. A comparison between the 3-D CME parameters directly measured from twin STEREO spacecraft and the above 3-D parameters shows that the parameters from multiview are more consistent with the STEREO measurements than those from single view.

## **Mass and energy of erupting solar plasma observed with the X-Ray Telescope on Hinode**

Jin-Yi Lee, John C. Raymond, Katharine K. Reeves, Yong-Jae Moon, and Kap-Sung Kim

ApJ, **798** 106 **2014**

<http://arxiv.org/pdf/1411.2229v1.pdf>

We investigate seven eruptive plasma observations by Hinode/XRT. Their corresponding EUV and/or white light CME features are visible in some events. Five events are observed in several passbands in X-rays, which allows the determination of the eruptive plasma temperature using a filter ratio method. We find that the isothermal temperatures vary from 1.6 to 10 MK. These temperatures are an average weighted toward higher temperature plasma. We determine the mass constraints of eruptive plasmas by assuming simplified geometrical structures of the plasma with isothermal plasma temperatures. This method provides an upper limit to the masses of the observed eruptive plasmas in X-ray passbands since any clumping causes the overestimation of the mass. For the other two events, we assume the temperatures are at the maximum temperature of the XRT temperature response function, which gives a lower limit of the masses. We find that the masses in XRT,  $\sim 3 \times 10^{13} - 5 \times 10^{14}$  g, are smaller in their upper limit than total masses obtained by LASCO,  $\sim 1 \times 10^{15}$  g. In addition, we estimate the radiative loss, thermal conduction, thermal, and kinetic energies of the eruptive plasma in X-rays. For four events, we find that the thermal conduction time scales are much shorter than the duration of eruption. This result implies that additional heating during the eruption may be required to explain the plasma observations in X-rays for the four events. **2007/05/23, 2008/04/09, 2008/12/30, 2009/01/11, 2009/12/13, 2010/01/22, 2010/01/30**

## **On Flux Rope Stability and Atmospheric Stratification in Models of Coronal Mass Ejections Triggered by Flux Emergence**

E. Lee, V.S. Lukin, M.G. Linton

A&A, 569, A94 **2014**

<http://arxiv.org/pdf/1403.0231v1.pdf>

Flux emergence is widely recognized to play an important role in the initiation of coronal mass ejections. The Chen-Shibata (2000) model, which addresses the connection between emerging flux and flux rope eruptions, can be implemented numerically to demonstrate how emerging flux through the photosphere can ultimately cause the eruption of a coronal flux rope. The model's sensitivity to the initial conditions is investigated with a parameter study. We aim to understand the stability of the coronal flux rope in the context of X-point collapse, and study the effect of boundary

driving on both unstratified and stratified atmospheres. A modified version of the model is implemented in a code with high numerical accuracy with different combinations of initial parameters governing the magnetic equilibrium and gravitational stratification of the atmosphere. In the absence of driving, we assess the behavior of waves in the vicinity of the X-point. With boundary driving applied, we study the effect of stratification on the eruption. We find that the Chen-Shibata equilibrium can be unstable to an X-point collapse even in the absence of driving due to wave accumulation at the X-point. Such a collapse can generate a coronal mass ejection, or produce a failed eruption. However, the equilibrium can be stabilized by reducing the compressibility of the plasma, which allows small-amplitude waves to pass through the X-point without accumulation. For stable initial configurations, simulations of the flux emergence via photospheric boundary driving demonstrate the impact of atmospheric stratification on the dynamics of resulting eruptions. In particular, in a stratified atmosphere, we identify a novel mechanism for producing quasi-periodic behavior at the reconnection site behind a coronal mass ejection as a possible explanation of similar phenomena previously observed in solar and stellar flares.

