https://doi.org/10.3847/1538-4357/abc4e0

In this study, we investigate motions in the hot plasma above the flare loops during the 2017 September 10 X8.2 flare event. We examine the region to the south of the main flare arcade, where there is data from the Interface Region Imaging Spectrograph (IRIS), and the Extreme ultraviolet Imaging Spectrometer (EIS) on Hinode. We find that there are initial blue shifts of 20--60 km/s observed in this region in the Fe XXI line in IRIS and the Fe XXIV line in EIS, and that the locations of these blue shifts move southward along the arcade over the course of about 10 min. The cadence of IRIS allows us to follow the evolution of these flows, and we find that at each location where there is an initial blue shift in the Fe XXIV line, there are damped oscillations in the Doppler velocity with periods of ~400 s. We conclude that these periods are independent of loop length, ruling out magnetoacoustic standing modes as a possible mechanism. Microwave observations from the Expanded Owens Valley Solar Array (EOVSA) indicate that there are non-thermal emissions in the region where the Doppler shifts are observed, indicating that accelerated particles are present. We suggest that the flows and oscillations are due to motions of the magnetic field that are caused by reconnection outflows disturbing the loop-top region.

ATMOSPHERIC IMAGING ASSEMBLY OBSERVATIONS OF HOT FLARE PLASMA

Katharine K. **Reeves** and Leon Golub

2011 ApJ 727 L52, **File**

We present observations of hot plasma from solar eruptions recorded by the Atmospheric Imaging Assembly (AIA) on the Solar Dynamics Observatory. AIA is the first narrowband instrument capable of taking images of hot plasma in the 5-15 MK range. We find that there are hot structures above flare loops, and that they are typically more diffuse and nebulous than the well-defined flare loops. Because of the narrowband response, high sensitivity, and high spatial

resolution of AIA, these supra-arcade structures are visible in exquisite detail, particularly in the 131 Å and 94 Å channels. In one event, a C4.9 flare observed on **2010 November 3**, hot plasma is seen to outline an erupting plasmoid and possibly a current sheet. We compare hot plasma observed with AIA to structures observed with the X-Ray Telescope on the Hinode mission and find that the plasma imaged in AIA contains more fine detail. These new AIA observations show that supra-arcade flare structures and coronal mass ejections are highly structured not only in space and time, but also in temperature. This thermal structuring is expected, based on modeling efforts, but has now been imaged directly for the first time over a large range of temperatures.

Field Line Shrinkage in Flares Observed by the X-Ray Telescope on Hinode

Katharine K. **Reeves**, Daniel B. Seaton, Terry G. Forbes
E-print, Nov 2007, ApJ, 675:868Y874, **2008**
http://www.journals.uchicago.edu/doi/pdf/10.1086/526336
The X-Ray Telescope on **Hinode** has observed individual loops of plasma moving downward in a manner that is consistent with field line shrinkage in the aftermath of reconnection at higher altitudes.
We measure the shrinkage in both of these events, and find that it is 17-27%, which is consistent with theoretical predictions.
The STEREO mission provides an unprecedented opportunity to reconstruct the 3D configuration of solar features. In this work, we combine SECCHI/EUVI data from both spacecraft by means of a local correlation tracking method. The technique allows an automatic (without user intervention) matching of pixels in both images. This information is then used to triangulate the 3D coordinates of each pixel. We use the method in order to reconstruct and analyze the 3D structure of active regions. In particular, we focus on the extraction of coronal loop heights, observed nearly simultaneously in the 171, 195 and 284 Å passbands. We compare the properties of loops in the different wavelengths and extract valuable information regarding their geometry. In particular, we demonstrate that some loops that look co-spatial in the 171 Å and 195 Å images have in fact different heights and thus occupy different volumes. Our results have important implications for multi-wavelength studies of coronal loops, especially for calculations using filter-ratio techniques.

Sparkling Extreme-ultraviolet Bright Dots Observed with Hi-C

S. **Régnier**1, C. E. Alexander1, R. W. Walsh1, A. R. Winebarger2, J. Cirtain2, L. Golub3, K. E. Korreck3, N. Mitchell4, S. Platt4, M. Weber3, B. De Pontieu5, A. Title5, K. Kobayashi6, S. Kuzin7, and C. E. DeForest
2014 ApJ 784 134
Observing the Sun at high time and spatial scales is a step toward understanding the finest and fundamental scales of heating events in the solar corona. The high-resolution coronal (Hi-C) instrument has provided the highest spatial and temporal resolution images of the solar corona in the EUV wavelength range to date. Hi-C observed an active region on **2012 July 11** that exhibits several interesting features in the EUV line at 193 Å. One of them is the existence of short, small brightenings "sparkling" at the edge of the active region; we call these EUV bright dots (EBDs). Individual EBDs have a characteristic duration of 25 s with a characteristic length of 680 km. These brightenings are not fully resolved by the SDO/AIA instrument at the same wavelength; however, they can be identified with respect to the Hi-C location of the EBDs. In addition, EBDs are seen in other chromospheric/coronal channels of SDO/AIA, which suggests a temperature between 0.5 and 1.5 MK. Based on their frequency in the Hi-C time series, we define four different categories of EBDs: single peak, double peak, long duration, and bursty. Based on a potential field extrapolation from an SDO/HMI magnetogram, the EBDs appear at the footpoints of large-scale, trans-equatorial coronal loops. The Hi-C observations provide the first evidence of small-scale EUV heating events at the base of these coronal loops, which have a free magnetic energy of the order of 1026 erg.

Relationship between photospheric currents and coronal magnetic helicity for force-free bipolar fields

S. **R´egnier**
E-print, March, **2009**; A&A
http://solar.physics.montana.edu/cgi-bin/eprint/index.pl?entry=9715
The origin and evolution of the magnetic helicity in the solar corona are not well understood. For instance, the magnetic helicity of an active region is often about 10^42 Mx^2 (10^26 Wb^2), but the observed processes whereby it is thought to be injected into the corona do not yet provide an accurate estimate of the resulting magnetic helicity budget or time evolution. The variation in magnetic helicity is important for understanding the physics of flares, coronal mass ejections, and their associated magnetic clouds. To shed light on this topic, we investigate here the changes in magnetic helicity due to electric currents in the corona for a single twisted flux tube that may model characteristic coronal structures such as active region filaments, sigmoids, or coronal loops. For a bipolar photospheric magnetic field and several distributions of current, we extrapolated the coronal field as a nonlinear force-free field. We then computed the

relative magnetic helicity, as well as the self and mutual helicities. Starting from a magnetic configuration with a moderate amount of current, the amount of magnetic helicity can increase by 2 orders of magnitude when the maximum current strength is increased by a factor of 2. The high sensitivity of magnetic helicity to the current density can partially explain discrepancies between measured values on the photosphere, in the corona, and in magnetic clouds. Our conclusion is that the magnetic helicity strongly depends on both the strength of the current density and also on its distribution. Only improved measurements of current density at the photospheric level will advance our knowledge of the magnetic helicity content in the solar atmosphere.

Self-consistent nanoflare heating in model active regions: MHD avalanches

J **Reid**, J Threlfall, A W Hood

MNRAS, Volume 518, Issue 1, January **2023**, Pages 1584–1600,

https://doi.org/10.1093/mnras/stac3188

Straightened cylindrical models of coronal loops have been standard for decades, and shown to support nanoflare-like heating, but the influence of geometric curvature in models upon the heating produced has not been discussed in depth. Heating, its spatiotemporal distributions, and the associated mechanisms responsible are discussed, and compared with those from straightened models of a coronal loop. Previously, magnetohydrodynamic avalanches have been generalized to curved loops, and shown to be viable. From that study, the associated heating is analysed and discussed in depth. Heating is seen to arise from processes originally instigated, yet not dominated, by magnetic reconnection, producing bursty, aperiodic nanoflares, dispersed evenly throughout the corona, but with a modest bias away from footpoints. One novelty arising is the simultaneous yet independent occurrence of nanoflare-like events at disjoint sites along individual strands, anticipating some features recently seen in ‘campfires’ by Solar Orbiter. With a view to future refinements in the model and to the inclusion of additional physical effects, the implications of this analysis are discussed.

Chromospheric Bubbles in Solar Flares

A. **Reid**1, B. Zhigulin1, M. Carlsson2,3, and M. Mathioudakis1

2020 ApJL 894 L21

https://arxiv.org/pdf/2005.10586.pdf

https://doi.org/10.3847/2041-8213/ab8d1e

We analyze a grid of radiative hydrodynamic simulations of solar flares to study the energy balance and response of the atmosphere to nonthermal electron beam heating. The appearance of chromospheric bubbles is one of the most notable features that we find in the simulations. These pockets of chromospheric plasma get trapped between the transition region and the lower atmosphere as it is superheated by the particle beam. The chromospheric bubbles are seen in the synthetic spectra, appearing as an additional component to Balmer line profiles with high Doppler velocities as high as 200 km s−1. Their signatures are also visible in the wings of Ca ii 8542 Å line profiles. These bubbles of chromospheric plasma are driven upward by a wave front that is induced by the shock of energy deposition, and require a specific heating rate and atmospheric location to manifest.

Chromospheric Inversions of a Micro-flaring Region

A. **Reid**, V. Henriques, M. Mathioudakis, J. G. Doyle, T. Ray

ApJ **2017**

https://arxiv.org/pdf/1707.00029.pdf

We use spectropolarimetric observations of the Ca II 8542~\AA\ line, taken from the Swedish 1-m Solar Telescope (SST), in an attempt to recover dynamic activity in a micro-flaring region near a sunspot via inversions. These inversions show localized mean temperature enhancements of ~1000~K in the chromosphere and upper photosphere, along with co-spatial bi-directional Doppler shifting of 5 - 10 km s−1. This heating also extends along a nearby chromospheric fibril, co-spatial to 10 - 15 km s−1 down-flows. Strong magnetic flux cancellation is also apparent in one of the footpoints, concentrated in the chromosphere. This event more closely resembles that of an Ellerman Bomb (EB), though placed slightly higher in the atmosphere than is typically observed. **2014 July 28**

Magnetic Flux Cancellation in Ellerman Bombs

A. **Reid**, M. Mathioudakis, J. G. Doyle, E. Scullion, V. Henriques, C. Nelson, T. Ray

ApJ **2016**

http://arxiv.org/pdf/1603.07100v1.pdf

Ellerman Bombs (EBs) are often found co-spatial with bipolar photospheric magnetic fields. We use Hα imaging spectroscopy along with Fe I 6302.5 \AA\ spectro-polarimetry from the Swedish 1-m Solar Telescope (SST), combined with data from the Solar Dynamic Observatory (SDO) to study EBs and the evolution of the local magnetic fields at EB locations. The EBs are found via an EB detection and tracking algorithm. We find, using NICOLE inversions of the spectro-polarimetric data, that on average (3.43 ± 0.49) x 1024 ergs of stored magnetic energy disappears from the bipolar region during the EBs burning. The inversions also show flux cancellation rates of 1014 - 1015 Mx s−1, and temperature enhancements of 200 K at the detection footpoints. We investigate near-simultaneous flaring of EBs due to

co-temporal flux emergence from a sunspot, which shows a decrease in transverse velocity when interacting with an existing, stationary area of opposite polarity magnetic flux and the EBs are formed. We also show that these EBs can get fueled further by additional, faster moving, negative magnetic flux regions. **2014 June 5**

The Low-High-Low Starting Frequency Trend in Groups of Type III Bursts," by Hamish Reid. The type III radio bursts echo the pattern of flare energy release.

Hamish **Reid**
RHESSI Science Nuggets, #242, December **2014**
The type III radio bursts echo the pattern of flare energy release. **10-Mar-2003, 18-Mar-2003**

The Low-High-Low Trend of Type III Radio Burst Starting Frequencies and Solar Flare Hard X-rays

Hamish A. S. **Reid**, Nicole Vilmer, Eduard P. Kontar
A&A, **2014**
http://arxiv.org/pdf/1403.1839v1.pdf
Using simultaneous X-ray and radio observations from solar flares, we investigate the link between the type III radio burst starting frequency and hard X-ray spectral index. For a proportion of events the relation derived between the starting height (frequency) of type III radio bursts and the electron beam velocity spectral index (deduced from X-rays) is used to infer the spatial properties (height and size) of the electron beam acceleration region. Both quantities can be related to the distance travelled before an electron beam becomes unstable to Langmuir waves. To obtain a list of suitable events we considered the RHESSI catalogue of X-ray flares and the Phoenix 2 catalogue of type III radio bursts. From the 200 events that showed both type III and X-ray signatures, we selected 30 events which had simultaneous emission in both wavelengths, good signal to noise in the X-ray domain and > 20 seconds duration. We find that > 50 % of the selected events show a good correlation between the starting frequencies of the groups of type III bursts and the hard X-ray spectral indices. A low-high-low trend for the starting frequency of type III bursts is frequently observed. Assuming a background electron density model and the thick target approximation for X-ray observations, this leads to a correlation between starting heights of the type III emission and the beam electron spectral index. Using this correlation we infer the altitude and vertical extents of the flare acceleration regions. We find heights from 183 Mm down to 25 Mm while the sizes range from 13 Mm to 2 Mm. These values agree with previous work that places an extended flare acceleration region high in the corona. We analyse the assumptions required and explore possible extensions to our assumed model. We discuss these results with respect to the acceleration heights and sizes derived from X-ray observations alone. **Table**

X-ray and UV investigation into the magnetic connectivity of a solar flare

H. A. S. **Reid**, N. Vilmer, G. Aulanier, E. Pariat
E-print, Oct **2012;** A&A 547, A52 **(2012)**
We investigate the X-ray and UV emission detected by RHESSI and TRACE in the context of a solar flare on the **16th November 2002** with the goal of better understanding the evolution of the flare. We analysed the characteristics of the X-ray emission in the 12-25 and 25-50 keV energy range while we looked at the UV emission at 1600 angstrom. The flare appears to have two distinct phases of emission separated by a 25-second time delay, with the first phase being energetically more important. We found good temporal and spatial agreement between the 25-50 keV X-rays and the most intense areas of the 1600 angstrom UV emission. We also observed an extended 100-arcsecond < 25 keV source that appears coronal in nature and connects two separated UV ribbons later in the flare. Using the observational properties in X-ray and UV wavelengths, we propose two explanations for the flare evolution in relation to the spine/fan magnetic field topology and the accelerated electrons. We find that a combination of quasi separatrix layer reconnection and null-point reconnection is required to account for the observed properties of the X-ray and UV emission.

Characteristics of the flare acceleration region derived from simultaneous hard X-ray and radio observations

H. A. S. **Reid**1,2, N. Vilmer2 and E. P. Kontar1
A&A, Volume 529, A66, 8 p. May **2011**
We investigate the type III radio bursts and X-ray signatures of accelerated electrons in a well-observed solar flare in order to find the spatial properties of the acceleration region. Combining simultaneous RHESSI hard X-ray flare data and radio data from Phoenix-2 and the Nançay radioheliograph, the outward transport of flare accelerated electrons is analysed. The observations show that the starting frequencies of type III bursts are anti-correlated with the HXR spectral index of solar flare accelerated electrons. We demonstrate both analytically and numerically that the type III

burst starting location is dependent upon the accelerated electron spectral index and the spatial acceleration region size, but weakly dependent on the density of energetic electrons for relatively intense electron beams. Using this relationship and the observed anti-correlation, we estimate the height and vertical extent of the acceleration region, giving values of around 50 Mm and 10 Mm, respectively. The inferred acceleration height and size suggest that electrons are accelerated well above the soft X-ray loop-top, which could be consistent with the electron acceleration between 40 Mm and 60 Mm above the flaring loop.

EVIDENCE THAT TEMPORAL CHANGES IN SOLAR SUBSURFACE HELICITY PRECEDE ACTIVE REGION FLARING

A. A. **Reinard**1, J. Henthorn2, R. Komm3, and F. Hill3

Astrophysical Journal Letters, 710:L121–L125, **2010** February

We report on the analysis of subsurface vorticity/helicity measurements for flare producing and quiet active regions. We have developed a parameter to investigate whether large, decreasing kinetic helicity density commonly occurs prior to active region flaring. This new parameter is effective at separating flaring and non-flaring active regions and even separates among C-, M-, and X-class flare producing regions. In addition, this parameter provides advance notice of flare occurrence, as it increases 2–3 days before the flare occurs. These results are striking on an average basis, though on an individual basis there is still considerable overlap between flare associated and non-flare associated values. We propose the following qualitative scenario for flare production: subsurface rotational kinetic energy twists the magnetic field lines into an unstable configuration, resulting in explosive reconnection and a flare.

Comprehensive radiative MHD simulations of eruptive flares above collisional polarity inversion lines

Matthias **Rempel**, Georgios Chintzoglou, Mark C. M. Cheung, Yuhong Fan, Lucia Kleint

ApJ **955** 105 **2023**

https://arxiv.org/pdf/2303.05299.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/aced4d/pdf

We present a new simulation setup using the MURaM radiative MHD code that allows to study the formation of collisional polarity inversion lines (cPILs) in the photosphere and the coronal response including flares. In the setup we start with a bipolar sunspot configuration and set the spots on collision course by imposing the appropriate velocity field at the footpoints in the subphotospheric boundary. We vary parameters such as the initial spot separation, collision speed and collision distance. While all setups lead to the formation of a sigmoid structure, only the cases with a close passing of the spots cause flares and mass eruptions. The energy release is in the 1−2×1031 ergs range, putting the simulated flares into the upper C to lower M-class range. While the case with the more distant passing of the spots does not lead to a flare, the corona is nonetheless substantially heated, suggesting non-eruptive energy release mechanisms. We focus our discussion on two setups that differ in spot coherence and resulting cPIL length. We find different timings in the transition from a sheared magnetic arcade (SMA) to magnetic flux rope (MFR); the setup with a short cPIL produces a MFR during the eruption, while the MFR is pre-existing in the setup with a longer cPIL. While both result in flares of comparable strength, only the setup with pre-existing MFR produces a CME.

Towards data-driven modeling and real-time prediction of solar flares and coronal mass ejections

M. **Rempel**, Y. Fan, M. Dikpati, A. Malanushenko (HAO/NCAR), M. D. Kazachenko (CU/NSO), M. C. M. Cheung, G. Chintzoglou (LMSAL), X. Sun (U. of Hawaii), G. H. Fisher (U. of Berkeley), T. Y. Chen (Columbia)

Heliophysics 2050 White Paper **2023**

https://arxiv.org/ftp/arxiv/papers/2212/2212.14384.pdf

Modeling of transient events in the solar atmosphere requires the confluence of 3 critical elements: (1) model sophistication, (2) data availability, and (3) data assimilation. This white paper describes required advances that will enable statistical flare and CME forecasting (e.g. eruption probability and timing, estimation of strength, and CME details, such as speed and magnetic field orientation) similar to weather prediction on Earth.

Observations of Current Sheet Heating in X-Ray during a Solar Flare

A. A **Reva**1, S. A. Bogachev1, I. P. Loboda1, A. S. Ulyanov1, and A. S. Kirichenko1

2022 ApJ 931 93

https://iopscience.iop.org/article/10.3847/1538-4357/ac6b3d/pdf

https://arxiv.org/pdf/2306.02355.pdf

In the solar corona, magnetic reconnection occurs due to the finite resistivity of the plasma. At the same time, this resistivity leads to ohmic heating. Therefore, the reconnecting current sheet should heat the surrounding plasma. This paper presents experimental evidence of such plasma heating being caused by magnetic reconnection. We observed the effect during a C1.4 solar flare on **2003 February 16** at the active region NOAA 10278, near the solar limb. Thanks to

such a location, we successfully identified all the principal elements of the flare: the flare arcade, the flux rope, and, most importantly, the presumed position of the current sheet. By analyzing the monochromatic X-ray images of the Sun obtained by the CORONAS-F/SPIRIT instrument in the Mg xii 8.42 Å spectral line, we detected a high-temperature ($T \geq 4$ MK) emission at the predicted location of the current sheet. The high-temperature emission appeared during the CME's impulsive acceleration phase. We believe that this additionally confirms that the plasma heating around the current sheet and the magnetic reconnection inside the current sheet are strongly connected.

CME-Flare Association and the Role of Reconnection in CME Acceleration.

Reva, A., Loboda, I., Bogachev, S. & Alexey Kirichenko
Sol Phys 299, 55 (**2024**).
https://doi.org/10.1007/s11207-024-02302-1
The association of coronal mass ejections (CMEs) with flares is related to the question of whether reconnection is necessary for the CME eruption. Indeed, if reconnection happens during a CME eruption, the plasma is heated, which can be observed as a flare. In this work, we study the CME-flare association using data obtained with the Mg XII spectroheliograph on board the *Complex Orbital Observations Near-Earth of Activity on the Sun* (CORONAS-F) satellite. This instrument is sensitive only to the emission of plasma with a temperature greater than 4 MK, which makes it a convenient tool for detection of flaring activity. During our analysis, we first searched for CMEs detected during the Mg XII observations by the *Large Angle and Spectroscopic Coronagraph* (LASCO). Then, we visually checked the Mg XII images for flaring activity. We found that during the Mg XII observations (2001 – 2003), 198 CMEs were detected by LASCO. One hundred sixty of them (81%) are associated with flares seen in the Mg XII images. The strength of flares associated with ***narrow CMEs*** – *jet-like ejecta* – is uniformly distributed in the A – C GOES class range. The speed of narrow CMEs does not depend on the flare strength. For normal CMEs (motion of both magnetic field and plasma), the flare strength varies from A to X class with a peak of the distribution at the C level. The median speed and the kinetic energy of normal CMEs weakly depend on flare strength for weak flares (below C) and strongly for strong ones (M and X). Our results suggest that at solar maximum reconnection occurs during most CMEs. For strong flares (M and X), the reconnection is a dominant acceleration mechanism. For weak flares (C and below), other mechanisms start to play a bigger role.

CORONAS/SPIRIT Mg XII and Nanoflares

Anton **Reva**
RHESSI Science Nuggets #335 October **2018**
http://sprg.ssl.berkeley.edu/~tohban/wiki/index.php/CORONAS/SPIRIT_Mg_XII_and_Nanoflares
The CORONAS-F/SPIRIT data constrain the high-temperature DEM levels in the solar corona, and do not find any evidence for the "smoking gun" signature expected for nanoflare heating. Because the instrument is uniquely monochromatic, and because of the extent of the data, these constraints are the most direct ones yet published.

Estimate of the Upper Limit on Hot Plasma Differential Emission Measure (DEM) in Non-Flaring Active Regions and Nanoflare Frequency Based on the Mg xiiSpectroheliograph Data from CORONAS-F/SPIRIT

Anton **Reva**, Artem Ulyanov, Alexey Kirichenko, Sergey Bogachev, Sergey Kuzin
Solar Physics October **2018**, 293:140
https://link.springer.com/content/pdf/10.1007%2Fs11207-018-1363-9.pdf
Nanoflare-heating theory predicts steady hot-plasma emission in non-flaring active regions. It is hard to find this emission with conventional non-monochromatic imagers (such as the Atmospheric Imaging Assembly or the X-Ray Telescope), because their images contain a cool-temperature background. In this work, we search for hot plasma in non-flaring active regions using the Mg xii spectroheliograph onboard the Complex Orbital Observations Near-Earth of Activity on the Sun (CORONAS)-F/SPectroheliographIc X-ray Imaging Telescope (SPIRIT). This instrument acquired monochromatic images of the solar corona in the Mg xii 8.42 Å line, which emits only at temperatures higher than 4 MK. The Mg xii images only contain the signal from hot plasma, without any low-temperature background. We studied the hot plasma in active regions using SPIRIT data from 18 – 28 February 2002. During this period, the Mg xiispectroheliograph worked with a 105-second cadence almost without data gaps. Hot plasma was observed only in the flaring active regions. We did not observe any hot plasma in non-flaring active regions. The hot-plasma column emission measure in the non-flaring active region is not expected to exceed 3×10243×1024 cm−5. The hot differential emission measure is lower than 0.01% of the DEM of the main temperature component. The absence of Mg xii emission in the non-flaring active regions can be explained by weak and frequent nanoflares (with a delay of less than 500 seconds) or by very short and intense nanoflares that lead to non-equilibrium ionization.

BREAKOUT RECONNECTION OBSERVED BY THE TESIS EUV TELESCOPE

A. A. **Reva**, A. S. Ulyanov, S. V. Shestov, and S. V. Kuzin

2016 ApJ 816 90
http://arxiv.org/pdf/1601.04511v1.pdf
We present experimental evidence of the coronal mass ejection (CME) breakout reconnection, observed by the TESIS EUV telescope. The telescope could observe solar corona up to 2 R⊙ from the Sun center in the Fe 171 Å line. Starting from **2009 April 8**, TESIS observed an active region (AR) that had a quadrupolar structure with an X-point 0.5 R⊙ above photosphere. A magnetic field reconstructed from the Michelson Doppler Imager data also has a multipolar structure with an X-point above the AR. At 21:45 UT on April 9, the loops near the X-point started to move away from each other with a velocity of ≈7 km s−1. At 01:15 UT on April 10, a bright stripe appeared between the loops, and the flux in the GOES 0.5–4 Å channel increased. We interpret the loops' sideways motion and the bright stripe as evidence of the breakout reconnection. At 01:45 UT, the loops below the X-point started to slowly move up. At 15:10 UT, the CME started to accelerate impulsively, while at the same time a flare arcade formed below the CME. After 15:50 UT, the CME moved with constant velocity. The CME evolution precisely followed the breakout model scenario.

Wave-like Formation of Hot Loop Arcades

A. **Reva** , S. Shestov, I. Zimovets, S. Bogachev, S. Kuzin
Solar Physics Volume 290, Issue 10, pp 2909-2921 **2015**
http://arxiv.org/pdf/1510.02319v1.pdf
We present observations of hot arcades made with the Mg xii spectroheliograph onboard the CORONAS-F mission, which provides monochromatic images of hot plasma in the Mg xii 8.42 Å resonance line. The arcades were observed to form above the polarity inversion line between active regions NOAA 09847 and 09848 at four successive episodes: at 09:18, 14:13, and 22:28 UT on **28 February 2002**, and at 00:40 UT on **1 March 2002**. The evolution of the arcades can be described as: a) a small flare (precursor) appeared near the edge of the still invisible arcade, b) the arcade brightened in a wave-like manner – closer loops brightened earlier, and c) the arcade intensity gradually decreased in ≈1 h. The estimated wave speed was ≈700 kms−1, and the distance between the hot loops was ≈50 Mm. The arcades formed without visible changes in their magnetic structure. The arcades were probably heated up by the instabilities of the current sheet above the arcade, which were caused by a magnetohydrodynamic wave excited by the precursor.

Investigation of Hot X-Ray Points (HXPs) Using Spectroheliograph Mg xii Experiment Data from CORONAS-F/SPIRIT

A. **Reva**, S. Shestov, S. Bogachev and S. Kuzin
Solar Physics, Volume 276, Numbers 1-2, 97-112, **2012**
http://arxiv.org/pdf/1509.07367v1.pdf

Observations in the Mg xii 8.42 Å line onboard the CORONAS-F satellite have revealed compact high temperature objects – hot X-ray points (HXPs) – and their major physical parameters were investigated. Time dependencies of temperature, emission measure, intensity, and electron density were measured for 169 HXPs. HXPs can be divided into two groups by their temperature variations: those with gradually decreasing temperature and those with rapidly decreasing temperature. HXP plasma temperatures lie in the range of 5−40 MK, the emission measure is 1045−1048 cm−3, and the electron density is above 1010 cm−3, which exceeds the electron density in the quiet Sun (108−109 cm−3). HXP lifetimes vary between 5−100 minutes, significantly longer than the conductive cooling time. This means that throughout a HXP's lifetime, the energy release process continues, which helps to maintain its high temperature. A HXP's thermal energy is not greater than 1028 erg, and the total energy which is released in HXPs does not exceed 1030 erg. HXPs differ in their physical properties from other flare-like microevents, such as microflares, X-ray bright points, and nanoflares.

DYNAMICS OF THE FLARING LOOP SYSTEM OF 2005 AUGUST 22 OBSERVED IN MICROWAVES AND HARD X-RAYS

V. E. **Reznikova**1,2, V. F. Melnikov1,3, H. Ji4, and K. Shibasaki1
Astrophysical Journal, 724:171–181, **2010**
We studied the spatial dynamics of the flaring loop in the **2005 August 22** event using microwave (NoRH) and hard X-ray (*RHESSI*) observations together with complementary data from *SOHO*/MDI, SMART at Hida, *SOHO*/EIT, and *TRACE*.We have found that (1) the pre-flare morphology of the active region exhibits a strongly sheared arcade seen in Hα and the J-shape filament seen in EUV; (2) energy release and high-energy electron acceleration occur in a sequence along the extensive arcade; (3) the shear angle and the parallel (to the magnetic neutral line) component of the footpoint (FP) distance steadily decrease during the flare process; (4) the radio loop shrinks in length and height during the first emission peak, and later it grows; after the fourth peak the simultaneous descending of the brightest loop and formation of a new microwave loop at a higher altitude occur; (5) the hard X-ray coronal source

is located higher than the microwave loop apex and shows faster upward motion; (6) the first peak on microwave time profiles is present in both the loop top and FP regions. However, the emission peaks that follow are present only in the FP regions.We conclude that after the first emission peak the acceleration site is located over the flaring arcade and particles are accelerated along magnetic field lines.We make use of the collapsing magnetic trap model to understand some observational effects.

MHD Wave Refraction and the Acoustic Halo Effect around Solar Active Regions: A 3D Study

Carlos **Rijs**, Hamed Moradi, Damien Przybylski, and Paul S. Cally
2015 ApJ 801 27
An enhancement in high-frequency acoustic power is commonly observed in the solar photosphere and chromosphere surrounding magnetic active regions. We perform three-dimensional linear forward wave modeling with a simple wavelet pulse acoustic source to ascertain whether the formation of the acoustic halo is caused by MHD mode conversion through regions of moderate and inclined magnetic fields. This conversion type is most efficient when high frequency waves from below intersect magnetic field lines at a large angle. We find a strong relationship between halo formation and the equipartition surface at which the Alfvén speed a matches the sound speed c, lending support to the theory that photospheric and chromospheric halo enhancement is due to the creation and subsequent reflection of magnetically dominated fast waves from essentially acoustic waves as they cross a = c. In simulations where we have capped a such that waves are not permitted to refract after reaching the a= c height, halos are non-existent, which suggests that the power enhancement is wholly dependent on returning fast waves. We also reproduce some of the observed halo properties, such as a dual 6 and 8 mHz enhancement structure and a spatial spreading of the halo with height.

Stochastic Electron Acceleration by Temperature Anisotropy Instabilities under Solar Flare Plasma Conditions

Mario **Riquelme**5,1, Alvaro Osorio1, Daniel Verscharen2,3, and Lorenzo Sironi4
2022 ApJ 924 52
https://arxiv.org/pdf/2103.05805.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ac3e67/pdf
Using 2D particle-in-cell plasma simulations, we study electron acceleration by temperature anisotropy instabilities, assuming conditions typical of above-the-loop-top sources in solar flares. We focus on the long-term effect of $T_{e,\perp} > T_{e,\parallel}$ instabilities by driving the anisotropy growth during the entire simulation time through imposing a shearing or a compressing plasma velocity ($T_{e,\perp}$ and $T_{e,\parallel}$ are the temperatures perpendicular and parallel to the magnetic field). This magnetic growth makes $T_{e,\perp}/T_{e,\parallel}$ grow due to electron magnetic moment conservation, and amplifies the ratio ω_{ce}/ω_{pe} from ~ 0.53 to ~ 2 (ω_{ce} and ω_{pe} are the electron cyclotron and plasma frequencies, respectively). In the regime $\omega_{ce}/\omega_{pe} \lesssim 1.2$–$1.7$, the instability is dominated by oblique, quasi-electrostatic modes, and the acceleration is inefficient. When ω_{ce}/ω_{pe} has grown to $\omega_{ce}/\omega_{pe} \gtrsim 1.2$–$1.7$, electrons are efficiently accelerated by the inelastic scattering provided by unstable parallel, electromagnetic z modes. After ω_{ce}/ω_{pe} reaches ~ 2, the electron energy spectra show nonthermal tails that differ between the shearing and compressing cases. In the shearing case, the tail resembles a power law of index $\alpha_s \sim 2.9$ plus a high-energy bump reaching ~ 300 keV. In the compressing runs, $\alpha_s \sim 3.7$ with a spectral break above ~ 500 keV. This difference can be explained by the different temperature evolutions in these two types of simulations, suggesting that a critical role is played by the type of anisotropy driving, ω_{ce}/ω_{pe}, and the electron temperature in the efficiency of the acceleration.

Clustering Behavior in Solar Flare Dynamics

Elmer C. **Rivera**1, Jay R. Johnson1, Jonathan Homan1, and Simon Wing2
2022 ApJL 937 L8
https://iopscience.iop.org/article/10.3847/2041-8213/ac8de9/pdf
The solar magnetic activity cycle provides energy input that is released in intense bursts of radiation known as solar flares. As such, the dynamics of the activity cycle is embedded in the sequence of times between the flare events. Recent analysis shows that solar flares exhibit memory on different timescales. These previous studies showed that the time ordering of flare events is not random, but rather there is dependence between successive flares. In the present work, the clustering of flares is demonstrated through a straightforward nonparametric method where the cumulative distribution function of successive flares is compared with the cumulative distribution function of surrogate sequences of flares obtained by random permutation of flares. The random permutation is performed within rate-variable Bayesian blocks during which the flare rate is assumed to be constant. Differences between the cumulative distribution functions are substantial on a timescale around 3 hr, suggesting that flare recurrence on that timescale is more likely than would be expected if the waiting time were drawn from a nonstationary Poisson process.

Scattering of energetic electrons by heat-flux-driven whistlers in flares

G. T. **Roberg-Clark**, O. V. Agapitov, J. F. Drake, M. M. Swisdak

2019 *ApJ* **887** 190

https://arxiv.org/pdf/1908.06481.pdf

https://doi.org/10.3847/1538-4357/ab5114

The scattering of electrons by heat-flux-driven whistler waves is explored with particle-in-cell (PIC) simulations relevant to the transport of energetic electrons in flares and the solar wind. The simulations are initiated with a large heat flux that is produced using a kappa distribution of electrons with positive velocity and a cold return current beam. This system represents energetic electrons escaping from a reconnection-driven energy release site. This heat flux system drives large amplitude oblique whistler waves propagating both along and against the heat flux, as well as electron acoustic waves. While the waves are dominantly driven by the low energy electrons, including the cold return current beam, the energetic electrons resonate with and are scattered by the whistlers on time scales of the order of a hundred electron cyclotron times. Electron perpendicular energy is increased while the field-aligned electron heat flux is suppressed. The resulting scattering mean-free-paths of energetic electrons are small compared with the typical scale size of energy release sites in flares, which might lead to the effective confinement of energetic electrons that is required for the production of very energetic particles.

Tracing the signatures of a quiet Sun nanoflare

Rebecca A. **Robinson**1,2 and Mats Carlsson1,2

A&A 677, A36 (**2023**)

https://www.aanda.org/articles/aa/pdf/2023/09/aa47089-23.pdf

Context. Nanoflare-scale reconnection events are difficult to detect, and even when they are detected, it is tricky to reconstruct the details and trigger mechanisms that power them. However, numerical models of nanoflare-scale reconnection can provide context to observations of small-scale reconnection events via the comparison of synthetic observables to observed signatures of the nanoflare.

Aims. We aim to demonstrate how a simulated nanoflare event would look if it were observed by the Solar Dynamics Observatory Atmospheric Imaging Assembly (SDO/AIA) and the upcoming Multi-slit Solar Explorer (MUSE). The goal is to determine the details (if any) of nanoflare-scale reconnection events that could reasonably be captured by current and future instruments.

Methods. We calculated synthetic observables from a quiet Sun simulation of a nanoflare-scale reconnection event, including integrated intensities of Fe IX at 171.073 Å and Fe XII at 195.119 Å. Then, we degraded the synthetic observables to SDO/AIA and MUSE resolutions in order to determine whether the instruments are capable of capturing the details of the reconnection event.

Results. We determine that even small-scale reconnection events in the quiet Sun can be detected by both SDO/AIA and MUSE. In the 171 channel of each instrument, it is possible to discern details of the two bidirectional jets that emanate from the reconnection site. These two bidirectional jets correspond to two different magnetic features undergoing large-angle reconnection with an overlying horizontal field in the corona. In the 193 channel of SDO/AIA, it is only possible to see one set of bidirectional jets, which corresponds to the most energetic reconnecting feature. However, the calculated count rate for AIA 193 is not sufficient for a reliable observation.

Conclusions. Quiet Sun activity is detectable with SDO/AIA and will be detectable with the future MUSE mission. It is possible to detect bidirectional jets with both instruments, which can give context clues as to the mechanisms causing the nanoflare event. The resolution and spectral information of MUSE will give a much more detailed observation of the event, making it much easier to reconstruct a possible trigger mechanism. However, we must be careful in our interpretations of observations when we have limited information, as vastly different physical processes can produce similar observational signatures.

Analyzing the Sequence of Phases Leading to the Formation of the Active Region 13664, with Potential Carrington-like Characteristics

Paolo **Romano**, Abouazza Elmhamdi, Alessandro Marassi, Lidia Contarino

2024 *ApJL* **973** L31

https://arxiv.org/pdf/2409.04408

https://iopscience.iop.org/article/10.3847/2041-8213/ad77cb/pdf

Several recurrent X-class flares from Active Region (AR) 13664 have triggered a severe G5-class geomagnetic storm between May 10 and 11, 2024. The morphology and compactness of this AR closely resemble the active region responsible for the famous Carrington Event of 1859. Although the induced geomagnetic currents produced a value of the Dst index, probably, an order of magnitude weaker than that of the Carrington Event, the characteristics of AR 13664 warrant special attention. Understanding the mechanisms of magnetic field emergence and transformation in the solar atmosphere that lead to the formation of such an extensive, compact and complex AR is crucial. Our analysis of the emerging flux and horizontal motions of the magnetic structures observed in the photosphere reveals the fundamental role of a sequence of emerging bipoles at the same latitude and longitude, followed by converging and shear motions. This temporal order of processes frequently invoked in magnetohydrodynamic models - emergence,

converging motions, and shear motions - is critical for the storage of magnetic energy preceding strong solar eruptions that, under the right timing, location and direction conditions, can trigger severe space weather events at Earth.

On the evolution of a sub-C class flare: a showcase for the capabilities of the revamped Catania Solar Telescope

Paolo **Romano**, Salvo L. Guglielmino, Pierfrancesco Costa, Mariachiara Falco, Salvatore Buttaccio, Alessandro Costa, Eugenio Martinetti, Giovanni Occhipinti, Daniele Spadaro, Rita Ventura, Giuseppe E. Capuano, Francesca Zuccarello

Solar Phys. **297**, Article number: 7 **2022**

https://arxiv.org/pdf/2111.08972.pdf

https://link.springer.com/content/pdf/10.1007/s11207-021-01932-z.pdf

https://doi.org/10.1007/s11207-021-01932-z

Solar flares are occasionally responsible for severe Space Weather events, which can affect space-borne and ground-based infrastructures, endangering anthropic technological activities and even human health and safety. Thus, an essential activity in the framework of Space Weather monitoring is devoted to the observation of the activity level of the Sun.

In this context, the acquisition system of the Catania Solar Telescope has been recently upgraded in order to improve its contribution to the European Space Agency (ESA) - Space Weather Service Network through the ESA Portal, which represents the main asset for Space Weather in Europe.

Here, we describe the hardware and software upgrades of the Catania Solar Telescope and the main data products provided by this facility, which include full-disc images of the photosphere and chromosphere, together with a detailed characterization of the sunspot groups. As a showcase of the observational capabilities of the revamped Catania Solar Telescope, we report the analysis of a B5.4 class flare occurred on **2020 December 7**, simultaneously observed by the IRIS and SDO satellites.

Two strong white-light solar flares in AR NOAA 12673 as potential clues for stellar superflares

Paolo **Romano**, Abouazza Elmhamdi, Ayman Kordi

Solar Physics 294:4 **2019**

https://arxiv.org/pdf/1812.04581.pdf

Recently, two strong homologous white light flares of X-GOES class occurred on the Sun on **Sept. 06, 2017**, providing a rare exceptional opportunity to study the mechanisms responsible for the formation of the magnetic field configurations suitable for the manifestation of such yet enigmatic eruptive events and their effects in the lower layers of the solar atmosphere.

Using photospheric vector magnetograms, taken before the beginning of the two X-class events, as boundary conditions to reconstruct the non−linear coronal magnetic field configuration, we identified two related 3D null points located at low heights above the photosphere (i.e. in very low corona). These null points are most likely responsible for the triggering of the two strong X-GOES class flares. We deduced that their formation at such low altitudes may plausibly be ascribed to the peculiar photospheric horizontal motions of the main magnetic structures of the hosting Active Region NOAA 12673.

These events can be adopted as a hint for a possible interpretation of the activity of young G-type stars, recently reported by the Kepler mission. We argued that a possible explanation of the acceleration of huge numbers of particles producing white light emission, during the Sept. 6 events as well as during white light flares in young Sun-like stars, might be attributed to the special accompanying conditions of the occurrence of magnetic reconnection at low altitudes of their atmospheres.

Homologous White Light Solar Flares Driven by Photospheric Shear Motions

P. **Romano**1, A. Elmhamdi2, M. Falco1, P. Costa1, A. S. Kordi2, H. A. Al-Trabulsy2, and R. M. Al-Shammari

2018 ApJL 852 L10 **File**

http://iopscience.iop.org.sci-hub.tw/2041-8205/852/1/L10/

https://arxiv.org/pdf/1812.04252.pdf

We describe the peculiarity of two recurrent white light flares that occurred on **2017 September 06**, in the super active region NOAA 12673, with a time interval, between their peaks, of about 3 hr. These events of the X2.2 and X9.3 GOES classes are very important, not only for their high level of emission and for the visible effects on the lower layers of the solar atmosphere, which are discernible as clear white light ribbons, but also for the strong horizontal photospheric motions, which seemed to drive them. In fact, we observed the displacement of a negative umbra located in the main delta spot of the active region for several hours before the flare occurrence. We measured velocities of up to 0.6 km s−1. The strong and persistent shear motion of the photospheric structures, together with the high intensity of the magnetic flux involved in these events, can be considered responsible for the new energy that is continuously supplied

to the magnetic system. From the timing of the emissions at different wavelengths, we were able to provide some constraints for the modeling of such events.