### **Dependence of Geomagnetic Storms on Their Associated Halo CME Parameters**

Jae-Ok Lee<sup>1</sup>, Y.-J. Moon<sup>1, 2</sup>, Kyoung-Sun Lee<sup>3</sup> and R.-S. Kim

Solar Phys, 2014, File

We compare the geoeffective parameters of halo coronal mass ejections (CMEs). We consider 50 front-side full-halo CMEs (FFH CMEs), which are from the list of Michalek, Gopalswamy, and Yashiro (Solar Phys. 246, 399, 2007), whose asymmetric-cone model parameters and earthward-direction parameter were available. For each CME we use its projected velocity [ $V_p$ ], radial velocity [ $V_r$ ], angle between cone axis and sky plane [ $\gamma$ ] from the cone model, earthward-direction parameter [D], source longitude [L], and magnetic-field orientation [M] of its CME source region. We make a simple linear-regression analysis to find out the relationship between CME parameters and Dst index. The main results are as follows: i) The combined parameters [ $(V_r D)^{1/2}$  and  $V_r \gamma$ ] have higher correlation coefficients [cc] with the Dst index than the other parameters [ $V_p$  and  $V_r$ ]: cc=0.76 for  $(V_r D)^{1/2}$ , cc=0.70 for  $V_r \gamma$ , cc=0.55 for  $V_r$ , and cc=0.17 for  $V_p$ . ii) Correlation coefficients between  $V_r \gamma$  and Dst index depend on L and M; cc=0.59 for 21 eastern events [E], cc=0.80 for 29 western events [W], cc=0.49 for 17 northward magnetic-field events [N], and cc=0.69 for 33 southward magnetic-field events [S]. iii) Super geomagnetic storms ( $Dst \leq -200$  nT) only appear in the western and southward magnetic-field events. The mean absolute Dst values of geomagnetic storms ( $Dst \leq -50$  nT) increase with an order of E+N, E+S, W+N, and W+S events; the mean absolute Dst value (169 nT) of W+S events is significantly larger than that (75 nT) of E+N events. Our results demonstrate that not only do the cone-model parameters together with the earthward-direction parameter improve the relationship between CME parameters and Dst index, but also the longitude and the magnetic-field orientation of a FFH CME source region play a significant role in predicting geomagnetic storms.

### **Are the Faint Structures Ahead of Solar Coronal Mass Ejections Real Signatures of Driven Shocks?**

Jae-Ok Lee<sup>1</sup>, Y.-J. Moon<sup>1,2</sup>, Jin-Yi Lee<sup>2</sup>, Kyoung-Sun Lee<sup>3</sup>, Sujin Kim<sup>4</sup>, and Kangjin Lee

2014 ApJ 796 L16

Recently, several studies have assumed that the faint structures ahead of coronal mass ejections (CMEs) are caused by CME-driven shocks. In this study, we have conducted a statistical investigation to determine whether or not the appearance of such faint structures depends on CME speeds. For this purpose, we use 127 Solar and Heliospheric Observatory/Large Angle Spectroscopic CORonagraph (LASCO) front-side halo (partial and full) CMEs near the limb from 1997 to 2011. We classify these CMEs into two groups by visual inspection of CMEs in the LASCO-C2 field of view: Group 1 has the faint structure ahead of a CME and Group 2 does not have such a structure. We find the following results. (1) Eighty-seven CMEs belong to Group 1 and 40 CMEs belong to Group 2. (2) Group 1 events have much higher speeds (average = 1230 km s<sup>-1</sup> and median = 1199 km s<sup>-1</sup>) than Group 2 events (average = 598 km s<sup>-1</sup> and median = 518 km s<sup>-1</sup>). (3) The fraction of CMEs with faint structures strongly depends on CME speeds (V): 0.93 (50/54) for fast CMEs with  $V \geq 1000$  km s<sup>-1</sup>, 0.65 (34/52) for intermediate CMEs with  $500 \text{ km s}^{-1} \leq V < 1000 \text{ km s}^{-1}$ , and 0.14 (3/21) for slow CMEs with  $V < 500 \text{ km s}^{-1}$ . We also find that the fraction of CMEs with deca-hecto metric type II radio bursts is consistent with the above tendency. Our results indicate that the observed faint structures ahead of fast CMEs are most likely an enhanced density manifestation of CME-driven shocks.