Observation of a 3D magnetic null point

P. **Romano**, M. Falco, S. L. Guglielmino, M. Murabito
ApJ **837** 173 **2017**
https://arxiv.org/pdf/1703.00665.pdf
We describe high resolution observations of a GOES B-class flare characterized by a circular ribbon at chromospheric level, corresponding to the network at photospheric level. We interpret the flare as a consequence of a magnetic reconnection event occurred at a three-dimensional (3D) coronal null point located above the supergranular cell. The potential field extrapolation of the photospheric magnetic field indicates that the circular chromospheric ribbon is cospatial with the fan footpoints, while the ribbons of the inner and outer spines look like compact kernels. We found new interesting observational aspects that need to be explained by models: 1) a loop corresponding to the outer spine became brighter a few minutes before the onset of the flare; 2) the circular ribbon was formed by several adjacent compact kernels characterized by a size of 1"-2"; 3) the kernels with stronger intensity emission were located at the outer footpoint of the darker filaments departing radially from the center of the supergranular cell; 4) these kernels start to brighten sequentially in clockwise direction; 5) the site of the 3D null point and the shape of the outer spine were detected by RHESSI in the low energy channel between 6.0 and 12.0 keV. Taking into account all these features and the length scales of the magnetic systems involved by the event we argued that the low intensity of the flare may be ascribed to the low amount of magnetic flux and to its symmetric configuration. **2015 May 20**

Recurrent flares in active region NOAA 11283

P. **Romano**, F. Zuccarello, S. L. Guglielmino, F. Berrilli, R. Bruno, V. Carbone, G. Consolini, M. de Lauretis, D. Del Moro, A. Elmhamdi et al. (14 more)
A&A 582, A55 (**2015**)
Context. Flares and coronal mass ejections (CMEs) are solar phenomena that are not yet fully understood. Several investigations have been performed to single out their related physical parameters that can be used as indices of the magnetic complexity leading to their occurrence.
Aims. In order to shed light on the occurrence of recurrent flares and subsequent associated CMEs, we studied the active region NOAA **11283** where recurrent M and X GOES-class flares and CMEs occurred.
Methods. We use vector magnetograms taken by HMI/SDO to calculate the horizontal velocity fields of the photospheric magnetic structures, the shear and the dip angles of the magnetic field, the magnetic helicity flux distribution, and the Poynting fluxes across the photosphere due to the emergence and the shearing of the magnetic field.
Results. Although we do not observe consistent emerging magnetic flux through the photosphere during the observation time interval, we detected a monotonic increase of the magnetic helicity accumulated in the corona. We found that both the shear and the dip angles have high values along the main polarity inversion line (PIL) before and after all the events. We also note that before the main flare of X2.1 GOES class, the shearing motions seem to inject a more significant energy than the energy injected by the emergence of the magnetic field.
Conclusions. We conclude that the very long duration (about 4 days) of the horizontal displacement of the main photospheric magnetic structures along the PIL has a primary role in the energy release during the recurrent flares. This peculiar horizontal velocity field also contributes to the monotonic injection of magnetic helicity into the corona. This process, coupled with the high shear and dip angles along the main PIL, appears to be responsible for the consecutive events of loss of equilibrium leading to the recurrent flares and CMEs.

Flare occurrence and the spatial distribution of the magnetic helicity flux

P. **Romano**1 and F. Zuccarello
A&A 535, A1 (**2011**)
Context. The accumulation of magnetic helicity via emergence of new magnetic flux and/or shearing photospheric motions is considered an important tool for understanding the processes that lead to eruptive phenomena.
Aims. We highlight a specific aspect of the magnetic helicity accumulation, providing new observational evidence of the role played by the interaction of magnetic field systems that are characterized by opposite signs of the magnetic helicity flux in triggering solar eruptions.
Methods. The amount of magnetic helicity injected into the corona through the photosphere in a sample of active regions (ARs) during their passage across the solar disk was measured by inferring the apparent motion of photospheric footpoints of magnetic field lines from a time series of MDI full-disk line-of-sight magnetograms. The temporal variation of the maps of magnetic helicity flux was analysed by measuring the fragmentation of the patches that are

characterized by the flux of magnetic helicity. The temporal correlation between the number of these patches and the flare and coronal mass ejection (CME) occurrence has also been studied.
Results. The fragmentation of the patches singled out in the maps of the magnetic helicity flux provides a useful indication of the evolution of the AR complexity. The more fragmented the maps of the magnetic helicity flux are, the higher is the flare and CME frequency. Moreover, most of the events occur for low values (~3 ÷ 17) of the difference of the number of patches with opposite signs of magnetic helicity flux.
Conclusions. These results indicate that not only the accumulation of magnetic helicity in the corona, but also its positive and negative fragmentation and distribution should be taken into account to provide a more confident indication of AR complexity and flare/CME productivity. In particular, the interaction of magnetic systems characterized by opposite sign of magnetic helicity flux may be responsible for many observed eruptions.

An M1.5 Flare Triggered by a Multireconnection Process

P. **Romano** · F. Zuccarello · L. Contarino
Solar Phys (**2007**) 240: 49–61
The analysis of full-disk SOHO/MDI magnetograms and of WL and
171 E TRACE images shows in fact that both flux emergence and horizontal displacements
of photospheric flux concentrations have a key role in triggering the event.

Photospheric magnetic evolution of super active regions:

P. **Romano** and F. Zuccarello
A&A 474 (**2007**) 633-637
We studied the magnetic flux evolution in 26 super active regions observed on the solar disc from Jan. 1, 2000 to Dec. 31, 2006, in order to determine a physical relationship between flares and some properties of the photospheric magnetic fields.
The deviations from magnetic polarity balance and the length of the inversion lines characterized by a horizontal magnetic gradient greater than 0.3 G km^{-1} seem to have a major role in producing a magnetic field topology able to trigger flares.

A Catalog of Solar Flare Events Observed by the SOHO/EIT

Sumanth A. **Rotti**, Petrus C.H. Martens, Berkay Aydin
ApJ S **249** 20 **2020**
https://arxiv.org/pdf/2007.05586.pdf
https://doi.org/10.3847/1538-4365/ab9a42
https://iopscience.iop.org/article/10.3847/1538-4365/ab9a42/pdf
We have compiled a catalog of solar flares as observed by the Extreme ultraviolet Imaging Telescope (EIT) aboard the Solar and Heliospheric Observatory (SOHO) spacecraft and the GOES spacecraft over a span from 1997 to 2010. During mid-1998, the cadence of EIT images was revised from two images per day to 12 minutes. However, the low temporal resolution causes significant data gaps in capturing much of the flaring phenomenon. Therefore, we monitor possible errors in flare detection by flare parameters such as temporal overlap, observational wavelength, and considering full field of view (FOV) images. We consider the GOES flare catalog as the primary source. We describe the technique used to enhance the GOES detected flares using the Extreme Ultraviolet (EUV) image captured by the EIT instrument. In order to detect brightenings, we subtract the images with a maximum cadence of 25 minutes. We have downloaded and analyzed the EIT data via the Virtual Solar Observatory (VSO). This flare dataset from the SOHO/EIT period proves indispensable to the process of the solar flare predictions as the instrument has covered most of Solar Cycle 23.

Evolution of the Ratio of Mg II Intensities During Solar Flares

Soumya **Roy**, Durgesh Tripathi
ApJ **964** 106 **2024**
https://arxiv.org/pdf/2402.11189.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ad2a46/pdf
The Mg II k \& h line intensity ratios can be used to probe the characteristics of the plasma in the solar atmosphere. In this study, using the observations recorded by the Interface Region Imaging Spectrometer (IRIS), we study the variation of the Mg II k \& h intensity ratio for three flares belonging to X-class, M-class, and C-class, throughout their evolution. We also study the k-to-h intensity ratio as a function of magnetic flux density obtained from the line-of-sight magnetograms recorded by the Helioseismic and Magnetic Imager (HMI) on board the Solar Dynamics Observatory (SDO). Our results reveal that while the intensity ratios are independent of magnetic flux density, they show significant changes during the evolution of the C-class and M-class flares. The intensity ratios start to increase at the start of the flare and peak during the impulsive phase before the flare peak and decrease rapidly thereafter. The values of the ratios

fall even below the pre-flare level during the peak and decline phases of the flare. These results are important in light of the heating and cooling of localized plasma and provide further constraints on the understanding of flare physics. **Oct 22, 2014, Feb 3, 2015, Nov 4, 2015**

The Lorentz force at work: multi-phase magnetohydrodynamics throughout a flare lifespan

Wenzhi **Ruan**, Rony Keppens, Limei Yan, Patrick Antolin
ApJ 967:82 **2024**
https://arxiv.org/pdf/2403.19204.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ad3915/pdf **File**
The hour-long, gradual phase of solar flares is well-observed across the electromagnetic spectrum, demonstrating many multi-phase aspects, where cold condensations form within the heated post-flare system, but a complete three-dimensional (3D) model is lacking. Using a state-of-the-art 3D magnetohydrodynamic simulation, we identify the key role played by the Lorentz force through the entire flare lifespan, and show that slow variations in the post-flare magnetic field achieve the bulk of the energy release. Synthetic images in multiple passbands closely match flare observations, and we quantify the role of conductive, radiative and Lorentz force work contributions from flare onset to decay. This highlights how the non-force-free nature of the magnetic topology is crucial to trigger Rayleigh-Taylor dynamics, observed as waving coronal rays in extreme ultraviolet observations. Our C-class solar flare reproduces multi-phase aspects such as post-flare coronal rain. In agreement with observations, we find strands of cooler plasma forming spontaneously by catastrophic cooling, leading to cool plasma draining down the post-flare loops. As there is force balance between magnetic pressure and tension and the plasma pressure in gradual-phase flare loops, this has potential for coronal seismology to decipher the magnetic field strength variation from observations. **June 22, 2015, May 22, 2013, September 10, 2017**

MHD turbulence formation in solar flares: 3D simulation and synthetic observations

Wenzhi **Ruan**, Limei Yan, Rony Keppens
2023 *ApJ* **947** 67
https://arxiv.org/pdf/2210.09856.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ac9b4e/pdf
Turbulent plasma motion is common in the universe, and invoked in solar flares to drive effective acceleration leading to high energy electrons. Unresolved mass motions are frequently detected in flares from extreme ultraviolet (EUV) observations, which are often regarded as turbulence. However, how this plasma turbulence forms during the flare is still largely a mystery. Here we successfully reproduce observed turbulence in our 3D magnetohydrodynamic simulation where the magnetic reconnection process is included. The turbulence forms as a result of an intricate non-linear interaction between the reconnection outflows and the magnetic arcades below the reconnection site, in which the shear-flow driven Kelvin-Helmholtz Instability (KHI) plays a key role for generating turbulent vortices. The turbulence is produced above high density flare loops, and then propagates to chromospheric footpoints along the magnetic field as Alfvenic perturbations. High turbulent velocities above 200 km s^-1 can be found around the termination shock, while the low atmosphere reaches turbulent velocities of 10 km s^-1 at a layer where the number density is about 10^11 cm^-3. The turbulent region with maximum non-thermal velocity coincides with the region where the observed high-energy electrons are concentrated, demonstrating the potential role of turbulence in acceleration. Synthetic views in EUV and fitted Hinode-EIS spectra show excellent agreement with observational results. An energy analysis demonstrates that more than 10% of the reconnection downflow kinetic energy can be converted to turbulent energy via KHI.

When hot meets cold: post-flare coronal rain

Wenzhi **Ruan**, Yuhao Zhou, Rony Keppens
ApJL **920** L15 **2021**
https://arxiv.org/pdf/2109.11873.pdf
https://iopscience.iop.org/article/10.3847/2041-8213/ac27b0/pdf
https://doi.org/10.3847/2041-8213/ac27b0
Most solar flares demonstrate a prolonged, hourlong post-flare (or gradual) phase, characterized by arcade-like, post-flare loops (PFLs) visible in many extreme ultraviolet (EUV) passbands. These coronal loops are filled with hot -- ~30MK -- and dense plasma, evaporated from the chromosphere during the impulsive phase of the flare, and they very gradually recover to normal coronal density and temperature conditions. During this gradual cooling down to ~1MK regimes, much cooler -- ~0.01MK -- and denser coronal rain is frequently observed inside PFLs. Understanding PFL dynamics in this long-duration, gradual phase is crucial to the entire corona-chromosphere mass and energy cycle. Here we report a simulation in which a solar flare evolves from pre-flare, over impulsive phase all the way into its gradual phase, which successfully reproduces post-flare coronal rain. This rain results from catastrophic cooling caused by thermal instability, and we analyse the entire mass and energy budget evolution driving this sudden

condensation phenomenon. We find that the runaway cooling and rain formation also induces the appearance of dark post-flare loop systems, as observed in EUV channels. We confirm and augment earlier observational findings, suggesting that thermal conduction and radiative losses alternately dominate the cooling of PFLs.

A fully self-consistent model for solar flares

https://iopscience.iop.org/article/10.3847/1538-4357/ab93db/pdf
The 'standard solar' flare model collects all physical ingredients identified by multi-wavelength observations of our Sun: magnetic reconnection, fast particle acceleration and the resulting emission at various wavelengths, especially in soft to hard X-ray channels. Its cartoon representation is found throughout textbooks on solar and plasma astrophysics, and guides interpretations of unresolved energetic flaring events on other stars, accretion disks and jets. To date, a fully self-consistent model that reproduces the standard scenario in all its facets is lacking, since this requires the combination of a large scale, multi-dimensional magnetohydrodynamic (MHD) plasma description with a realistic fast electron treatment. Here, we demonstrate such a novel combination, where MHD combines with an analytic fast electron model, adjusted to handle time-evolving, reconnecting magnetic fields and particle trapping. This allows to study (1) the role of fast electron deposition in the triggering of chromospheric evaporation flows; (2) the physical mechanisms that generate various hard X-ray sources at chromospheric footpoints or looptops; and (3) the relationship between soft X-ray and hard X-ray fluxes throughout the entire flare loop evolution. For the first time, this self-consistent solar flare model demonstrates the observationally suggested relationship between flux swept out by the hard X-ray footpoint regions, and the actual reconnection rate at the X-point, which is a major unknown in flaring scenarios. We also demonstrate that a looptop hard X-ray source can result from fast electron trapping.

Extreme-ultraviolet and X-Ray Emission of Turbulent Solar Flare Loops

Wenzhi **Ruan** (1), Chun Xia (1,2), Rony Keppens
2019 ApJL 877 L11
https://iopscience.iop.org/article/10.3847/2041-8213/ab1f78/pdf
Turbulence has been observed in flare loops and is believed to be crucial for the acceleration of particles and in the emission of X-ray photons in flares, but how the turbulence is produced is still an open question. A scenario proposed by Fang et al. suggests that fast evaporation flows from flare loop footpoints can produce turbulence in the looptop via the Kelvin–Helmholtz instability (KHI). We revisit and improve on this scenario and study how the KHI turbulence influences extreme-ultraviolet (EUV) and X-ray emission. A 2.5D numerical simulation is performed in which we incorporate the penetration of high-energy electrons as a spatio-temporal dependent trigger for chromospheric evaporation flows. EUV, soft X-ray (SXR), and hard X-ray (HXR) emission are synthesized based on the evolving plasma parameters and given energetic electron spectra. KHI turbulence leads to clear brightness fluctuations in the EUV, SXR, and HXR emission, with the SXR light curve demonstrating a clear quasi-periodic pulsation (QPP) with period of 26 s. This QPP derives from a locally trapped, fast standing wave that resonates in between KHI vortices. The spectral profile of the Fe xxi 1354 line is also synthesized and found to be broadened due to the turbulent motion of plasma. HXR tends to mimic the variation of SXR flux and the footpoint HXR spectrum is flatter than the looptop HXR spectrum.

Solar flares and Kelvin-Helmholtz instabilities: A parameter survey

Wenzhi **Ruan** (1), Chun Xia (1,2), Rony Keppens
A&A **2018**
https://arxiv.org/pdf/1809.02410.pdf
Hard X-ray (HXR) sources are frequently observed near the top of solar flare loops, and the emission is widely ascribed to bremsstrahlung. We here revisit an alternative scenario which stresses the importance of *inverse Compton processes* and the Kelvin- Helmholtz instability (KHI) proposed by Fang et al. (2016). This scenario adds a novel ingredient to the standard flare model, where evaporation flows from flare-impacted chromospheric foot-points interact with each other near the loop top and produce turbulence via KHI. The turbulence can act as a trapping region and as an efficient accelerator to provide energetic electrons, which scatter soft X-ray (SXR) photons to HXR photons via the inverse Compton mechanism. This paper focuses on the trigger of the KHI and the resulting turbulence in this new scenario. We perform a parameter survey to investigate the necessary ingredients to obtain KHI through interaction of chromospheric evaporation flows. When turbulence is produced in the loop apex, an index of -5/3 can be found in the spectra of velocity and magnetic field fluctuations. The KHI development and the generation of turbulence are controlled by the amount of energy deposited in the chromospheric foot-points and the time scale of its energy deposition, but typical values for M class flares show the KHI development routinely. Asymmetry of energy deposition

determines the location where the turbulence is produced, and the synthesized SXR light curve shows a clear periodic signal related to the sloshing motion of the vortex pattern created by the KHI.

Gradual Magnetic Evolution of Sunspot Structure and Filament-Corona Dynamics Associated with the X1.8 Flare in AR 11283

Guiping **Ruan**, Yao Chen, Haimin Wang
ApJ 812 120 **2015**
http://arxiv.org/pdf/1509.04407.pdf
In this paper, we present a study on persistent and gradual penumbral decay and correlated decline of the photospheric transverse field component during 10-20 hours before a major flare (X1.8) eruption on **2011 September 7**. This long-term pre-eruption behavior is corroborated with the well-imaged pre-flare filament rising, the consistent expansion of coronal arcades overlying the filament, as well as the NLFFF modelling results in the literature. We suggest that both the long-term pre-flare penumbral decay and the transverse field decline are the photospheric manifestation of the gradual rise of the coronal filament-flux rope system. We also suggest that a C3 flare and subsequent reconnection process preceding the X1.8 flare play an important role in triggering the later major eruption.

Plasma heating in the initial phase of solar flares

P. **Rudawy**1, M. Siarkowski2 and R. Falewicz1
Solar and Stellar Variability: Impact on Earth and Planets, Proceedings IAU Symposium No. 264, **2009**, p. 282-284, A.G. Kosovichev, A.H. Andrei & J.-P. Rozelot, eds.
Y:\obridko\otchet09
In this paper we analyze soft and hard X-ray emission of the **2002 September 20** M1.8 GOES class solar flare observed by RHESSI and GOES satellites, where soft X-ray emission precedes the onset of the main bulk hard X-ray emission by »5 min. This suggests that an additional heating mechanism may be at work at the early beginning of the flare. However RHESSI spectra indicate presence of the non-thermal electrons also before impulsive phase. So, we assumed that a dominant energy transport mechanism during rise phase of solar flares is electron beam-driven evaporation. We used non-thermal electron beams derived from RHESSI spectra as the heating source in a hydrodynamic model of the analyzed flare. We showed that energy delivered by non-thermal electron beams is sufficient to heat the flare loop to temperatures in which it emits soft X-ray closely following the GOES 1-8 °A light-curve.

Validity of NLFFF Optimization Reconstruction

G. V. **Rudenko**, I. S. Dmitrienko
Solar Phys. **2020**
https://arxiv.org/pdf/2001.05660.pdf
We evaluate validity of NLFFF extrapolation performed with Optimization class (OPTI) codes. While explaining inevitable for OPTI partial non-solenoidality caused by the gas pressure notable role in pressure balance at photospheric heights and by mathematical aspects related to optimization and BVP (boundary value problem), we justify elimination of the non-solenoidal component (postprocessing) from the OPTI result obtained. In essence, postprocessing converts the entire non-solenoidal part into a solenoidal force part, which possibly reflects factual deviation of magnetic field from its force-free pproximation on the photosphere and in the solar corona. Two forms of postprocessing have been analyzed in this paper.Postprocessing I eliminates the non-solenoidal component without changing transverse field at the measurement level, and Postprocessing II leaves the field normal component unchanged. Extrapolation, postprocessing, and then comparison of metric and energy characteristics are performed over AR 11158 active region for a small fragment of its evolution containing the February X-class flare.Our version of OPTI code showed that free energy decreased by ∼1032 erg within 1 hour, which corresponds to theoretical estimations of the flare-caused magnetic energy loss. This result differs significantly from the one in Sun et al. (2012).Therefore, we also comment on some features of our OPTI code implementation, which may cause significant differences between our results and those obtained using the Wiegelmann (2004) version of OPTI code in study by Sun et al. (2012). **2011/02/-14-15**

Flux-Rope Mediated Turbulent Magnetic Reconnection

Alexander J. B. **Russell**
ApJ **2024**
https://arxiv.org/pdf/2406.16149
We present a new model of magnetic reconnection in the presence of turbulence, applicable when the magnetic helicity is non-zero. The new model differs from the Lazarian-Vishniac turbulent reconnection theory by emphasizing the role of locally coherent magnetic structures, whose existence is shown to be permitted by the properties of magnetic field line separation in turbulent plasma. Local coherence allows storage of magnetic helicity inside the reconnection layer and we argue that helicity conservation produces locally coherent twisted flux ropes. We then introduce the "Alfvén

horizon" to explain why the global reconnection rate can be governed by locally coherent magnetic field structure instead of by field line wandering, formally extending to 3D the principle that reconnection can be made fast by fragmentation of the global current layer. Coherence is shown to dominate over field line dispersion if the anisotropy of the turbulence at the perpendicular scale matching the thickness of a marginally stable current layer exceeds the aspect ratio of the current layer. Finally, we conjecture that turbulence generated within the reconnection layer may produce a balance of anisotropies that maintains the system in the flux-rope mediated regime. The new model successfully accounts for the major features of 3D numerical simulations of self-generated turbulent reconnection, including reconnection rates of 0.01 in resistive MHD and 0.1 with collisionless physics.

Alfvén Waves in Solar Flares **Review**

Alexander J. B. **Russell**

"Alfvén Waves Across Heliophysics: Progress, Challenges, and Opportunities" (American Geophysical Union). **2023**

https://arxiv.org/pdf/2311.02144.pdf

Solar flares are dramatic events in which magnetic reconnection in the corona leads to heating of plasma to tens of MK and acceleration of particles to high energies. They also centrally involve transport between the corona (where the magnetic reconnection occurs) and the lower solar atmosphere (where most energy is radiated from). There is substantial evidence for the presence of Alfvénic waves/turbulence in solar flares, for example, in the ubiquitous nonthermal broadening of flare spectral lines. The physical role that Alfvénic waves have in the flare has attracted considerable attention, especially since 2007-2010. This article reviews what spectroscopic observations reveal about the properties and importance of Alfvénic waves, turbulence and transport in solar flares; mechanisms for wave excitation by magnetic reconnection at high Lundquist numbers and braking of the sunward reconnection jet; and models of wave energy transport to the lower atmosphere and the resulting heating and dynamics. The article finishes with discussion of the outlook for new progress.

A unified view of coronal loop contraction and oscillation in flares

Alexander J. B. **Russell**, Paulos J. A. Simoes, Lyndsay Fletcher

A&A 581, A8 **2015**

http://arxiv.org/pdf/1506.07716v1.pdf

http://www.aanda.org/articles/aa/pdf/2015/09/aa25746-15.pdf

Context: Transverse loop oscillations and loop contractions are commonly associated with solar flares, but the two types of motion have traditionally been regarded as separate phenomena.

Aims: We present an observation of coronal loops contracting and oscillating following onset of a flare. We aim to explain why both behaviours are seen together and why only some of the loops oscillate.

Methods: A time sequence of SDO/AIA 171 \r{A} images is analysed to identify positions of coronal loops following the onset of M6.4 flare SOL**2012-03-09**T03:53. We focus on five loops in particular, all of which contract during the flare, with three of them oscillating as well. A simple model is then developed for contraction and oscillation of a coronal loop.

Results: We propose that coronal loop contractions and oscillations can occur in a single response to removal of magnetic energy from the corona. Our model reproduces the various types of loop motion observed and explains why the highest loops oscillate during their contraction while no oscillation is detected for the shortest contracting loops. The proposed framework suggests that loop motions can be used as a diagnostic for the removal of coronal magnetic energy by flares, while rapid decrease of coronal magnetic energy is a newly-identified excitation mechanism for transverse loop oscillations.

Solar flares and focused energy transport by MHD waves

A. J. B. **Russell**1⋆ and D. J. Stackhouse2

A&A 558, A76 (**2013**)

Context. Transport of flare energy from the corona to the chromosphere has traditionally been assigned to electron beams; however, interest has recently been renewed in magnetohydrodynamic (MHD) waves as a complementary or alternative mechanism.

Aims. We determine whether, and under what conditions, MHD waves deliver spatially localised energy to the chromosphere, as required if MHD waves are to contribute to emission from flare ribbons and kernels. This paper also highlights several properties of MHD waves that are relevant to solar flares and demonstrates their application to the flare problem.

Methods. Transport is investigated using a magnetic arcade model and 2.5D MHD simulations. Different wave polarisations are considered and the effect of fine structuring transverse to the magnetic field is also examined. Ray tracing provides additional insight into the evolution of waveguided fast waves.

Results. Alfvén waves are very effective at delivering energy fluxes to small areas of chromosphere, localisation being enhanced by magnetic field convergence and phase mixing. Fast waves, in the absence of fine coronal structure, are more suited to powering emission from diffuse rather than compact sources; however, fast waves can be strongly localised by coronal waveguides, in which case focused energy is best transported to the chromosphere when waveguides are directly excited by the energy release.
Conclusions. MHD waves pass an important test for inclusion in future flare models.

On The Solar Origins of Open Magnetic Fields in the Heliosphere

Rust, D.M., Haggerty, D.K., Georgoulis, M.K., Sheeley, N.R., Wang, Y.-M., DeRosa, M.L., Schriver, C.J.
E-print, Oct 2008; ApJ, v. 687, 635–645, **2008**
http://www.journals.uchicago.edu/doi/abs/10.1086/592017
A combination of heliospheric and solar data was used to identify open magnetic fields stretching from the lower corona to Earth orbit. 35 near-relativistic electron beams detected at the ACE spacecraft ??labeled?? the heliospheric segments of the open fields. An X-ray flare occurred<20 minutes before injection of the electrons in 25 events. These flares labeled the solar segment of the open fields. The flares occurred in western-hemisphere active regions (ARs) with *coronal holes whose polarity agreed with the polarity of the beam-carrying interplanetary fields in 23 of the 25 events.* We conclude that electron beams reach 1 AU from open AR fields adjacent to flare sites. The Wang & Sheeley implementation of the potential-field source-surface model successfully identified the open fields in 36% of cases. Success meant that the open fields reached the source surface within 3 heliographic deg of the interplanetary magnetic field connected to ACE at 1 AU. Inclusion of five near misses improves the success rate to 56%. The success rate for the Schrijver & DeRosa PFSS implementation was 50%. Our results suggest that, even if the input magnetic data are updated frequently, the PFSS models succeed in only 50% of cases to identify the coronal segment of open fields. Development of other techniques is in its infancy.

Triangulation of Hard X-Ray Sources in an X-Class Solar Flare with ASO-S/HXI and Solar Orbiter/STIX.

Ryan, D.F., Massa, P., Battaglia, A.F. et al.
Sol Phys 299, 114 (**2024**).
https://doi.org/10.1007/s11207-024-02341-8
https://link.springer.com/content/pdf/10.1007/s11207-024-02341-8.pdf
HXI on ASO-S and STIX onboard Solar Orbiter are the first simultaneously operating solar hard X-ray imaging spectrometers. ASO-S's low Earth orbit and Solar Orbiter's periodic displacement from the Sun–Earth line enables multi-viewpoint solar hard X-ray spectroscopic imaging analysis for the first time. Here, we demonstrate the potential of this new capability by reporting the first results of 3D triangulation of hard X-ray sources in the SOL**2023-12-31**T21:55 X5 flare. HXI and STIX observed the flare near the east limb with an observer separation angle of 18°. We triangulated the brightest regions within each source, which enabled us to characterise the large-scale hard X-ray geometry of the flare. The footpoints were found to be in the chromosphere within uncertainty, as expected, while the thermal looptop source was centred at an altitude of 15.1 ± 1 Mm. Given the footpoint separation, this implies a more elongated magnetic-loop structure than predicted by a semi-circular model. These results show the strong diagnostic power of joint HXI and STIX observations for understanding the 3D geometry of solar flares. We conclude by discussing the next steps required to fully exploit their potential.

3D evolution of a solar flare thermal X-ray loop-top source⋆

D. F. **Ryan**1, S. Laube1, B. Nicula2, S. Krucker1,3, S. A. Maloney4, A. F. Battaglia1,5, A. Warmuth6, A. Csillaghy1 and D. Müller7
A&A 681, A61 (**2024**)
https://www.aanda.org/articles/aa/pdf/2024/01/aa47212-23.pdf
Context. The recent launch of Solar Orbiter has placed a solar X-ray imager (Spectrometer/Telescope for Imaging X-rays; STIX) beyond Earth orbit for the first time. This introduces the possibility of deriving the 3D locations and volumes of solar X-ray sources by combining STIX observations with those of Earth-orbiting instruments such as the Hinode X-ray Telescope (XRT). These measurements promise to improve our understanding of the evolution and energetics of solar flares. However, substantial design differences between STIX and XRT present important challenges that must first be overcome.
Aims. We aim to: 1) explore the validity of combining STIX and XRT for 3D analysis given their different designs, 2) understand uncertainties associated with 3D reconstruction and their impact on the derived volume and thermodynamic properties, 3) determine the validity of the scaling law that is traditionally used to estimate source volumes from single-viewpoint observations, 4) chart the temporal evolution of the location, volume, and thermodynamic properties of a thermal X-ray loop-top source of a flare based on a 3D reconstruction for the first time.
Methods. The **SOL2021-05-07T18**:43 M3.9-class flare is analysed using co-temporal observations from STIX and XRT, which, at the time, were separated by an angle of 95.4° relative to the flare site. The 3D reconstruction is

performed via elliptical tie-pointing and the visualisation by JHelioviewer, which is enabled by new features developed for this project. Uncertainties associated with the 3D reconstruction are derived from an examination of projection effects given the observer separation angle and the source orientation and elongation.
Results. Firstly, we show that it is valid to combine STIX 6–10 keV and XRT Be-thick observations for 3D analysis for the flare examined in this study. However, the validity of doing so in other cases may depend on the nature of the observed source. Therefore, careful consideration should be given on a case-by-case basis. Secondly, the optimal observer separation angle for 3D reconstruction is 90° ± 5°, but the uncertainties are still relatively small in the range 90° ± 20°. Other angles are viable, but are associated with higher uncertainties, which can be quantified. Thirdly, the traditional area-to-volume scaling law may overestimate the 3D-derived volume of the thermal X-ray loop-top source studied here by over a factor of 2. This is beyond the uncertainty of the 3D reconstruction. The X-ray source was not very asymmetric, and so the overestimation may be greater for more elongated sources. In addition, the degree of overestimation can vary with time and viewing angle, demonstrating that the true source geometry can evolve differently in different dimensions. 3D reconstruction is therefore necessary to derive more reliable volumes. Simply applying a modified scaling law to single-viewpoint observations is not sufficient. Finally, the vertical motion of the X-ray source is consistent with previous observations of limb flares. This indicates that 3D reconstruction by elliptical tie-pointing provides reliable 3D locations. The uncertainties of thermodynamic properties derived from volume, temperature, and/or emission measure are dominated by those of the volume. In contrast to single-viewpoint studies, observationally constrained volume uncertainties can be assigned via 3D reconstruction, which lends quantifiable credibility to scientific conclusions drawn from the derived thermodynamic properties. **2021-05-07**

Effects of flare definitions on the statistics of derived flare distributions

Daniel F. **Ryan**, Marie Dominique, Dan Seaton, Koen Stegen, Arthur White
2016 A&A 592, A133
http://arxiv.org/pdf/1606.04472v1.pdf

The statistical examination of solar flares is crucial to revealing their global characteristics and behaviour. Such examinations can tackle large-scale science questions or give context to detailed single-event studies. However, they are often performed using standard but basic flare detection algorithms relying on arbitrary thresholds. This arbitrariness may lead to important scientific conclusions being drawn from results caused by subjective choices in algorithms rather than the true nature of the Sun. In this paper, we explore the effect of the arbitrary thresholds used in the GOES (Geostationary Operational Environmental Satellite) event list and LYRA (Large Yield RAdiometer) Flare Finder algorithms. We find that there is a small but significant relationship between the power law exponent of the GOES flare peak flux frequency distribution and the flare start thresholds of the algorithms. We also find that the power law exponents of these distributions are not stable, but appear to steepen with increasing peak flux. This implies that the observed flare size distribution may not be a power law at all. We show that depending on the true value of the exponent of the flare size distribution, this deviation from a power law may be due to flares missed by the flare detection algorithms. However, it is not possible determine the true exponent from GOES/XRS observations. Additionally we find that the PROBA2/LYRA flare size distributions are artificially steep and clearly non-power law. We show that this is consistent with an insufficient degradation correction. This means that PROBA2/LYRA should not be used for flare statistics or energetics unless degradation is adequately accounted for. However, it can be used to study variations over shorter timescales and for space weather monitoring.

The Compatibility of Flare Temperatures Observed with AIA, GOES, and RHESSI

Daniel F. **Ryan**, Aidan M. O'Flannagain, Markus J. Aschwanden…
Solar Physics, July **2014**, Volume 289, Issue 7, pp 2547-2563

We test the compatibility and biases of multi-thermal flare DEM (differential emission measure) peak temperatures determined with AIA with those determined by GOES and RHESSI using the isothermal assumption. In a set of 149 M- and X-class flares observed during the first two years of the SDO mission, AIA finds DEM peak temperatures at the time of the peak GOES 1 – 8 Å flux to have an average of T p=12.0±2.9 MK and Gaussian DEM widths of log10(σ T)=0.50±0.13. From GOES observations of the same 149 events, a mean temperature of T p=15.6±2.4 MK is inferred, which is systematically higher by a factor of T GOES/T AIA=1.4±0.4. We demonstrate that this discrepancy results from the isothermal assumption in the inversion of the GOES filter ratio. From isothermal fits to photon spectra at energies of $\epsilon \approx 6-12$ keV of 61 of these events, RHESSI finds the temperature to be higher still by a factor of T RHESSI/T AIA=1.9±1.0. We find that this is partly a consequence of the isothermal assumption. However, RHESSI is not sensitive to the low-temperature range of the DEM peak, and thus RHESSI samples only the high-temperature tail of the DEM function. This can also contribute to the discrepancy between AIA and RHESSI temperatures. The higher flare temperatures found by GOES and RHESSI imply correspondingly lower emission measures. We conclude that self-consistent flare DEM temperatures and emission measures require simultaneous fitting of EUV (AIA) and soft X-ray (GOES and RHESSI) fluxes.

Decay-phase Cooling and Inferred Heating of M- and X-class Solar Flares

Daniel F. **Ryan**1,2,3, Phillip C. Chamberlin2, Ryan O. Milligan2,3,4, and Peter T. Gallagher
2013 ApJ 778 68.
http://arxiv.org/pdf/1401.4079v1.pdf

In this paper, the cooling of 72 M- and X-class flares is examined using GOES/XRS and SDO/EVE. The observed cooling rates are quantified and the observed total cooling times are compared with the predictions of an analytical zero-dimensional hydrodynamic model. We find that the model does not fit the observations well, but does provide a well-defined lower limit on a flare's total cooling time. The discrepancy between observations and the model is then assumed to be primarily due to heating during the decay phase. The decay-phase heating necessary to account for the discrepancy is quantified and found be ~50% of the total thermally radiated energy, as calculated with GOES. This decay-phase heating is found to scale with the observed peak thermal energy. It is predicted that approximating the total thermal energy from the peak is minimally affected by the decay-phase heating in small flares. However, in the most energetic flares the decay-phase heating inferred from the model can be several times greater than the peak thermal energy.

The Thermal Properties of Solar Flares over Three Solar Cycles Using GOES X-Ray Observations

Ryan, Daniel F.; Milligan, Ryan O.; Gallagher, Peter T.; Dennis, Brian R.; Tolbert, A. Kim; Schwartz, Richard A.; Young, C. Alex
E-print, March **2013**

Solar flare X-ray emission results from rapidly increasing temperatures and emission measures in flaring active region loops. To date, observations from the X-Ray Sensor (XRS) on board the Geostationary Operational Environmental Satellite (GOES) have been used to derive these properties, but have been limited by a number of factors, including the lack of a consistent background subtraction method capable of being automatically applied to large numbers of flares. In this paper, we describe an automated Temperature and Emission measure-Based Background Subtraction method (TEBBS), that builds on the methods of Bornmann. Our algorithm ensures that the derived temperature is always greater than the instrumental limit and the pre-flare background temperature, and that the temperature and emission measure are increasing during the flare rise phase. Additionally, TEBBS utilizes the improved estimates of GOES temperatures and emission measures from White et al. TEBBS was successfully applied to over 50,000 solar flares occurring over nearly three solar cycles (1980-2007), and used to create an extensive catalog of the solar flare thermal properties. We confirm that the peak emission measure and total radiative losses scale with background subtracted GOES X-ray flux as power laws, while the peak temperature scales logarithmically. As expected, the peak emission measure shows an increasing trend with peak temperature, although the total radiative losses do not. While these results are comparable to previous studies, we find that flares of a given GOES class have lower peak temperatures and higher peak emission measures than previously reported. The TEBBS database of flare thermal plasma properties is publicly available at **http://www.SolarMonitor.org/TEBBS/.**

The Thermal Properties of Solar Flares over Three Solar Cycles Using GOES X-Ray Observations

Daniel F. **Ryan**, Ryan O. Milligan, Peter T. Gallagher, Brian R. Dennis, A. Kim Tolbert, Richard A. Schwartz, C. Alex Young
ApJS Volume 202, Issue 2, article id. 11, **2012**
https://iopscience.iop.org/article/10.1088/0067-0049/202/2/11/pdf

Solar flare X-ray emission results from rapidly increasing temperatures and emission measures in flaring active region loops. To date, observations from the X-Ray Sensor (XRS) onboard the Geostationary Operational Environmental Satellite (GOES) have been used to derive these properties, but have been limited by a number of factors, including the lack of a consistent background subtraction method capable of being automatically applied to large numbers of flares. In this paper, we describe an automated temperature and emission measure-based background subtraction method (TEBBS), which builds on the methods of Bornmann (1990). Our algorithm ensures that the derived temperature is always greater than the instrumental limit and the pre-flare background temperature, and that the temperature and emission measure are increasing during the flare rise phase. Additionally, TEBBS utilizes the improved estimates of GOES temperatures and emission measures from White et al. (2005). TEBBS was successfully applied to over 50,000 solar flares occurring over nearly three solar cycles (1980-2007), and used to create an extensive catalog of the solar flare thermal properties. We confirm that the peak emission measure and total radiative losses scale with background subtracted GOES X-ray flux as power-laws, while the peak temperature scales logarithmically. As expected, the peak emission measure shows an increasing trend with peak temperature, although the total radiative losses do not. While these results are comparable to previous studies, we find that flares of a given GOES class have lower peak temperatures and higher peak emission measures than previously reported. The resulting TEBBS database of thermal

flare plasma properties is publicly available on Solar Monitor (www.solarmonitor.org/TEBBS/) and will be available on Heliophysics Integrated Observatory (www.helio-vo.eu).

FLARES PRODUCING WELL-ORGANIZED POST-FLARE ARCADES (SLINKIES) HAVE EARLY PRECURSORS

M. P. **Ryutova**1, Z. Frank2, H. Hagenaar2 and T. Berger
2011 ApJ 733 125
Exploding loop systems producing X-ray flares often, but not always, bifurcate into a long-living, well-organized system of multi-threaded loop arcades resembling solenoidal slinkies. The physical conditions that cause or prevent this process are not known. To address this problem, we examined most of the major (X-class) flares that occurred during the last decade and found that the flares that bifurcate into long-living slinky arcades have different signatures than those that do not "produce" such structures. The most striking difference is that, in all cases of slinky formation, GOES high energy proton flux becomes significantly enhanced 10-24 hr before the flare occurs. No such effect was found prior to the "non-slinky" flares. This fact may be associated with the difference between energy production by a given active region and the amount of energy required to bring the entire system into the form of well-organized, self-similar loop arcades. As an example illustrating the process of post-flare slinky formation, we present observations taken with the Hinode satellite, in several wavelengths, showing a time sequence of pre-flare and flare activity, followed by the formation of dynamically stable, well-organized structures. One of the important features revealed is that post-flare coronal slinky formation is preceded by scale invariant structure formation in the underlying chromosphere/transition region. We suggest that the observed regularities can be understood within the framework of self-organized critical dynamics characterized by scale invariant structure formation with critical parameters largely determined by energy saturation level. The observed regularities per se may serve as a long-term precursor of strong flares and may help to study predictability of system behavior.

Propagation of the Alfvén Wave and Induced Perturbations in the Vicinity of a 3D Proper Magnetic Null Point

S. **Sabri**1, H. Ebadi1, and S. Poedts2,3
2022 ApJ 924 126
https://iopscience.iop.org/article/10.3847/1538-4357/ac3b5f/pdf
The aim of the present work is to study the propagation of the Alfvén wave around a 3D proper magnetic null point and its accompanying perturbations. In this line, the shock-capturing Godunov-type PLUTO code is used to solve the magnetohydrodynamic (MHD) equations. It is found that the Alfvén wave propagates toward the null point at the fan plane and the wave−wave interaction could be the main reason for the Alfvén wave energy dissipation, ehile, at two other planes including the spine axis, the Alfvén wave spreads toward the spine axis and accumulates along it. Furthermore, the fast magnetoacoustic wave moves toward the null point at the fan plane and also at two other planes including the spine axis. The fast magnetoacoustic wave also refracts around the null point without any significant accumulation along the spine axis. Finally, the slow mode moves toward the null point at the fan plane. It is illustrated that, at the x,z plane, in addition to the refraction of the slow wave around the null point, there is an accumulation of the slow mode along the spine axis, while, at the other plane including the spine axis, the slow magnetoacoustic wave refracts around the null point. Moreover, it is found that the 3D structure results in the high amplitude of MHD wave energy in comparison with the 2.5D structure. Finally, it is found that the Alfvén wave gives its energy to the induced fast and slow magnetoacoustic waves and they have more time to heat the plasma.

Can Proton Beam Heating Flare Models Explain Sunquakes?