### **FAST EXTREME-ULTRAVIOLET DIMMING ASSOCIATED WITH A CORONAL JET SEEN IN MULTI-WAVELENGTH AND STEREOSCOPIC OBSERVATIONS**

K.-S. Lee<sup>1</sup>, D. E. Innes<sup>2</sup>, Y.-J. Moon<sup>1,3</sup>, K. Shibata<sup>4</sup>, Jin-Yi Lee<sup>1</sup>, and Y.-D. Park

2013 ApJ 766 1

We have investigated a coronal jet observed near the limb on **2010 June 27** by the Hinode/X-Ray Telescope (XRT), EUV Imaging Spectrograph (EIS), and Solar Optical Telescope (SOT), and by the Solar Dynamics Observatory (SDO)/Atmospheric Imaging Assembly (AIA), and on the disk by STEREO-A/EUVI. From EUV (AIA and EIS) and soft X-ray (XRT) images we have identified both cool and hot jets. There was a small loop eruption seen in Ca II images of the SOT before the jet eruption. We found that the hot jet preceded its associated cool jet by about 2 minutes. The cool jet showed helical-like structures during the rising period which was supported by the spectroscopic analysis of the jet's emission. The STEREO observation, which enabled us to observe the jet projected against the disk, showed dimming at 195 Å along a large loop connected to the jet. We measured a propagation speed of ~800 km s<sup>-1</sup> for the dimming front. This is comparable to the Alfvén speed in the loop computed from a magnetic field extrapolation of the

photospheric field measured five days earlier by the SDO/Helioseismic and Magnetic Imager, and the loop densities obtained from EIS Fe XIV  $\lambda 264.79/274.20$  line ratios. We interpret the dimming as indicating the presence of Alfvénic waves initiated by reconnection in the upper chromosphere.

### Ensemble Modeling of CME Propagation

C. O. Lee<sup>1</sup>, C. N. Arge<sup>1</sup>, D. Odstrčil<sup>2</sup>, G. Millward<sup>3</sup>, V. Pizzo<sup>3</sup>, J. M. Quinn<sup>1</sup> and C. J. Henney  
Solar Phys. **2012**, doi 10.1007/s11207-012-9980-1, **File**

The current progression toward solar maximum provides a unique opportunity to use multi-perspective spacecraft observations together with numerical models to better understand the evolution and propagation of coronal mass ejections (CMEs). Of interest to both the scientific and forecasting communities are the Earth-directed “halo” CMEs, since they typically produce the most geoeffective events. However, determining the actual initial geometries of halo CMEs is a challenge due to the plane-of-sky projection effects. Thus the recent **15 February 2011** halo CME event has been selected for this study. During this event the Solar TERrestrial RELations Observatory (STEREO) A and B spacecraft were fortuitously located  $\sim 90^\circ$  away from the Sun–Earth line such that the CME was viewed as a limb event from these two spacecraft, thereby providing a more reliable constraint on the initial CME geometry. These multi-perspective observations were utilized to provide a simple geometrical description that assumes a cone shape for a CME to calculate its angular width and central position. The event was simulated using the coupled Wang–Sheeley–Arge (WSA)-Enlil 3D numerical solar corona-solar wind model. Daily updated global photospheric magnetic field maps were used to drive the background solar wind. To improve our modeling techniques, the sensitivity of the modeled CME arrival times to the initial input CME geometry was assessed by creating an ensemble of numerical simulations based on multiple sets of cone parameters for this event. It was found that the accuracy of the modeled arrival times not only depends on the initial input CME geometry, but also on the accuracy of the modeled solar wind background, which is driven by the input maps of the photospheric field. To improve the modeling of the background solar wind, the recently developed data-assimilated magnetic field synoptic maps produced by the Air Force Data Assimilative Photospheric flux Transport (ADAPT) model were used. The ADAPT maps provide a more instantaneous snapshot of the global photospheric field distribution than that provided by traditional daily updated synoptic maps. Using ADAPT to drive the background solar wind, an ensemble set of eight different CME arrival times was generated, where the spread in the predictions was  $\sim 13$  hours and was nearly centered on the observed CME shock arrival time.