Viacheslav **Sadykov**, John Stefan, Alexander Kosovichev, Joel Allred, Graham S Kerr, Andrey Stejko, Adam Kowalski
ApJ **2023**
https://arxiv.org/pdf/2306.13162.pdf
SDO/HMI observations reveal a class of solar flares with substantial energy and momentum impacts in the photosphere, concurrent with white-light emission and helioseismic responses, known as sunquakes. Previous radiative hydrodynamic modeling has demonstrated the challenges of explaining sunquakes in the framework of the standard flare model of `electron beam' heating. One of the possibilities to explain the sunquakes and other signatures of the photospheric impact is to consider additional heating mechanisms involved in solar flares, for example, via flare-accelerated protons. In this work, we analyze a set of single-loop RADYN+FP simulations where the atmosphere is heated by non-thermal power-law-distributed proton beams which can penetrate deeper than the electron beams into the low atmospheric layers. Using the output of the RADYN models, we calculate synthetic Fe I 6173 A line Stokes profiles and from those the line-of-sight (LOS) observables of the SDO/HMI instrument, as well as the 3D helioseismic response and compare them with the corresponding observational characteristics. These initial results show that the models with proton beam heating can produce the enhancement of the HMI continuum observable and explain qualitatively generation of sunquakes. The continuum observable enhancement is evident in all models but is more

prominent in ones with Ec≥500 keV. In contrast, the models with Ec≤100 keV provide a stronger sunquake-like helioseismic impact according to the 3D acoustic modeling, suggesting that low-energy (deka- and hecto-keV) protons have an important role in the generation of sunquakes.

Response of SDO/HMI observables to heating of the solar atmosphere by precipitating high-energy electrons

Viacheslav M **Sadykov**, Alexander G Kosovichev, Irina N Kitiashvili, Graham S Kerr
2019
https://arxiv.org/pdf/1906.10788.pdf

We perform modeling of the line-of-sight (LOS) observables of the Helioseismic and Magnetic Imager (HMI) onboard the Solar Dynamics Observatory (SDO) for models of the solar atmosphere heated by precipitating high-energy electrons during solar flares. The radiative hydrodynamic (RADYN) flare models are obtained from the F-CHROMA database. The Stokes profiles for the Fe 6173 A line observed by SDO/HMI are calculated using the radiative transfer code RH1.5D assuming statistical equilibrium for atomic level populations and imposing a 100 G or 1000 G uniform vertical magnetic field. The SDO/HMI data processing pipeline algorithm is applied to derive the observables (continuum intensity, line depth, Doppler velocity, LOS magnetic field). Our results reveal that the deviations of the observables from the actual spectroscopic line parameters can reach 0.7 km/s for Doppler velocities and almost 100 G for the LOS magnetic field for the flare models with an average deposited energy flux of ≥5.0×1010 erg cm−2 s−1. Such deviations are significantly smaller for weaker flares with lower deposited energy fluxes. The LOS magnetic field observable does not reverse its sign for any considered flare model. The results show that sharp magnetic transients in SDO/HMI observations during solar flares may partly be due to rapid changes of the line profile. These changes are likely caused by heating of the atmosphere by accelerated electrons and should be interpreted with caution.

Statistical study of properties of the Soft X-ray emission during solar flares

Viacheslav M **Sadykov**, Alexander G Kosovichev, Irina N Kitiashvili, Alexander Frolov
ApJ **874** 19 **2018**
https://arxiv.org/pdf/1810.05610.pdf

We present a statistical analysis of properties of the Soft X-Ray (SXR) emission, plasma temperature (T), and emission measure (EM), derived from GOES observations of flares in 2002-2017. The temperature and emission measures are obtained using the TEBBS algorithm (Ryan et al. 2012), which delivers reliable results together with uncertainties even for weak B-class flare events. More than 96% of flares demonstrate a sequential appearance of T, SXR, and EM peaks, in agreement with the expected behavior of the chromospheric evaporation process. The relative number of such flares increases with increasing the SXR peak flux. The SXR peak is closer in time to the T peak for B-class flares than for >=C-class flares, while it is very close to the EM peak for MX-class flares. We define flares as "T-controlled events" if the SXR-T time delay is at least two times shorter than the EM-SXR delay, and as "EM-controlled events" if the EM-SXR delay is at least two times shorter than the SXR-T delay. For any considered flare class range, the T-controlled events compared to EM-controlled events have: a) higher EM but lower T; b) longer durations and shorter relative growth times; c) longer FWHM and characteristic decay times. Interpretation of these statistical results based on a dynamic loop model suggests that for flares of the same class range, the T-controlled events are developed in longer loops than the EM-controlled events.

Statistical Study of Chromospheric Evaporation in Impulsive Phase of Solar Flares

Viacheslav M **Sadykov**, Alexander G Kosovichev, Ivan N Sharykin, Graham S Kerr
ApJ **871** 2 **2019**
https://arxiv.org/pdf/1805.10729.pdf
sci-hub.tw/10.3847/1538-4357/aaf6b0

We present a statistical study of chromospheric evaporation in solar flares using simultaneous observations by the RHESSI X-ray telescope and the IRIS UV spectrograph. The results are compared with radiation hydrodynamic flare models from the F-CHROMA RADYN database. For each event, we study spatially-resolved Doppler shifts of spectral lines formed in the transition region (C II 1334.5 A) and hot coronal plasma (Fe XXI 1354.1 A) to investigate the dynamics of the solar atmosphere during the flare impulsive phase. We estimate the energy fluxes deposited by high-energy electrons using X-ray imaging spectroscopy and assuming the standard thick-target model. Using the RADYN flare models, the RH 1.5D radiative transfer code and the Chianti atomic line database, we calculate C II and Fe XXI line profiles and compare with the observations. While the models predict a correlation between the Doppler shifts and deposited energy flux for both lines, this was only observed in the C II data, and not in the Fe XXI data. In addition, the C II and Fe XXI Doppler shifts are not correlated with each other in the observations and strongly correlated in models. Several quantitative discrepancies are found between the observations and models: the Fe XXI Doppler shifts are substantially stronger in the models than in the data, the C II mean blueshifts are absent in the observations but predicted by the models. The transition energy between "gentle" and "explosive" evaporation regimes derived from the observations ([Math Processing Error]~erg~cm[Math Processing Error]~s[Math Processing Error]) and the models ([Math Processing Error]~erg~cm[Math Processing Error]~s[Math Processing Error]) are comparable with each other.

The results illustrate, for the first time, observational relationships among the processes of chromospheric evaporation, response of the colder layers, and the flare energy flux deposited by high-energy electrons. **2014-02-13, 2014-03-29, 2014-06-12, 2014-06-13, 2015-03-11, 2015-08-27**

Interactive Multi-Instrument Database of Solar Flares

Viacheslav M **Sadykov**, Rishabh Gupta, Alexander G Kosovichev, Vincent Oria, Gelu M Nita
Astrophysical Journal Supplement Series, Volume 231, Issue 1, article id. 6 **2017**
https://arxiv.org/pdf/1702.02991.pdf
https://iopscience.iop.org/article/10.3847/1538-4365/aa79a9/pdf
Solar flares represent a complicated physical phenomenon observed in a broad range of the electromagnetic spectrum, from radiowaves to gamma-rays. For a complete understanding of the flares it is necessary to perform a combined multi-wavelength analysis using observations from many satellites and ground-based observatories. For efficient data search, integration of different flare lists and representation of observational data, we have developed the Interactive Multi-Instrument Database of Solar Flares (this https URL). The web database if fully functional and allows the user to search for uniquely-identified flare events based on their physical descriptors and availability of observations of a particular set of instruments. Currently the data from three primary flare lists (GOES, RHESSI and HEK) and a variety of other event catalogs (Hinode, Fermi GBM, Konus-Wind, OVSA flare catalogs, CACTus CME catalog, Filament eruption catalog) and observing logs (IRIS and Nobeyama coverage), are integrated, and an additional set of physical descriptors (temperature and emission measure) is provided along with observing summary, data links and multi-wavelength light curves for each flare event since January, 2002. We think that the created instrument will allow researchers significantly speed up the search of events of interest for statistical and case studies.

Relationships Between Characteristics of the Line-of-Sight Magnetic Field and Solar Flare Forecasts

Viacheslav M **Sadykov**, Alexander G Kosovichev
2017 *ApJ* **849** 148
https://arxiv.org/pdf/1704.03423.pdf
We analyze the relationship between the flare X-ray peak flux, and characteristics of the polarity inversion line (PIL) and active regions (ARs), derived from line-of-sight (LOS) magnetograms. The PIL detection algorithm based on a magnetogram segmentation procedure is applied for each AR with 1 hr cadence. The PIL and AR characteristics are associated with the AR flare history and divided into flaring and nonflaring cases. Effectiveness of the derived characteristics for flare forecasting is determined by the number of nonflaring cases separated from flaring cases by a certain threshold, and by their Fisher ranking score. The Support Vector Machine (SVM) classifier trained only on the PIL characteristics is used for the flare prediction. We have obtained the following results: (1) the PIL characteristics are more effective than global characteristics of ARs, (2) the highest True Skill Statistics (TSS) values of 0.76 ± 0.03 for ≥M1.0 flares and 0.84 ± 0.07 for ≥X1.0 flares are obtained using the "Sigmoid" SVM kernel, (3) the TSS scores obtained using only the LOS magnetograms are slightly lower than the scores obtained using vector magnetograms, but significantly better than current expert-based predictions, (4) for prediction of ≥M1.0 class flares 74.4% of all cases, and 91.2% for ≥X1.0 class, can be pre-classified as negative with no significant effect on the results, (5) the inclusion of global AR characteristics does not improve the forecast. The study confirms the unique role of the PIL region characteristics in the flare initiation process, and demonstrates possibilities of flare forecasting using only the LOS magnetograms.. **2011-02-16**

Relationship between chromospheric evaporation and magnetic field topology in M-class solar flare

V.M. **Sadykov**, A.G. Kosovichev, I.N. Sharykin, I.V. Zimovets, S. Vargas Dominguez
2016 *ApJ* **828** 4
http://arxiv.org/pdf/1604.05346v1.pdf
Chromospheric evaporation is observed as Doppler blueshift during solar flares. It plays one of key roles in dynamics and energetics of solar flares, however, its mechanism is still unknown. In this paper we present a detailed analysis of spatially-resolved multi-wavelength observations of chromospheric evaporation during an M 1.0 class solar flare (SOL**2014-06-12**T21:12) using data from the NASA's IRIS (Interface Region Imaging Spectrograph) and HMI/SDO (Helioseismic and Magnetic Imager onboard Solar Dynamics Observatory) telescopes, and VIS/NST (Visible Imaging Spectrometer at New Solar Telescope) high-resolution observations, covering the temperature range from 10^4 K to 10^7 K. The results show that the averaged over the region Fe XXI blueshift of the hot evaporating plasma is delayed relative to the C II redshift of the relatively cold chromospheric plasma by about 1 min. The spatial distribution of the delays is not uniform across the region and can be as long as 2 min in several zones. Using vector magnetograms from HMI we reconstruct the magnetic field topology and the quasi-separatrix layer (QSL) and find that the blueshift delay regions as well as the H-alpha flare ribbons are connected to the region of magnetic polarity inversion line (PIL) and an expanding flux rope via a system of low-lying loop arcades with height < ~4.5 Mm. This allows us to propose an

interpretation of the chromospheric evaporation based on the geometry of local magnetic fields, and the primary energy source associated with the PIL.

Properties of Chromospheric Evaporation and Plasma Dynamics of a Solar Flare from Iris

Viacheslav M. **Sadykov**1,2,3,4, Santiago Vargas Dominguez1,5, Alexander G. Kosovichev1,2, Ivan N. Sharykin3, Alexei B. Struminsky3,4, and Ivan Zimovets

2015 ApJ 805 167

The dynamics of hot chromospheric plasma of solar flares is a key to understanding the mechanisms of flare energy release and particle acceleration. A moderate M1.0 class flare of **2014 June 12**, (SOL2014-06-12T21:12) was simultaneously observed by NASA's Interface Region Imaging Spectrograph (IRIS) and other spacecraft, and also by the New Solar Telescope at the BBSO. This paper presents the first part of our investigation focused on analysis of the IRIS data. Our analysis of the IRIS data in different spectral lines reveals a strong redshifted jet-like flow with a speed of ~100 km s−1 of the chromospheric material before the flare. Strong nonthermal emission of the C ii k 1334.5 Å line, formed in the chromosphere–corona transition region, is observed at the beginning of the impulsive phase in several small (with a size of ~1") points. It is also found that the C ii k line is redshifted across the flaring region before, during, and after the impulsive phase. A peak of integrated emission of the hot (1.1 ▪ 107 K) plasma in the Fe xxi 1354.1 Å line is detected approximately five minutes after the integrated emission peak of the lower temperature C ii k. A strong blueshift of the Fe xxi line across the flaring region corresponds to evaporation flows of the hot chromospheric plasma with a speed of 50 km s−1. Additional analysis of the RHESSI data supports the idea that the upper chromospheric dynamics observed byIRIS has features of "gentle" evaporation driven by heating of the solar chromosphere by accelerated electrons and by a heat flux from the flare energy release site.

Analysis of IRIS and NST observations of the 12.06.2014 flare event

Viacheslav M. **Sadykov**, Santiago Vargas Dominguez, Alexander G. Kosovichev, Ivan N. Sharykin

2014

http://arxiv.org/pdf/1412.0172v1.pdf

We present results of analysis of a M1.0 class flare event of **12 June, 2014** (SOL2014-06-12T21:12), observed with the NASA's Interface Region Imaging Spectrograph (IRIS) mission and New Solar Telescope (NST) at Big Bear Solar Observatory (BBSO). The IRIS observed this event in the coarse raster mode and obtained high-resolution UV spectra and Slit-Jaw (SJ) images for almost the whole flaring region. Our analysis of the IRIS data in different spectral lines reveals strong redshifted fluxes of the chromospheric material before the flare. It is also found that most of the chromospheric and transition region lines are redshifted across the flaring region during the flare. Expansion of a photospheric flux-rope structure is observed in the high-resolution images from the NST with the Broadband Filter Imager (BFI) using the TiO filter. Emission of the hot (20 MK) coronal Fe XXI line is detected ~400 seconds after the emission peaks of the lower temperature lines in the O I IRIS spectral window. We found that the Fe XXI line is blueshifted across the flaring region. This corresponds to evaporation flow with a speed of 50 km/s of the chromospheric plasma heated to the high temperature, as predicted by hydrodynamic flare models.

From Chromospheric Evaporation to Coronal Rain: An Investigation of the Mass and Energy Cycle of a Flare

Seray **Sahin**, Patrick Antolin

ApJ **970** 106 **2024**

https://arxiv.org/pdf/2406.02280

https://iopscience.iop.org/article/10.3847/1538-4357/ad4ed9/pdf

Chromospheric evaporation (CE) and coronal rain (CR) represent two crucial phenomena encompassing the circulation of mass and energy during solar flares. While CE marks the start of the hot inflow into the flaring loop, CR marks the end, indicating the outflow in the form of cool and dense condensations. With \textit{IRIS} and \textit{AIA/SDO}, we examine and compare the evolution, dynamics, morphology, and energetics of the CR and CE during a C2.1 flare. The CE is directly observed in imaging and spectra in the \ion{Fe}{XXI} line with \textit{IRIS} and in the \ion{Fe}{XVIII} line of AIA, with upward average total speeds of 138±[35] km~s−1 and a temperature of [9.03±3.28]×106~K. An explosive to gentle CE transition is observed, with an apparent reduction in turbulence. From quiescent to gradual flare phase, the amount and density of CR increases by a factor of ≈4.4 and 6, respectively. The rain's velocity increases by a 1.4, in agreement with gas pressure drag. In contrast, the clump widths variation is negligible. The location and morphology of CE match closely those of the rain showers, with similar CE sub-structure to the rain strands, reflecting fundamental scales of mass and energy transport. We obtain a CR outflow mass three times larger than the CE inflow mass, suggesting the presence of unresolved CE, perhaps at higher temperatures. The CR energy corresponds to half that of the CE. These results suggest an essential role of coronal rain in the mass-energy cycle of a flare. **2014 September 17**

Prevalence of Thermal Nonequilibrium over an Active Region

Seray **Şahin**1 and Patrick Antolin1

2022 ApJL 931 L27

https://iopscience.iop.org/article/10.3847/2041-8213/ac6fe9/pdf

https://arxiv.org/pdf/2205.10794.pdf

Recent observations have shown that besides the characteristic multimillion degree component, the corona also contains a large amount of cool material called coronal rain, whose clumps are 10–100 times cooler and denser than the surroundings and are often organized in larger events, termed showers. Thermal instability (TI) within a coronal loop in a state of thermal nonequilibrium (TNE) is the leading mechanism behind the formation of coronal rain but no investigation on showers exists to date. In this study, we conduct a morphological and thermodynamic multiwavelength study of coronal rain showers observed in an active region (AR) off-limb with IRIS and the Solar Dynamics Observatory, spanning chromospheric to transition region and coronal temperatures. Rain showers were found to be widespread across the AR over the 5.45 hr observing time, with an average length, width, and duration of 27.37 ± 11.95 Mm, 2.14 ± 0.74 Mm, and 35.22 ± 20.35 minutes, respectively. We find a good correspondence between showers and the cooling coronal structures consistent with the TNE–TI scenario, thereby properly identifying coronal loops in the "coronal veil", including the strong expansion at low heights and an almost zero expansion in the corona. This agrees with previous work suggesting that the observed zero expansion in the EUV is due to specific cross-field temperature distribution. We estimate the total number of showers to be 155 ± 40, leading to a TNE volume of 4.56 ± [3.71] × 1028 cm3, i.e., on the same order of the AR volume. This suggests a prevalence of TNE over the AR indicating strongly stratified and high-frequency heating on average. **2017 June 2**

Evolution of magnetic fields and energy release processes during homologous eruptive flares

Suraj **Sahu** (USO/PRL), Bhuwan Joshi (USO/PRL), Avijeet Prasad (University of Oslo), Kyung-Suk Cho (SSD/KASI)

ApJ **943** 70 **2023**

https://arxiv.org/pdf/2212.04150.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/acac2d/pdf

We explore the processes of repetitive build-up and explosive release of magnetic energy together with the formation of magnetic flux ropes that eventually resulted into three homologous eruptive flares of successively increasing intensities (i.e., M2.0, M2.6, and X1.0). The flares originated from NOAA active region 12017 during **2014 March 28-29**. EUV observations and magnetogram measurements together with coronal magnetic field modeling suggest that the flares were triggered by the eruption of flux ropes embedded by a densely packed system of loops within a small part of the active region. In X-rays, the first and second events show similar evolution with single, compact sources, while the third event exhibits multiple emission centroids with a set of strong non-thermal conjugate sources at 50-100 keV during the HXR peak. The photospheric magnetic field over an interval of approximately 44 hr encompassing the three flares undergoes important phases of emergence and cancellation processes together with significant changes near the polarity inversion lines within the flaring region. Our observations point toward the tether-cutting mechanism as the plausible triggering process of the eruptions. Between the second and third event, we observe a prominent phase of flux emergence which temporally correlates with the build-up phase of free magnetic energy in the active region corona. In conclusion, our analysis reveals an efficient coupling between the rapidly evolving photospheric and coronal magnetic fields in the active region that led to a continued phase of the build-up of free energy, resulting into the homologous flares of successively increasing intensities. **Spikes**

HXR emission from an activated flux rope and subsequent evolution of an eruptive long duration solar flare

Suraj **Sahu**, Bhuwan Joshi, Prabir K. Mitra, Astrid M. Veronig, V. Yurchyshyn

ApJ **897** 157 **2020**

https://arxiv.org/pdf/2005.06221.pdf

https://doi.org/10.3847/1538-4357/ab962b

In this paper, we present a comprehensive study of the evolutionary phases of a major M6.6 long duration event (LDE) with special emphasize on its pre-flare phase. The event occurred in NOAA 12371 on **2015 June 22**. A remarkable aspect of the event was an active pre-flare phase lasting for about an hour during which a hot EUV coronal channel was in build-up stage and displayed co-spatial hard X-ray (HXR) emission up to energies of 25 keV. As such, this is the first evidence of HXR coronal channel. The coronal magnetic field configuration based on NLFFF modeling clearly exhibited a magnetic flux rope (MFR) oriented along the polarity inversion line (PIL) and co-spatial with the coronal channel. We observed significant changes in the AR's photospheric magnetic field during an extended period of ≈42 hours in the form of rotation of sunspots, moving magnetic features, and flux cancellation along the PIL. Prior to the flare onset, the MFR underwent a slow rise phase (≈14 km s−1) for ≈12 min which we attribute to the faster build-up and activation of the MFR by tether-cutting reconnection occurring at multiple locations along the MFR itself. The sudden transition in the kinematic evolution of the MFR from the phase of slow to fast rise (≈109 km s−1 with

acceleration ≈110 m s−2) precisely divides the pre-flare and impulsive phase of the flare, which points toward the feedback process between the early dynamics of the eruption and the strength of the flare magnetic reconnection.

Grid-based imaging of X-rays and gamma-rays with high angular resolution

Pascal **Saint-Hilaire** ∗ , Albert Y. Shih, Gordon J. Hurford, Brian Dennis
In the 'Handbook of X-ray and Gamma-Ray Astrophysics' **2022**
http://sprg.ssl.berkeley.edu/~shilaire/papers/Grid_imaging_in_X_rays_and_gamma_ray.pdf
This chapter contains an overview of the basic principles of X-ray and gamma-ray imaging for astronomy that achieve high angular resolution with nonfocusing optics. Specific topics include systems with single-grid masks, with pairs of grids known as bi-grid collimators, and with more than two grids known as multigrid collimators. A discussion of each type is given along with advantages and limitations of the various design options and descriptions of actual implementations. **1980 April 30, January 20, 2005, 7-9 May 2021**

X-RAY EMISSION FROM THE BASE OF A CURRENT SHEET IN THE WAKE OF A CORONAL MASS EJECTION

P. **Saint-Hilaire**, S. Krucker, and R.P. Lin
E-print, May **2009, File**; ApJ, 699:245–253, **2009, File**
Following a coronal mass ejection (CME) which started on **2002 November 26**, RHESSI observed for 12 hr an X-ray source above the solar limb, at altitudes between 0.1 and 0.3 R_S above the photosphere. The Geostationary Operational Environmental Satellite baseline was remarkably high throughout this event. The X-ray source?s temperature peaked around 10?11 MK, and its emission measure increased throughout this time interval. Higher up, at 0.7 R_S, hot (initially >8 MK) plasma has been observed by Ultraviolet Coronograph Spectrometer on Solar and Heliospheric Observatory for 2.3 days. This hot plasma was interpreted as the signature of a current sheet (CS) trailing the CME. The thermal energy content of the X-ray source is more than an order of magnitude larger than in the CS. Hence, it could be the source of the hot plasma in the CS, although CS heating by magnetic reconnection within it cannot be discounted. To better characterize the X-ray spectrum, we have used novel techniques (back-projection-based and visibility-based) for long integration (several hours) imaging spectroscopy. There is no observed non-thermal hard X-ray bremsstrahlung emission, leading to the conclusion that there is either very little particle acceleration occurring in the vicinity of this post-flare X-ray source, or that either the photon spectral index would have had to be uncharacteristically (in flare parlance) high (γ >= 8) and/or the low-energy cutoff very low (Ec <= 6 keV).

THE X-RAY DETECTABILITY OF ELECTRON BEAMS ESCAPING FROM THE SUN

Pascal **Saint-Hilaire**, S¨am Krucker, Steven Christe, and Robert P. Lin
Astrophysical Journal, 696:941–952, **2009** May
http://www.iop.org/EJ/toc/-alert=43190/0004-637X/696/1
We study the detectability and characterization of electron beams as they leave their acceleration site in the low corona toward interplanetary space through their nonthermal X-ray bremsstrahlung emission. We demonstrate that the largest interplanetary electron beams (_10^{35} electrons above 10 keV) can be detected in X-rays with current and future instrumentation, such as *RHESSI* or the X-Ray Telescope (XRT) onboard *Hinode*.We make a list of optimal observing conditions and beam characteristics. Amongst others, good imaging (as opposed to mere localization or detection in spatially integrated data) is required for proper characterization, putting the requirement on the number of escaping electrons (above 10 keV) to _3 Ч 10^{36} for *RHESSI*, _3 Ч 10^{35} for *Hinode*/XRT, and _10^{33} electrons for the *FOXSI* sounding rocket scheduled to fly in 2011. Moreover, we have found that simple modeling hints at the possibility that coronal soft X-ray jets could be the result of local heating by propagating electron beams.

A Trigger Mechanism of Magnetic Reconnection and Particle Acceleration during Thinning of the Current Sheet

S. **Saito** and J. I. Sakai
Page 793 [http://www.journals.uchicago.edu/cgi-bin/resolve?ApJ64916]
The generated magnetic islands successively coalesce and the magnetic energy is converted into plasma kinetic energy. Through the coalescence, high-energy electrons are quasi-periodically produced. (Type III groups ?)

Continuous Plasma Outflows from the Edge of a Solar Active Region as a Possible Source of Solar Wind.

Probability Distribution Functions of Solar and Stellar Flares

Takashi **Sakurai**
Physics, vol. 5, issue 1, pp. 11-23 **2022**
https://arxiv.org/ftp/arxiv/papers/2212/2212.02678.pdf
https://www.mdpi.com/2624-8174/5/1/2
We studied the soft X-ray data of solar flares and found that the distribution functions of flare fluence are successfully modeled by tapered power law or gamma function distributions whose power exponent is slightly smaller than 2, indicating that the total energy of the flare populations is mostly contributed from a small number of large flares. The largest possible solar flares in 1000 years are predicted to be around X70 in terms of the GOES flare class. We also studied superflares (more energetic than solar flares) from solar-type stars, and found that their power exponent in the fitting of the gamma function distribution is around 1.05, much flatter than solar flares. The distribution function of stellar flare energy extrapolated downward does not connect to the distribution function of solar flare energy.

Hard X-Ray Spectral Evolution and Production of Solar Energetic Particle Events during the January 2005 X-Class Flares

R. **Saldanha**, Sam Krucker, and R. P. Lin
The Astrophysical Journal, Vol. 673, No. 2: 1169-1173, **2008**; **File**
http://www.journals.uchicago.edu/doi/pdf/10.1086/524929
High-resolution hard X-ray observations provided by the Reuven Ramaty High Energy Solar Spectroscopic Imager (RHESSI) are used to study the spectral evolution of _50Y200 keV nonthermal electron bremsstrahlung emissions of five X-class flares observed during the January 2005 solar storm events. Four of these flares show progressive spectral hardening during at least some hard X-ray peaks, while only one event shows the otherwise more commonly observed soft-hard-soft behavior. Imaging observations reveal that_50Y100 keV nonthermal electron bremsstrahlung emissions originate from footpoints of flare loops at all times, including during times of progressive spectral hardening, indicating that the spectral hardening component is produced by precipitating electrons, and not by electrons trapped in the corona. The four flares with progressive spectral hardening are all related to solar energetic particle (SEP) events, while the only X-class flare with soft-hard-soft behavior is not. This finding is consistent with earlier studies, suggesting that electron acceleration and transport in flares is somehow linked to the production of SEPs escaping into interplanetary space.

Plasma Heating Induced by Tadpole-Like Downflows in the Flaring Solar Corona

Tanmoy **Samanta**, Hui Tian, Bin Chen, Katharine K. Reeves, Mark C. M. Cheung, Angelos Vourlidas, Dipankar Banerjee
The Innovation 2(1), 100083 (**2021**)
https://arxiv.org/ftp/arxiv/papers/2103/2103.14257.pdf
https://doi.org/10.1016/j.xinn.2021.100083
As one of the most spectacular energy release events in the solar system, solar flares are generally powered by magnetic reconnection in the solar corona. As a result of the re-arrangement of magnetic field topology after the reconnection process, a series of new loop-like magnetic structures are often formed and are known as flare loops. A hot diffuse region, consisting of around 5-10 MK plasma, is also observed above the loops and is called a supra-arcade fan. Often, dark, tadpole-like structures are seen to descend through the bright supra-arcade fans. It remains unclear what role these so-called supra-arcade downflows (SADs) play in heating the flaring coronal plasma. Here we show a unique flare observation, where many SADs collide with the flare loops and strongly heat the loops to a temperature of 10-20 MK. Several of these interactions generate clear signatures of quasi-periodic enhancement in the full-Sun-integrated soft X-ray emission, providing an alternative interpretation for quasi-periodic pulsations that are commonly observed during solar and stellar flares**. 2013 April 11**

Probabilistic solar flare forecasting using historical magnetogram data

Kiera van der **Sande**, Andrés Muñoz-Jaramillo, Subhamoy Chatterjee
ApJ **2023**
https://arxiv.org/pdf/2308.15410.pdf
Solar flare forecasting research using machine learning (ML) has focused on high resolution magnetogram data from the SDO/HMI era covering Solar Cycle 24 and the start of Solar Cycle 25, with some efforts looking back to SOHO/MDI for data from Solar Cycle 23. In this paper, we consider over 4 solar cycles of daily historical magnetogram data from multiple instruments. This is the first attempt to take advantage of this historical data for ML-

based flare forecasting. We apply a convolutional neural network (CNN) to extract features from full-disk magnetograms together with a logistic regression model to incorporate scalar features based on magnetograms and flaring history. We use an ensemble approach to generate calibrated probabilistic forecasts of M-class or larger flares in the next 24 hours. Overall, we find that including historical data improves forecasting skill and reliability. We show that single frame magnetograms do not contain significantly more relevant information than can be summarized in a small number of scalar features, and that flaring history has greater predictive power than our CNN-extracted features. This indicates the importance of including temporal information in flare forecasting models.

Machine learning correlation of SDO/AIA EUV images to GOES/XRS X-ray flare magnitudes

Kiera van der **Sande**, Natasha Flyer, Thomas Berger, and Riana Gagnon
Front. Astron. Space Sci. 9:1031211. **2022**
https://www.frontiersin.org/articles/10.3389/fspas.2022.1031211/pdf
https://doi.org/10.3389/fspas.2022.1031211
Supervised Machine Learning (ML) models for solar flare prediction rely on accurate labels for a given input data set, commonly obtained from the GOES/XRS X-ray flare catalog. With increasing interest in utilizing ultraviolet (UV) and extreme ultraviolet (EUV) image data as input to these models, we seek to understand if flaring activity can be defined and quantified using EUV data alone. This would allow us to move away from the GOES single pixel measurement definition of flares and use the same data we use for flare prediction for label creation. In this work, we present a Solar Dynamics Observatory (SDO) Atmospheric Imaging Assembly (AIA)-based flare catalog covering flare of GOES X-ray magnitudes C, M and X from 2010 to 2017. We use active region (AR) cutouts of full disk AIA images to match the corresponding SDO/Helioseismic and Magnetic Imager (HMI) SHARPS (Space weather HMI Active Region Patches) that have been extensively used in ML flare prediction studies, thus allowing for labeling of AR number as well as flare magnitude and timing. Flare start, peak, and end times are defined using a peak-finding algorithm on AIA time series data obtained by summing the intensity across the AIA cutouts. An extremely randomized trees (ERT) regression model is used to map SDO/AIA flare magnitudes to GOES X-ray magnitude, achieving a low-variance regression. We find an accurate overlap on 85% of M/X flares between our resulting AIA catalog and the GOES flare catalog. However, we also discover a number of large flares unrecorded or mislabeled in the GOES catalog**. 2010/10/16, 2012/07/12,, 2014/01/01, 2015/01/04.**

Comparison of STEREO/EUVI Loops with Potential Magnetic Field Models

A. W. **Sandman**, M. J. Aschwanden[2], M. L. DeRosa[2], J. P. Wülser[2] and D. Alexander
E-print, June 2009**;** Solar Phys. (**2009**) 259: 1–11
The *Solar Terrestrial Relations Observatory* (STEREO) provides the first opportunity to triangulate the three-dimensional coordinates of active region loops simultaneously from two different vantage points in space. Three-dimensional coordinates of the coronal magnetic field have been calculated with theoretical magnetic field models for decades, but it is only with the recent availability of STEREO data that a rigorous, quantitative comparison between observed loop geometries and theoretical magnetic field models can be performed. Such a comparison provides a valuable opportunity to assess the validity of theoretical magnetic field models. Here we measure the misalignment angles between model magnetic fields and observed coronal loops in three active regions, as observed with the Extreme Ultraviolet Imager (EUVI) on STEREO on 30 April, 9 May, and 19 May 2007. We perform stereoscopic triangulation of some 100 – 200 EUVI loops in each active region and compute extrapolated magnetic field lines using magnetogram information from the Michelson Doppler Imager (MDI) on the *Solar and Heliospheric Observatory* (SOHO). We examine two different magnetic extrapolation methods: (1) a potential field and (2) a radially stretched potential field that conserves the magnetic divergence. *We find considerable disagreement between each theoretical model and the observed loop geometries, with an average misalignment angle on the order of 20° – 40°. We conclude that there is a need for either more suitable (coronal rather than photospheric) magnetic field measurements or more realistic field extrapolation models.*

Trigger Mechanism of Solar Subflares in a Braided Coronal Magnetic Structure

Sanjiv K. Tiwari, Caroline E. Alexander, Amy R. Winebarger, Ronald L. Moore
ApJL, **2014**
http://arxiv.org/pdf/1410.4260v1.pdf
Fine-scale braiding of coronal magnetic loops by continuous footpoint motions may power coronal heating via nanoflares, which are spontaneous fine-scale bursts of internal reconnection. An initial nanoflare may trigger an avalanche of reconnection of the braids, making a microflare or larger subflare. In contrast to this internal triggering of subflares, we observe external triggering of subflares in a braided coronal magnetic field observed by the {\it High-resolution Coronal Imager (Hi-C)}. We track the development of these subflares using 12 s cadence images acquired by {\it SDO}/AIA in 1600, 193, 94 \AA, and registered magnetograms of {\it SDO}/HMI, over four hours centered on the {\it Hi-C} observing time. These data show numerous recurring small-scale brightenings in transition-region emission happening on polarity inversion lines where flux cancellation is occurring. We present in detail an example of an apparent burst of reconnection of two loops in the transition region under the braided coronal field, appropriate for

releasing a short reconnected loop downward and a longer reconnected loop upward. The short loop presumably submerges into the photosphere, participating in observed flux cancellation. A subflare in the overlying braided magnetic field is apparently triggered by the disturbance of the braided field by the reconnection-released upward loop. At least 10 subflares observed in this braided structure appear to be triggered this way. How common this external trigger mechanism for coronal subflares is in other active regions, and how important it is for coronal heating in general, remain to be seen. **11 July 2012,**

Reorganization of Photospheric Magnetic Fields in Active Regions During Energetic Flares

J. C. **Santos** , C. M. Wrasse

Solar Phys. Volume 291, Issue 4, pp 1107-1114 **2016**

The reorganization of the photospheric magnetic field may be important for flaring activity. In this work we use the time evolution of the magnetic power spectra to identify for which length scales the reorganization of the active region magnetic field is most closely related to energetic flares. Our results show that the reorganization occurs mainly for length scales larger than 12.6 Mm and may start much before the time of the flare, but the time evolution of magnetic power spectra does not show regular patterns. An analysis of the dissipation spectra suggests that the dissipation takes place at all spatial scales, including small wavenumbers in which more energy is available.

3D MHD simulations of electric current development in a rotating sunspot: active region NOAA 8210

J. C. **Santos**1,2, J. Büchner1 and A. Otto

A&A 535, A111 (**2011**)

Context. Active region (AR) 8210 was the host of many flares and coronal mass ejections (CMEs). Studies of its temporal evolution indicated that the clockwise rotation of a negative magnetic polarity, together with the motion of a positive polarity located close to it are a major source of magnetic energy to the corona above.

Aims. Search for the mechanisms of energy storage and release above AR8210. For this sake we locate the current system generated by the photospheric plasma motion suggested as source of coronal energy supply above AR8210 and compare it with the location of identified flaring regions.

Methods. We simulated the reaction of the corona using a three-dimensional (3D) MagnetoHydroDynamic (MHD) model. The initial coronal magnetic field is extrapolated out of the observed line-of-sight (LOS) component of the photospheric magnetic field. The corresponding photospheric plasma motion is imposed close to the bottom boundary of the simulation box. Current dependent resistivity and compressibility of the plasma are considered in the model.

Results. The horizontal plasma motion causes a current system that spatially coincides with the flaring region associated to AR8210. Particularly, the rotation of the plasma over the main negative polarity gives rise to strong currents localized over the main negative polarity, i.e. close to the position of a flare site. Above this region a strong magnetic field divergence is indicated by large differential flux tube volumes. Intense currents also form along the eastern border of a positive polarity region, over a polarity inversion line (PIL), in a site where a flare appears later. The southward motion of a positive flux concentration generates a current system extending mainly along the eastern border of it, over a polarity inversion line. Magnetic energy is deposited mainly over the main negative polarity, where the major flare activity is observed at later times.

Conclusions. The two patterns of photospheric plasma motion suggested as being responsible for the flaring activity of AR8210 generate current systems spatially coincident with the flaring area associated to this active region. These currents generate magnetic fields that contribute to the increase in magnetic energy inside the simulation volume. The transport of magnetic flux by the photospheric plasma motion also contributes to the redistribution of magnetic energy. The increase in magnetic energy occurs mainly over the main negative polarity and close to where a strong current system is formed. We conclude that in the case of AR8210 the rotation of the negative polarity region is the main contributor to its flare activity. The southward motion of a positive magnetic flux concentration plays an important role in the formation of current systems at its eastern border.

On the relation between DC current locations and an EUV bright point: A case study

J. C. **Santos**[1, 2], J. Büchner[1], M. S. Madjarska[1], and M. V. Alves

A&A 490, 345-352 (**2008**), DOI: 10.1051/0004-6361:200809975

Context. Motion of the photospheric plasma forces the footpoints of magnetic flux tubes to move. This can give rise to electric currents in the solar atmosphere. The dissipation of these electric currents and the consequent heating of the solar plasma may be responsible for the formation of Extreme-UltraViolet (EUV) and X-ray bright points. Earlier bright point models usually consider either the emergence or the canceling of photospheric magnetic features as being responsible for reconnection causing the bright point.

Aims. We investigate the consequences of different patterns of horizontal photospheric plasma motion for the generation of electric currents in the solar atmosphere and locate them with respect to an observed EUV bright point. The goal is to find out whether these currents might be responsible for the heating of bright points.

Results. A comparison with data obtained by TRACE in the 1550 Å channel and by the EIT in the 195 Å channel shows that the region where the strongest current concentrations are formed coincides with the region where the EUV bright point appears.

Efficiency of solar microflares in accelerating electrons when rooted in a sunspot⋆

Jonas **Saqri**1, Astrid M. Veronig1,2, Andrea Francesco Battaglia3,4, Ewan C. M. Dickson1, Dale E. Gary5 and Säm Krucker3,6

A&A 683, A41 (**2024**)

https://arxiv.org/pdf/2312.06856.pdf

https://www.aanda.org/articles/aa/pdf/2024/03/aa48295-23.pdf

https://doi.org/10.1051/0004-6361/202348295

Context. The spectral shape of the X-ray emission in solar flares varies with the event size, with small flares generally exhibiting softer spectra than large events, indicative of a relatively lower number of accelerated electrons at higher energies.

Aims. We investigate two microflares of GOES classes A9 and C1 (after background subtraction) observed by STIX onboard Solar Orbiter with exceptionally strong nonthermal emission. We complement the hard X-ray imaging and spectral analysis by STIX with co-temporal observations in the (E)UV and visual range by AIA and HMI to investigate what makes these microflares so efficient in high-energy particle acceleration.

Methods. We made a preselection of events in the STIX flare catalog based on the ratio of the thermal to nonthermal quicklook X-ray emission. The STIX spectrogram science data were used to perform spectral fitting to identify the non-thermal and thermal components. The STIX X-ray images were reconstructed to analyze the spatial distribution of the precipitating electrons and the hard X-ray emission they produce. The EUV images from SDO/AIA and SDO/HMI LOS magnetograms were analyzed to better understand the magnetic environment and the chromospheric and coronal response. For the A9 event, EOVSA microwave observations were available, allowing for image reconstruction in the radio domain.

Results. We performed case studies of two microflares observed by STIX on **October 11, 2021 and November 10, 2022**, which showed unusually hard microflare X-ray spectra with power-law indices of the electron flux distributions of $\delta = (2.98 \pm 0.25)$ and $\delta = (4.08 \pm 0.23)$, during their non-thermal peaks and photon energies up to 76 keV and 50 keV, respectively. For both events under study, we found that one footpoint is located within a sunspot covering areas with mean magnetic flux densities in excess of 1500 G, suggesting that the hard electron spectra are caused by the strong magnetic fields the flare loops are rooted in. Additionally, we revisited a previously published unusually hard RHESSI microflare and found that in this event, there was also one flare kernel located within a sunspot, which corroborates the result from the two hard STIX microflares under study in this work.

Conclusions. The characteristics of the strong photospheric magnetic fields inside the sunspot umbrae and penumbrae where flare loops are rooted play an important role in the generation of exceptionally hard X-ray spectra in these microflares. **November 17, 2006**

Multi-point study of the energy release and impulsive CME dynamics in an eruptive C7 flare

J. **Saqri**, A. M. Veronig, E. C. M. Dickson, T. Podladchikova, A. Warmuth, H. Xiao, D. E. Gary, A. F. Battaglia, S. Krucker

A&A **2023**

https://arxiv.org/pdf/2302.11232.pdf

Context. The energy release in eruptive flares and the kinematics of the associated coronal mass ejections (CMEs) are interlinked and require favorable observing positions as both on–disk and off–limb signatures are necessary to characterize these events. Aims. We combine observations from different vantage points to perform a detailed study of a long duration eruptive C7 class flare that occurred on **17 April 2021** and was partially occulted from Earth view. The dynamics and thermal properties of the flare-related plasma flows, the flaring arcade, and the energy releases and particle acceleration are studied together with the kinematic evolution of the associated CME in order to place this long duration event in context of previous eruptive flare studies. Methods. We use data from the Spectrometer-Telescope for Imaging X-rays (STIX) onboard the Solar Orbiter to analyze the spectral characteristics, timing, and spatial distribution of the flare X-ray emission. Data from the Extreme Ultraviolet Imager (EUVI) onboard the Solar TErrestrial RElations Observatory-Ahead (STEREO-A) spacecraft are used for context images as well as to track the ejected plasma close to the Sun. With Atmospheric Imaging Assembly extreme ultraviolet (EUV) images from the Solar Dynamics Observatory, the flare is observed off–limb and differential emission measure maps are reconstructed. The coronagraphs onboard STEREO-A are used to track the CME out to around 8 R.

Results. The flare showed hard X-ray (HXR) bursts over the duration of an hour in two phases lasting from 16:04 UT to 17:05 UT. During the first phase, a strong increase in emission from hot plasma and impulsive acceleration of the CME was observed. The CME acceleration profile shows a three-part evolution of slow rise, acceleration, and propagation in line with the first STIX HXR burst phase, which is triggered by a rising hot (14 MK) plasmoid. During the CME acceleration phase, we find signatures of ongoing magnetic reconnection behind the erupting structure, in agreement with the standard eruptive flare scenario. The subsequent HXR bursts that occur about 30 minutes after the primary

CME acceleration show a spectral hardening (from $\delta \approx 7$ to $\delta \approx 4$) but do not correspond to further CME acceleration and chromospheric evaporation. Therefore, the CME-flare feedback relationship may only be of significance within the first 25 minutes of the event under study, as thereafter the flare and the CME eruption evolve independently of each other.