### Three Dimensional Structure and Energy Balance of a Coronal Mass Ejection

J.-Y. Lee, J. C. Raymond, Y.-K. Ko, and K.-S. Kim

E-print, Oct 2008; Astrophysical Journal, 692:1271–1286, **2009** February; **File**

<http://solar.physics.montana.edu/cgi-bin/eprint/index.pl?entry=8608>

The Ultraviolet Coronagraph Spectrometer (UVCS) observed Doppler shifted material of a partial Halo Coronal Mass Ejection (CME) on **December 13 2001**. The observed ratio of [O VI]/[O V] is a reliable density diagnostic important for assessing the state of the plasma. Earlier UVCS observations of CMEs found evidence that the ejected plasma is heated long after the eruption. We have investigated the heating rates, which represent a significant fraction of the CME energy budget. The parameterized heating and radiative and adiabatic cooling have been used to evaluate the temperature evolution of the CME material with a time dependent ionization state model. The functional form of a flux rope model for interplanetary magnetic clouds was also used to parameterize the heating. We find that continuous heating is required to match the UVCS observations. To match the O VI-bright knots, a higher heating rate is required such that the heating energy is greater than the kinetic energy. The temperatures for the knots bright in Ly $\alpha$  and C III emission indicate that smaller heating rates are required for those regions. In the context of the flux rope model, about 75% of the magnetic energy must go into heat in order to match the O VI observations. We derive tighter constraints on the heating than earlier analyses, and we show that thermal conduction with the Spitzer conductivity is not sufficient to account for the heating at large heights.

### Three-dimensional Structure of the 2002 April 21 Coronal Mass Ejection

J.-Y. Lee, J. C. Raymond, Y.-K. Ko, and K.-S. Kim

*The Astrophysical Journal*, 651:566–575, **2006**

The reconstructed [Fe xviii] emission allows two interpretations, as ejection of preexisting hot plasma or as a current sheet.

### Stellar Coronal Mass Ejections

[Martin Leitzinger](#), [Petra Odert](#)

Serb. Astron. J. } 200 (2020), 1 – 5

<https://arxiv.org/pdf/2212.09079.pdf>

Stellar coronal mass ejections (CMEs) are a growing research field, especially during the past decade. The large number of so far detected exoplanets raises the open question for the CME activity of stars, as CMEs may strongly affect exoplanetary atmospheres. In addition, as CMEs contribute to stellar mass- and angular momentum loss and are

**Review**

therefore relevant for stellar evolution, there is need for a better characterization of this phenomenon. In this article we review the different methodologies used up to now to attempt the detection of stellar CMEs. We discuss the limitations of the different methodologies and conclude with possible future perspectives of this research field.

### **A census of Coronal Mass Ejections on solar-like stars**

MNRAS Volume 493, Issue 3, April 2020, Pages 4570–4589,

<https://doi.org/10.1093/mnras/staa504>

<https://arxiv.org/pdf/2002.04430.pdf>

Coronal Mass Ejections (CMEs) may have major importance for planetary and stellar evolution. Stellar CME parameters, such as mass and velocity, have yet not been determined statistically. So far only a handful of stellar CMEs has been detected mainly on dMe stars using spectroscopic observations. We therefore aim for a statistical determination of CMEs of solar-like stars by using spectroscopic data from the ESO phase 3 and Polarbase archives. To identify stellar CMEs we use the Doppler signal in optical spectral lines being a signature of erupting filaments which are closely correlated to CMEs. We investigate more than 3700 hours of on-source time of in total 425 dF-dK stars. We find no signatures of CMEs and only few flares. To explain this low level of activity we derive upper limits for the non-detections of CMEs and compare those with empirically modelled CME rates. To explain the low number of detected flares we adapt a flare power law derived from EUV data to the H $\{\alpha\}$  regime, yielding more realistic results for H $\{\alpha\}$  observations. In addition we examine the detectability of flares from the stars by extracting Sun-as-a-star H $\{\alpha\}$  light curves. The extrapolated maximum numbers of observable CMEs are below the observationally determined upper limits, which indicates that the on-source times were mostly too short to detect stellar CMEs in H $\{\alpha\}$ . We conclude that these non-detections are related to observational biases in conjunction with a low level of activity of the investigated dF-dK stars.