Multi-instrument STIX microflare study

J. **Saqri**, A.M. Veronig, A. Warmuth, E.C.M. Dickson, A.F. Battaglia, T. Podladchikova, H. Xiao, M. Battaglia, G.J. Hurford, S. Krucker
A&A 659, A52 **2022**
https://arxiv.org/pdf/2201.00712.pdf
https://doi.org/10.1051/0004-6361/202142373
https://www.aanda.org/articles/aa/pdf/2022/03/aa42373-21.pdf

Context. During its commissioning phase in 2020, the Spectrometer/Telescope for Imaging X-rays (STIX) on board the Solar Orbiter spacecraft observed 69 microflares. The two largest events from this set (of GOES class B2 and B6), both of which were observed on-disk from the spacecraft as well as from Earth, are analysed in terms of the spatial, temporal and spectral characteristics. Aims. We complement observations from the STIX instrument with EUV imagery from SDO/AIA and GOES soft X-ray data to add imaging and plasma diagnostics over different temperature ranges for a detailed microflare case study in terms of energy release and transport.
Methods. We use data from GOES for SXR plasma diagnostics and SDO/AIA for high cadence EUV imaging and the reconstruction of differential emission measure (DEM) maps of the thermal flare plasma. The reconstructed DEM profiles are used to study the temporal evolution of thermal flare plasma in the kernels and loops independently. We derive the time evolution of the flare plasma parameters (EM, T) and thermal energy from STIX, GOES and AIA observations, and study STIX spectra to determine the nonthermal emission from accelerated electrons.
Results. Spectral fitting of the STIX data shows clear nonthermal emission for both microflares under study. For both events the plasma temperature and EM derived from STIX, GOES as well as the reconstructed DEM maps differ in absolute values and timing with AIA (sensitive to lower plasma temperatures) lagging behind. The deduced plasma parameters from either method roughly agree with values in the literature for microflares as do the nonthermal fit parameters from STIX. This finding is corroborated by the Neupert effect exhibited between the time derivative of the GOES SXR emission and the STIX HXR profiles. For the B6 event where such an analysis was possible, the nonthermal energy deduced from STIX roughly coincides with the lower estimates of the thermal energy requirement deduced from the SXR and EUV emissions.
Conclusions. The observed Neupert effects and impulsive/ gradual phases indicate that both events under study are consistent with the standard chromospheric evaporation flare scenario. For the B6 event on **June 7th, 2020**, this interpretation is further supported by the temporal evolution seen in the DEM profiles of the flare ribbons and loops. For this event we further find that accelerated electrons can roughly account for the required thermal energy. The **June 6th, 2020** event demonstrates that STIX can detect nonthermal emission for GOES class B2 events albeit smaller than the background rate level. We demonstrate for the first time how detailed multi-instrument studies of solar flares can be performed with STIX.

Lorentz Force Evolution Reveals the Energy Buildup Processes during Recurrent Eruptive Solar Flares

Ranadeep **Sarkar**, Nandita Srivastava, Astrid M. Veronig
ApJL **885** L17 **2019**
https://arxiv.org/pdf/1910.13264.pdf
sci-hub.se/10.3847/2041-8213/ab4da2

The energy release and build-up processes in the solar corona have significant implications in particular for the case of large recurrent flares, which pose challenging questions about the conditions that lead to the episodic energy release processes. It is not yet clear whether these events occur due to the continuous supply of free magnetic energy to the solar corona or because not all of the available free magnetic energy is released during a single major flaring event. In order to address this question, we report on the evolution of photospheric magnetic field and the associated net Lorentz force changes in ARs 11261 and 11283, each of which gave rise to recurrent eruptive M- and X-class flares. Our study reveals that after the abrupt downward changes during each flare, the net Lorentz force increases by (2-5)x10^22 dyne in between the successive flares. This distinct rebuild-up of net Lorentz forces is the first observational evidence found in the evolution of any non-potential parameter of solar active regions (ARs), which suggests that new energy was supplied to the ARs in order to produce the recurrent large flares. The rebuild-up of magnetic free energy of the ARs is further confirmed by the observations of continuous shearing motion of moving magnetic features of opposite polarities near the polarity inversion line. The evolutionary pattern of the net Lorentz force changes reported in this study has significant implications, in particular, for the forecasting of recurrent large eruptive flares from the same AR and hence the chances of interaction between the associated CMEs. **2011/08/03-04, 2011/09/06-07**
RHESSI Science Nuggets # 364 Dec **2019**

http://sprg.ssl.berkeley.edu/~tohban/wiki/index.php/Lorentz_Force_Evolution_Reveals_the_Energy_Build-up_Processes_during_Recurrent_Eruptive_Solar_Flares

A Comparative Study of the Eruptive and Non-Eruptive Flares Produced by the Largest Active Region of Solar Cycle 24

Ranadeep **Sarkar**, Nandita Srivastava
Solar Phys. 293:16 **2018**
https://arxiv.org/pdf/1801.00473.pdf
https://link.springer.com/content/pdf/10.1007%2Fs11207-017-1235-8.pdf
We investigate the morphological and magnetic characteristics of solar active region (AR) NOAA 12192. AR 12192 was the largest region of Solar Cycle 24; it underwent noticeable growth and produced 6 X-class flares, 22 M-class flares, and 53 C-class flares in the course of its disc passage. However, the most peculiar fact of this AR is that it was associated with only one CME in spite of producing several X-class flares. In this work, we carry out a comparative study between the eruptive and non-eruptive flares produced by AR 12192. We find that the magnitude of abrupt and permanent changes in the horizontal magnetic field and Lorentz force are significantly smaller in the case of the confined flares compared to the eruptive one. We present the areal evolution of AR 12192 during its disc passage. We find the flare-related morphological changes to be weaker during the confined flares, whereas the eruptive flare exhibits a rapid and permanent disappearance of penumbral area away from the magnetic neutral line after the flare. Furthermore, from the extrapolated nonlinear force-free magnetic field, we examine the overlying coronal magnetic environment over the eruptive and non-eruptive zones of the AR. We find that the critical decay index for the onset of torus instability was achieved at a lower height over the eruptive flaring region, than for the non-eruptive core area. These results suggest that the decay rate of the gradient of overlying magnetic field strength may play a decisive role to determine the CME productivity of the AR. In addition, the magnitude of changes in the flare-related magnetic characteristics are found to be well correlated with the nature of solar eruptions. **2014.10.22-25**

Simulating coronal loop implosion and compressible wave modes in a flare hit active region

Aveek **Sarkar**, Bhargav Vaidya, Soumitra Hazra, Jishnu Bhattacharyya
ApJ **851** 120 **2017**
https://arxiv.org/pdf/1711.05273.pdf
There is considerable observational evidence of implosion of magnetic loop systems inside solar coronal active regions following high energy events like solar flares. In this work, we propose that such collapse can be modeled in three dimensions quite accurately within the framework of ideal magnetohydrodynamics. We furthermore argue that the dynamics of loop implosion is only sensitive to the transmitted disturbance of one or more of the system variables, e.g. velocity generated at the event site. This indicates that to understand loop implosion, it is sensible to leave the event site out of the simulated active region. Towards our goal, a velocity pulse is introduced to model the transmitted disturbance generated at the event site. Magnetic field lines inside our simulated active region are traced in real time, and it is demonstrated that the subsequent dynamics of the simulated loops closely resemble observed imploding loops. Our work highlights the role of plasma β in regards to the rigidity of the loop systems and how that might affect the imploding loops' dynamics. Compressible magnetohydrodynamic modes such as kink and sausage are also shown to be generated during such processes, in accordance with observations.

Statistical techniques for the detection and analysis of solar explosive events⋆

L. M. **Sarro**1 and A. Berihuete
A&A 528, A62 (**2011**)
Context. Solar explosive events are commonly explained as small-scale magnetic reconnection events, although an unambiguous confirmation of this scenario remains elusive owing to the lack of spatial resolution and the statistical analysis of sufficiently large samples of this type of events.
Aims. We propose a sound statistical treatment of data cubes consisting of a temporal sequence of long-slit spectra of the solar atmosphere. The analysis comprises all stages from the explosive event detection to its characterization and the subsequent sample study.
Methods. We designed two complementary approaches based on the combination of standard statistical techniques (the robust principal component analysis in one approach and wavelet decomposition and independent component analysis in the second) to obtain least biased samples. These techniques are implemented in the spirit of letting the data speak for themselves. The analysis is carried out for two spectral lines: the C iv line at 1548.2 Å and the Ne viii line at 770.4 Å.
Results. We find significant differences between the characteristics of the line profiles emitted in the proximities of two active regions, and in the quiet Sun, most visible in the relative importance of a separate population of red shifted profiles. We also find a higher frequency of explosive events near the active regions, and in the C iv line. The distribution of the explosive events characteristics is interpreted in the light of recent numerical simulations. Finally, we point out several regions of the parameter space where the reconnection model has to be refined in order to explain the observations.

YOHKOH/WBS Recalibration and a Comprehensive Catalogue of Solar Flares Observed by YOHKOH SXT, HXT and WBS Instruments

J. **Sato**, Y. Matsumoto, K. Yoshimura, S. Kubo, J. Kotoku, S. Masuda, M. Sawa, K. Suga, M. Yoshimori, T. Kosugi & T. Watanabe

Solar Physics, Volume 236, Issue 2, pp.351-368, **2006**

https://link.springer.com/content/pdf/10.1007/s11207-006-1831-5.pdf

The flare catalogue of the Yohkoh mission is compiled and linked to this article as an electronic supplement. For showing flare characteristics over wide energy range concisely, we provide the images of Hard X-ray Telescope (HXT) and the Soft X-ray Telescope (SXT), and the spectra of Hard X-ray Spectrometer (HXS) and Gamma-Ray Spectrometer (GRS) with the Wide Band Spectrometer (WBS) time profiles. The energy versus pulse height (PH) data channels in HXS and GRS are re-calibrated by using the data of the whole mission period. Secular gain changes are recognized in HXS, and the characteristics of power-law flare spectra simultaneously observed by HXT and HXS confirms the trend. The GRS gains are different for the flare observations during the previous maximum and for the current maximum. The total of 33 γ -ray events are observed, and for 12 of them γ-ray flare spectra are obtained. **27 Oct 1991, 16 Jul 1992, 6 Nov 1997**

LOW-ALTITUDE RECONNECTION INFLOW-OUTFLOW OBSERVATIONS DURING A 2010 NOVEMBER 3 SOLAR ERUPTION

Sabrina L. **Savage**1, Gordon Holman1, Katharine K. Reeves2, Daniel B. Seaton3, David E. McKenzie4, and Yang Su

2012 ApJ 754 13

For a solar flare occurring on **2010 November 3**, we present observations using several SDO/AIA extreme-ultraviolet (EUV) passbands of an erupting flux rope followed by inflows sweeping into a current sheet region. The inflows are soon followed by outflows appearing to originate from near the termination point of the inflowing motion—an observation in line with standard magnetic reconnection models. We measure average inflow plane-of-sky speeds to range from ~150 to 690 km s–1 with the initial, high-temperature inflows being the fastest. Using the inflow speeds and a range of Alfvén speeds, we estimate the Alfvénic Mach number which appears to decrease with time. We also provide inflow and outflow times with respect to RHESSI count rates and find that the fast, high-temperature inflows occur simultaneously with a peak in the RHESSI thermal light curve. Five candidate inflow-outflow pairs are identified with no more than a minute delay between detections. The inflow speeds of these pairs are measured to be ~102 km s–1 with outflow speeds ranging from ~102 to 103 km s–1—indicating acceleration during the reconnection process. The fastest of these outflows are in the form of apparently traveling density enhancements along the legs of the loops rather than the loop apexes themselves. These flows could possibly either be accelerated plasma, shocks, or waves prompted by reconnection. The measurements presented here show an order of magnitude difference between the retraction speeds of the loops and the speed of the density enhancements within the loops—presumably exiting the reconnection site.

RE-INTERPRETATION OF SUPRA-ARCADE DOWNFLOWS IN SOLAR FLARES

Sabrina L. **Savage**1, David E. McKenzie2 and Katharine K. Reeves

2012 ApJ 747 L40

Following the eruption of a filament from a flaring active region, sunward-flowing voids are often seen above developing post-eruption arcades. First discovered using the soft X-ray telescope aboard Yohkoh, these supra-arcade downflows (SADs) are now an expected observation of extreme ultra-violet and soft X-ray coronal imagers and spectrographs (e.g, TRACE, SOHO/SUMER, Hinode/XRT, SDO/AIA). Observations made prior to the operation of AIA suggested that these plasma voids (which are seen in contrast to bright, high-temperature plasma associated with current sheets) are the cross-sections of evacuated flux tubes retracting from reconnection sites high in the corona. The high temperature imaging afforded by AIA's 131, 94, and 193 Å channels coupled with the fast temporal cadence allows for unprecedented scrutiny of the voids. For a flare occurring on **2011 October 22**, we provide evidence suggesting that SADs, instead of being the cross-sections of relatively large, evacuated flux tubes, are actually wakes (i.e., trailing regions of low density) created by the retraction of much thinner tubes. This re-interpretation is a significant shift in the fundamental understanding of SADs, as the features once thought to be identifiable as the shrinking loops themselves now appear to be "side effects" of the passage of the loops through the supra-arcade plasma. In light of the fact that previous measurements have attributed to the shrinking loops characteristics that may instead belong to their wakes, we discuss the implications of this new interpretation on previous parameter estimations and on reconnection theory.

QUANTITATIVE EXAMINATION OF A LARGE SAMPLE OF SUPRA-ARCADE DOWNFLOWS IN ERUPTIVE SOLAR FLARES

Sabrina L. **Savage**1,2 and David E. McKenzie2

The Astrophysical Journal, 730:98 (16pp), **2011** April
Sunward-flowing voids above post-coronal mass ejection flare arcades were first discovered using the soft X-ray telescope aboard *Yohkoh* and have since been observed with *TRACE* (extreme ultraviolet (EUV)), *SOHO*/LASCO (white light), *SOHO*/SUMER (EUV spectra), and *Hinode*/XRT (soft X-rays). Supra-arcade downflow (SAD) observations suggest that they are the cross-sections of thin flux tubes retracting from a reconnection site high in the corona. Supra-arcade downflowing loops (SADLs) have also been observed under similar circumstances and are theorized to be SADs viewed from a perpendicular angle. Although previous studies have focused on dark flows because they are easier to detect and complementary spectral data analysis reveals their magnetic nature, the signal intensity of the flows actually ranges from dark to bright. This implies that newly reconnected coronal loops can contain a range of hot plasma density. Previous studies have presented detailed SAD observations for a small number of flares. In this paper, we present a **substantial SADs and SADLs flare catalog**. We have applied semiautomatic detection software to several of these events to detect and track individual downflows thereby providing statistically significant samples of parameters such as velocity, acceleration, area, magnetic flux, shrinkage energy, and reconnection rate. We discuss these measurements (particularly the unexpected result of the speeds being an order of magnitude slower than the assumed Alfv´en speed), how they were obtained, and potential impact on reconnection models.

RECONNECTION OUTFLOWS AND CURRENT SHEET OBSERVED WITH *HINODE*/XRT IN THE 2008 APRIL 9 "CARTWHEEL CME" FLARE
Sabrina L. **Savage**1, David E. McKenzie1, Katharine K. Reeves2, Terry G. Forbes3, and Dana W. Longcope1
Astrophysical Journal, 722:329–342, **2010, File**
Supra-arcade downflows (SADs) have been observed with *Yohkoh*/SXT (soft X-rays (SXR)), *TRACE* (extreme ultraviolet (EUV)), *SOHO*/LASCO (white light), *SOHO*/SUMER (EUV spectra), and *Hinode*/XRT (SXR). Characteristics such as low emissivity and trajectories, which slow as they reach the top of the arcade, are consistent with post-reconnection magnetic flux tubes retracting from a reconnection site high in the corona until they reach a lower-energy magnetic configuration. Viewed from a perpendicular angle, SADs should appear as shrinking loops rather than downflowing voids. We present X-ray Telescope (XRT) observations of supra-arcade downflowing loops (SADLs) following a coronal mass ejection (CME) on 2008 April 9 and show that their speeds and decelerations are consistent with those determined for SADs. We also present evidence for a possible current sheet observed during this flare that extends between the flare arcade and the CME. Additionally, we show a correlation between reconnection outflows observed with XRT and outgoing flows observed with LASCO.

The two solar flares diagnostics based on the soft X-ray emission recording

https://www.sciencedirect.com/science/article/pii/S240572231730097X
The time history of the temperature and the emission measure of the solar flare plasma have been studied relying upon the experimental data on the soft X-rays recorded by the IRIS spectrometer on **June 29, 2002** (F1) and **March 27, 2003** (F2). F1 was a thermal flare and was not accompanied by hard X-rays. This data analysis revealed that at least two sequential energy-release processes occurred during the F1 event. The F2 event took place behind the limb, so only the top part of the flare loop being the soft X-ray source was recorded by the satellite-based spectrometer. From this data analysis it appeared that fast plasma heating occurred in the initial stage of F2 and then the flare region expanded and the emission measure of flare plasma increased.

The Relation between Solar Eruption Topologies and Observed Flare Features II: Dynamical Evolution
A. **Savcheva**, E. Pariat, S. McKillop, P. McCauley, E. Hanson, Y. Su, & E. DeLuca
2016 ApJ 817 43
http://www.pergamentum.com/eprint/savcheva_etal_ribbonsA_II.pdf
A long established goal of solar physics is to build understanding of solar eruptions and develop flare and CME forecasting models. In this paper, we continue our investigation of non-linear forces free field (NLFFF) models by comparing topological properties of the solutions to the evolution of the flare ribbons. In particular, we show that data constrained NLFFF models of three erupting sigmoid regions (**SOL2010-04-08, SOL2010-08-07, and SOL2012-05-**

12) built to reproduce the active region magnetic field in the pre-flare state can be rendered unstable and the subsequent sequence of unstable solutions produce quasi-separatrix layers (QSLs) that match the flare ribbon evolution as observed by SDO/AIA. We begin with a best-fit equilibrium model for the pre-flare active region; we than add axial flux to the flux rope in the model to move it across the stability boundary; at this point the magnetofrictional code no longer converges to an equilibrium solution, the flux rope rises as the solutions are iterated. We interpret the sequence of magnetofrictional steps as an evolution of the active region as the flare/CME begins. The magnetic field solutions at different steps are compared with the flare ribbons. The results are fully consistent with the 3D extension of the standard flare/CME model. Our ability to capture essential topological features of flaring active regions with a non-dynamic magneto-frictional code strongly suggests that the pre-flare, large scale topological structures are preserved as the flux rope becomes unstable and lifts off.

The Relation between Solar Eruption Topologies and Observed Flare Features I: Flare Ribbons

2015 *ApJ* **810** 96
http://arxiv.org/pdf/1506.03452v1.pdf
In this paper we present a topological magnetic field investigation of seven two-ribbon flares in sigmoidal active regions observed with Hinode, STEREO, and SDO. We first derive the 3D coronal magnetic field structure of all regions using marginally unstable 3D coronal magnetic field models created with the flux rope insertion method. The unstable models have been shown to be a good model of the flaring magnetic field configurations. Regions are selected based on their pre-flare configurations along with the appearance and observational coverage of flare ribbons, and the model is constrained using pre-flare features observed in extreme ultraviolet and X-ray passbands. We perform a topology analysis of the models by computing the squashing factor, Q, in order to determine the locations of prominent quasi-separatrix layers (QSLs). QSLs from these maps are compared to flare ribbons at their full extents. We show that in all cases the straight segments of the two J-shaped ribbons are matched very well by the flux-rope-related QSLs, and the matches to the hooked segments are less consistent but still good for most cases. In addition, we show that these QSLs overlay ridges in the electric current density maps. This study is the largest sample of regions with QSLs derived from 3D coronal magnetic field models, and it shows that the magnetofrictional modeling technique that we employ gives a very good representation of flaring regions, with the power to predict flare ribbon locations in the event of a flare following the time of the model.

FIELD TOPOLOGY ANALYSIS OF A LONG-LASTING CORONAL SIGMOID

A. S. **Savcheva**1,2, A. A. van Ballegooijen2 and E. E. DeLuca
2012 ApJ 744 78
We present the first field topology analysis based on nonlinear force-free field (NLFFF) models of a long-lasting coronal sigmoid observed in **2007 February 7-12** with the X-Ray Telescope on Hinode. The NLFFF models are built with the flux rope insertion method and give the three-dimensional coronal magnetic field as constrained by observed coronal loop structures and photospheric magnetograms. Based on these models, we have computed horizontal maps of the current and the squashing factor Q for 25 different heights in the corona for all six days of the evolution of the region. We use the squashing factor to quantify the degree of change of the field line linkage and to identify prominent quasi-separatrix layers (QSLs). We discuss the major properties of these QSL maps and devise a way to pick out important QSLs since our calculation cannot reach high values of Q. The complexity in the QSL maps reflects the high degree of fragmentation of the photospheric field. We find main QSLs and current concentrations that outline the flux rope cavity and that become characteristically S-shaped during the evolution of the sigmoid. We note that, although intermittent bald patches exist along the length of the sigmoid during its whole evolution, the flux rope remains stable for several days. However, shortly after the topology of the field exhibits hyperbolic flux tubes (HFT) on February 7 and February 12 the sigmoid loses equilibrium and produces two B-class flares and associated coronal mass ejections (CMEs). The location of the most elevated part of the HFT in our model coincides with the inferred locations of the two flares. Therefore, we suggest that the presence of an HFT in a coronal magnetic configuration may be an indication that the system is ready to erupt. We offer a scenario in which magnetic reconnection at the HFT drives the system toward the marginally stable state. Once this state is reached, loss of equilibrium occurs via the torus instability, producing a CME.