### **DIRECT OBSERVATIONAL EVIDENCE OF FILAMENT MATERIAL WITHIN INTERPLANETARY CORONAL MASS EJECTIONS**

S. T. [Lepri](#) and T. H. Zurbuchen

The Astrophysical Journal Letters, 723:L22–L27, 2010

Coronal mass ejections (CMEs) are explosive events that escape the Sun's corona carrying solar material and energy into the heliosphere. The classic picture of a CME observed in the corona presents a "three-part structure," including a bright front at the leading edge indicating dense plasma, a low-density cavity, the possible signature of an embedded magnetic flux rope, and the so-called core, a high-density region observed to be associated with an erupting filament. Although there are experimental analogs to the first two parts of the CME when observed in situ, there are only a handful of in situ observations of cold, filament-type plasma. This has been a source of major uncertainty and qualitative disagreement between remote and in situ observations of these ejecta. We present the first comprehensive and long-term survey of such low charge states observed by the *Advanced Composition Explorer* SolarWind Ion Composition Spectrometer, using a novel data analysis process developed to identify ions with low ionic charge states. Using a very stringent set of observational signatures, we find that more than 4% of detected interplanetary CMEs have significant contributions of ions with low charge states. These time periods of low-charge ions often occur concurrent with some of the hottest ions, previously interpreted to be affected by flare heating during the CME initiation.

### **Observations of Twist, Current Helicity, and Writhe in the Magnetic Knots of $\delta$ -sunspots Consistent with the Kink Instability of a Highly Twisted Flux Rope**

Peter J. [Levens](#)<sup>1</sup>, Aimee A. Norton<sup>1</sup>, Mark G. Linton<sup>2</sup>, Kalman J. Knizhnik<sup>2</sup>, and Yang Liu<sup>1</sup>

2023 ApJL 954 L20

<https://iopscience.iop.org/article/10.3847/2041-8213/acf0c6/pdf>

We measure current helicity (Hrc) as well as proxies for twist ( $\alpha$ ) and writhe (W) in the isolated magnetic knots of three  $\delta$ -sunspots and report that the observations are consistent with a kink instability acting on a highly twisted flux tube.  $\delta$ -spots are active regions (ARs) in which positive and negative umbrae share a penumbra. We identify and isolate "magnetic knots," i.e., opposite polarity umbrae that are in close proximity and forming the  $\delta$ -configuration, in ARs NOAA 11158, 11267, and 11476 as observed with data from the Solar Dynamic Observatory Helioseismic and Magnetic Imager. We find that Hrc,  $\alpha$ , and W have the same sign for each magnetic knot, as predicted in simulations of a kink instability acting on highly twisted flux tubes. The deformed flux tube causing the  $\delta$ -formation, the magnetic knot, is only a portion of the entire AR and demonstrates the potential for the kink instability to act on a smaller spatial scale within the AR. Each magnetic footpoint contains a single sign of the radial current,  $J_r$ , which suggests that we are observing the core of the flux rope without return currents. As a counterexample, we analyze one  $\beta$ -spot that shows Hrc and  $\alpha$  have the opposite signs of W. While our observations support the formation mechanism of the magnetic knots in  $\delta$ -spots being the kink instability, a much larger sample is needed to determine confidently the prevalence of the kink instability as the cause of flux tube deformation. 2011-02-14, 2011-08-07, 2012-05-07