Non-Linear Force-Free Modeling of a Long-Lasting Coronal Sigmoid

Antonia **Savcheva** and Adrian van Ballegooijen
E-print, Sept **2009**; ApJ, 703(2), 1766-1777, **2009**

A study of the magnetic configuration and evolution of a long-lasting quiescent coronal sigmoid is presented. The sigmoid was observed by {it Hinode}/XRT and TRACE between **2007 Feb 6 and Feb 12** when it finally erupted. We construct non-linear force-free field models for several observations during this period, using the flux rope insertion method. The high spatial and temporal resolution of XRT allows us to finely select best-fit models that match the observations. The modeling shows that a highly sheared field, consisting of a weakly twisted flux rope inbedded in a potential field, very well describes the structure of the X-ray sigmoid. The flux rope reaches a stable equilibrium, but its axial flux is close to the stability limit of about $5 imes 10^{20}$ Mx. The relative magnetic helicity increases with time from Feb 8 until just prior to the eruption on Feb 12. We study the spatial distribution of the torsion parameter $alpha$ in the vicinity of the flux rope, and find that it has a hollow-core distribution, i.e., electric currents are concentrated in a current layer at the boundary between the flux rope and its surroundings. The current layer is located near the Bald Patch Separatrix Surface (BPSS) of the magnetic configuration, and the X-ray emission appears to come from this current layer/BPSS, consistent with the Titov & D'{e}moulin model. We find that the twist angle Phi of the magnetic field increases with time to about $2 pi$ just prior to the eruption, but never reaches the value necessary for the kink instability.

Identification of multiple hard X-ray sources in solar flares: A Bayesian analysis of the February 20 2002 event

Federica **Scacchiano**, Alberto Sorrentino, A Gordon Emslie, Anna Maria Massone, Michele Piana
ApJ **2018**
https://arxiv.org/pdf/1801.09141.pdf
Hard X-ray emission in solar flares is typically characterized by a number of discrete sources, each with its own spectral, temporal, and spatial variability. Establishing the relationship amongst these sources is critical to determine the role of each in the energy release and transport processes that occur within the flare. In this paper we present a novel method to identify and characterize each source of hard X-ray emission. In particular, the method permits a quantitative determination of the most likely number of subsources present, and of the relative probabilities that the hard X-ray emission in a given subregion of the flare is represented by a complicated multiple source structure or by a simpler single source. We apply the method to a well-studied flare on **2002~February~20** in order to assess competing claims as to the number of chromospheric footpoint sources present, and hence to the complexity of the underlying magnetic geometry/toplogy. Contrary to previous claims of the need for multiple sources to account for the chromospheric hard X-ray emission at different locations and times, we find that a simple two-footpoint-plus-coronal-source model is the most probable explanation for the data. We also find that one of the footpoint sources moves quite rapidly throughout the event, a factor that presumably complicated previous analyses. The inferred velocity of the footpoint corresponds to a very high induced electric field, compatible with those in thin reconnecting current sheets.

The effects of resistivity on oscillatory reconnection and consequences for solar flare Quasi Periodic Pulsations

Luiz A. C. A. **Schiavo**, James Stewart, Philippa K. Browning
2024
https://arxiv.org/pdf/2410.14563
Quasi-periodic pulsations (QPPs) are often observed in flare emissions. While these may reveal much about the time-dependent reconnection involved in flare energy release, the underlying mechanisms are still poorly understood. In this paper, we use 2D magnetohydrodynamic simulations to investigate the magnetic reconnection in two merging flux ropes, focusing on the effects of the resistivity on the time variation of the reconnection. We consider both uniform resistivity and current-dependent anomalous resistivity profiles. Our findings reveal that resistivity plays a critical role in controlling the reconnection dynamics, including reconnection rate oscillations and the rate of decay of the reconnection rate. Resistivity also influences the oscillations in emitted gyrosynchrotron radiation. However, in contrast to this strong influence of resistivity on reconnection rates, we observed a different behaviour for the emitted waves, whose frequencies are almost independent of resistivity variations.

Self-similar solutions of oscillatory reconnection: parameter study of magnetic field strength and background temperature

Luiz A. C. A. **Schiavo**, Gert J. J. Botha, James A. McLaughlin
ApJ **975** 10 **2024**
https://arxiv.org/pdf/2409.12130
https://iopscience.iop.org/article/10.3847/1538-4357/ad7600/pdf
Oscillatory reconnection is a specific type of time-dependent reconnection which involves periodic changes in the magnetic topology of a null point. The mechanism has been reported for a variety of magnetic field strengths and configurations, background temperatures and densities. All these studies report an oscillation in the current density at the null point, but also report a variety of periods, amplitudes and overall behaviors. We conduct a parametric study for equilibrium magnetic field strength and initial background temperature, solving 2D resistive MHD equations around a

magnetic X-point. We introduce a parameter space for the ratio of internal-to-magnetic energy and find self-similar solutions for simulations where this ratio is below 0.1 (which represents a magnetically-dominated environment or, equivalently, a low-beta plasma). Self-similarity can be seen in oscillations in the current density at the null (including amplitude and period), Ohmic heating and the temperature generated via reconnection jets. The parameter space of energy ratios also allows us to contextualize previous studies of the oscillatory reconnection mechanism and bring those different studies together into a single unified understanding.

The Cold Shoulder: Emission Measure Distributions of Active Region Cores

J.T. **Schmelz** and S. Pathak
EIS nugget, July **2013**
We have used EIS, XRT, and xrt_dem_iterative2 to determine the EMD(T) of eight inter-moss areas located in the cores of five different active regions. We then calculated b, where EMD(T) $\propto$ Tb, between Log T = 6.0 and the temperature of the peak of the EMD. For regions (1) and (2) in AR 11113 the exponents were rather large, indicating that steady heating was most likely dominating. The steady-heating model of Winebarger (2011) resembles the EMD for these regions.
For regions (3) and (5-8), b was lower, indication nanoflare heating. Our results are consistent with those of O'Dwyer et al. (2013), who suggested that active region age could be a strong indicator of the dominant heating. Older regions are more likely to be dominated by steady heating, while younger regions show more evidence of nanoflares.

HINODE X-RAY TELESCOPE DETECTION OF HOT EMISSION FROM QUIESCENT ACTIVE REGIONS: A NANOFLARE SIGNATURE?

J. T. **Schmelz** et al
ApJ 693 L131-L135 **2009**
http://www.iop.org/EJ/abstract/1538-4357/693/2/L131
The X-Ray Telescope (XRT) on the Japanese/USA/UK Hinode (Solar-B) spacecraft has detected emission from a quiescent active region core that is consistent with nanoflare heating. The fluxes from 10 broadband X-ray filters and filter combinations were used to construct differential emission measure (DEM) curves. In addition to the expected active region peak at log T = 6.3-6.5, we find a high-temperature component with significant emission measure at log T > 7.0. This emission measure is weak compared to the main peak—the DEM is down by almost three orders of magnitude—which accounts of the fact that it has not been observed with earlier instruments. It is also consistent with spectra of quiescent active regions: no Fe XIX lines are observed in a CHIANTI synthetic spectrum generated using the XRT DEM distribution. The DEM result is successfully reproduced with a simple two-component nanoflare model.

Empirical atmosphere model in a mini flare during magnetic reconnection

HVAR proceedings **2021**
Cent. Eur. Astrophys. Bull. vol (**2021**) 1, 5
https://arxiv.org/pdf/2112.06790.pdf
A spatio-temporal analysis of IRIS spectra of MgII, CII, and SiIV ions allows us to study the dynamics and the stratification of the flare atmosphere along the line of sight during the magnetic reconnection phase at the jet base. Strong asymmetric MgII and CII line profiles with extended blue wings observed at the reconnection site are interpreted by the presence of two chromospheric temperature clouds: one explosive cloud with blueshifts at 290 km/s and one cloud with smaller Doppler shift (around 36 km/s). Simultaneously at the same location a mini flare was observed with strong emission in multi temperatures (AIA), in several spectral IRIS lines (e.g. Oiv and Siiv, Mgii), absorption of identified chromospheric lines in Siiv line profile, enhancement of the Balmer continuum and X-ray emission by FERMI/GBM. With the standard thick-target flare model we calculate the energy of non thermal electrons observed by FERMI and compare it to the energy radiated by the Balmer continuum emission. We show that the low energy input by non thermal electrons above 20 keV was still sufficient to produce the excess of Balmer continuum. **March 22, 2019**

Solar Active Region Electric Currents Before and During Eruptive Flares **Review**

Brigitte **Schmieder**, Guillaume Aulanier
AGU book , A&A **2019**
https://arxiv.org/pdf/1903.04050.pdf
The chapter "Solar Active Region Electric Currents Before and During Eruptive Flares" is a discussion on electric currents in the pre-eruption state and in the course of eruptions of solar magnetic structures, using information from solar observations, nonlinear force-free field extrapolations relying on these observations, and three-dimensional magnetohydrodynamic (MHD) models. The discussion addresses the issue of neutralized vs. non-neutralized currents in

active regions and concludes that MHD models are able to explain non-neutralized currents in active regions by the existence of strong magnetic shear along the polarity inversion lines, thus confirming previous observations that already contained this result. The models have also captured the essence of the behavior of electric currents in active regions during solar eruptions, predicting current-density increases and decreases inside flare ribbons and in the interior of expanding flux ropes respectively. The observed photospheric current density maps, inferred from vector magnetic field observations, exhibit similar whirling ribbon patterns to the MHD model results, that are interpreted as the signatures of flux ropes and of quasi-separatrix layers (QSLs) between the magnetic systems in active regions. Enhancement of the total current in these QSLs during the eruptions and decreasing current densities at the footpoint of erupting flux ropes, has been confirmed in the observations. **February 15, 2011 , September 10, 2014**

Extreme solar storms based on solar magnetic field

Brigitte **Schmieder**

Varsiti Conference in Varna June 2016 **2017**

https://arxiv.org/pdf/1708.01790.pdf **File**

Many questions have to be answered before understanding the relationship between the emerging magnetic flux through the solar surface and the extreme geoeffective events. Which threshold determines the onset of the eruption? What is the upper limit in energy for a flare? Is the size of sunspot the only criteria to get extreme solar events?
Based on observations of previous solar cycles, and theory, the main ingredients for getting X ray class flares and large Interplanetary Corona Mass Ejections e.g. the built up of the electric current in the corona, are presented such as the existence of magnetic free energy, magnetic helicity, twist and stress in active regions. The upper limit of solar flare energy in space research era and the possible chances to get super-flares and extreme solar events can be predicted using MHD simulation of coronal mass ejections. **September 1, 1859, July 25 1946, April 4-5, 1947, August 1972, October 28 2003, October 28, October 29 and November 4, November 17 2003, October 2014.**

Flare-CME models: an observational perspective **Review**

Schmieder B., Aulanier G., Vrsnak B.

Solar Phys. *Solar and Stellar Flares: Observations, Simulations, and Synergies Volume 290, Issue 12, pp 3457-3486* **2015 File**

http://www.lesia.obspm.fr/perso/guillaume-aulanier/73_2015.FlareCmeObs.pdf

Eruptions, flares, and coronal mass ejection (CMEs) are due to physical phenomena mainly driven by an initially force-free current-carrying magnetic field.We review some key observations relevant to the current theoretical trigger mechanisms of the eruption and to the energy release via reconnection. Sigmoids observed in X-rays and UV, as well as the pattern (double J-shaped) of electric currents in the photosphere show clear evidence of the existence of currents parallel to the magnetic field and can be the signature of a flux rope that is detectable in CMEs. The magnetic helicity of filaments and active regions is an interesting indirectly measurable parameter because it can quantify the twist of the flux rope. On the other hand, the magnetic helicity of the solar structures allows us to associate solar eruptions and magnetic clouds in the heliosphere. The magnetic topology analysis based on the 3D magnetic field extrapolated from vector magnetograms is a good tool for identifying the reconnection locations (null points and/or the 3D large volumes ? hyperbolic flux tube, HFT). Flares are associated more with quasi-separatrix layers (QSLs) and HFTs than with a single null point, which is a relatively rare case. We review various mechanisms that have been proposed to trigger CMEs and their observable signatures: by "breaking" the field lines overlying the flux rope or by reconnection below the flux rope to reduce the magnetic tension, or by letting the flux rope to expand until it reaches a minimum threshold height (loss of equilibrium or torus instability). Additional mechanisms are commonly operating in the solar atmosphere. Examples of observations are presented throughout the article and are discussed in this framework.

Actors of the main activity in large complex centres during the 23 solar cycle maximum

B. **Schmieder** a,*, P. Dermoulin a, E. Pariat a, T. ToËroËk a,1, G. Molodij a, C.H. Mandrini b, S. Dasso b, R. Chandra c, W. Uddin d, P. Kumar d, P.K. Manoharan e, P. Venkatakrishnan f, N. Srivastava

Advances in Space Research 47 (**2011**) 2081–2091, **File**

During the maximum of Solar Cycle 23, large active regions had a long life, spanning several solar rotations, and produced large numbers of X-class flares and CMEs, some of them associated to magnetic clouds (MCs). This is the case for the Halloween active regions in 2003. The most geoeffective MC of the cycle (Dst = _457) had its source during the disk passage of one of these active regions (NOAA 10501) on 18 November 2003. Such an activity was presumably due to continuous emerging magnetic flux that was observed during this passage. Moreover, the region exhibited a complex topology with multiple domains of different magnetic helicities. The complexity was observed to reach such unprecedented levels that a detailed multi-wavelength analysis is necessary to precisely identify the solar sources of CMEs and MCs. Magnetic clouds are identified using in situ measurements and interplanetary scintillation (IPS) data. Results from these two different sets of data are also compared.

The nonpotentiality of coronae of solar active regions, the dynamics of the surface magnetic field, and the potential for large flares

C.J. **Schrijver**

ApJ 820 103 **2016**

http://arxiv.org/pdf/1602.07244v1.pdf

Flares and eruptions from solar active regions are associated with atmospheric electrical currents accompanying distortions of the coronal field away from a lowest-energy potential state. In order to better understand the origin of these currents and their role in M- and X-class flares, I review all active-region observations made with SDO/HMI and SDO/AIA from 2010/05 through 2014/10 within approximately 40 degrees from disk center. I select the roughly 4% of all regions that display a distinctly nonpotential coronal configuration in loops with a length comparable to the scale of the active region, and all that emit GOES X-class flares. The data for 41 regions confirm, with a single exception, that strong-field, high-gradient polarity inversion lines (SHILs) created during emergence of magnetic flux into, and related displacement within, pre-existing active regions are associated with X-class flares. Obvious nonpotentiality in the active region-scale loops occurs in 6 of 10 selected regions with X-class flares, all with relatively long SHILs along their primary polarity inversion line, or with a long internal filament there. Nonpotentiality can exist in active regions well past the flux-emergence phase, often with reduced or absent flaring. I conclude that the dynamics of the flux involved in the compact SHILs is of preeminent importance for the large-flare potential of active regions within the next day, but that their associated currents may not reveal themselves in active region-scale nonpotentiality. In contrast, active region-scale nonpotentiality, which can persist for many days, may inform us about the eruption potential other than those from SHILs which is almost never associated with X-class flaring. **01.07.2010, 15.02.11, 09.03.2011, 23.02.2011, 20.06.2011, 07.07.2011, 28.03.2012, 04.12.2011, 06.03.2012, 12.07.2012, 03.12.2012, 10.06.2013, 08.11.2013, 10.11.2013, 07.01.2014, 29.03.2014, 10.09.2014, 24.10.2014,**

The set of 41 selected regions with 78 distinct dates is listed in Table 1.

A Statistical Study of Distant Consequences of Large Solar Energetic Events

Carolus J. **Schrijver**, Paul A. Higgins

Solar Phys. Volume 290, Issue 10, pp 2943-2950 **2015**

http://arxiv.org/pdf/1509.05680v1.pdf **File**

Large solar flares and eruptions may influence remote regions through perturbations in the outer-atmospheric magnetic field, leading to causally related events outside of the primary or triggering eruptions that are referred to as "sympathetic events." We quantify the occurrence of sympathetic events using the full-disk observations by the Atmospheric Imaging Assembly onboard the Solar Dynamics Observatory associated with all flares of GOES class M5 or larger from 01 May 2010 through 31 December 2014. Using a superposed-epoch analysis, we find an increase in the rate of flares, filament eruptions, and substantial sprays and surges more than 20 degrees away from the primary flares within the first four hours at a significance of 1.8 standard deviations. We also find that the rate of distant events drops by two standard deviations, or a factor of 1.2, when comparing intervals between 4 hours and 24 hours before and after the start times of the primary large flares. We discuss the evidence for the concluding hypothesis that the gradual evolution leading to the large flare and the impulsive release of the energy in that flare both contribute to the destabilization of magnetic configurations in distant active regions and quiet-Sun areas. These effects appear to leave distant regions, in an ensemble sense, in a more stable state, so that fewer energetic events happen for at least a day following large energetic events**. 2011-09-07**

Table 1. 18 flares with no distant events within 24 hours; 13 flares with one distant event within 24 hours; 16 flares with two or more distant events within 24 hours:

THE 2011 FEBRUARY 15 X2 FLARE, RIBBONS, CORONAL FRONT, AND MASS EJECTION: INTERPRETING THE THREE-DIMENSIONAL VIEWS FROM THE SOLAR DYNAMICS OBSERVATORY AND STEREO GUIDED BY MAGNETOHYDRODYNAMIC FLUX-ROPE MODELING

Carolus J. **Schrijver**1, Guillaume Aulanier2, Alan M. Title1, Etienne Pariat2 and Cecile Delannée

E-print, June **2011**, **File**; **2011** ApJ 738 167, **File?**

The **2011 February 15** X2.2 flare and associated Earth-directed halo coronal mass ejection were observed in unprecedented detail with high resolution in spatial, temporal, and thermal dimensions by the Atmospheric Imaging Assembly (AIA) on the Solar Dynamics Observatory, as well as by instruments on the two STEREO spacecraft, then at near-quadrature relative to the Sun-Earth line. These observations enable us to see expanding loops from a flux-rope-like structure over the shearing polarity-inversion line between the central δ-spot groups of AR 11158, developing a propagating coronal front ("EIT wave"), and eventually forming the coronal mass ejection moving into the inner heliosphere. The observations support the interpretation that all of these features, including the "EIT wave," are signatures of an expanding volume traced by loops (much larger than the flux rope only), surrounded by a moving front rather than predominantly wave-like perturbations; this interpretation is supported by previously published MHD

models for active-region and global scales. The lateral expansion of the eruption is limited to the local helmet-streamer structure and halts at the edges of a large-scale domain of connectivity (in the process exciting loop oscillations at the edge of the southern polar coronal hole). The AIA observations reveal that plasma warming occurs within the expansion front as it propagates over quiet Sun areas. This warming causes dimming in the 171 Å (Fe IX and Fe X) channel and brightening in the 193 and 211 Å (Fe XII-XIV) channels along the entire front, while there is weak 131 Å (Fe VIII and Fe XXI) emission in some directions. An analysis of the AIA response functions shows that sections of the front running over the quiet Sun are consistent with adiabatic warming; other sections may require additional heating which MHD modeling suggests could be caused by Joule dissipation. Although for the events studied here the effects of volumetric expansion are much more obvious than true wave phenomena, we discuss how different magnetic environments within and around the erupting region can lead to the signatures of either or both of these aspects.

Long-range magnetic couplings between solar flares and coronal mass ejections observed by SDO and STEREO

C.J. **Schrijver** and A.M. Title

E-print, 18 Jan **2011**, **File**; JGR, 116, A04108, doi:10.1029/2010JA016224, **2011**

The combination of SDO and STEREO observations enable us to view much of the solar surface and atmosphere simultaneously and continuously. These near-global observations often show near-synchronous long-distance interactions between magnetic domains that exhibit flares, eruptions, and frequent minor forms of activity. Here, we analyze a series of flares, filament eruptions, coronal mass ejections, and related events which occurred on **2010/08/01-02**. These events extend over a full hemisphere of the Sun, only two-thirds of which is visible from the Earth's perspective. The combination of coronal observations and global field modeling reveals the many connections between these events by magnetic field lines, particularly those at topological divides. We find that all events of substantial coronal activity, including those where flares and eruptions initiate, are connected by a system of separatrices, separators, and quasi-separatrix layers, with little activity within the deep interiors of domains of connectivity. We conclude that for this sequence of events the evolution of field on the hemisphere invisible from Earth's perspective is essential to the evolution, and possibly even to the initiation, of the flares and eruptions over an area that spans at least 180 degrees in longitude. Our findings emphasize that the search for the factors that play a role in the initiation and evolution of eruptive and explosive phenomena, sought after for improved space-weather forecasting, requires knowledge of much, if not all, of the solar surface field.

Driving Major Solar Flares and Eruptions: A Review

Carolus J. **Schrijver**

Advances in Space Research

Volume 43, Issue 5, 2 March **2009**, Pages 739-755; **File**

This review focuses on the processes that energize and trigger M- and X-class solar flares and associated flux-rope destabilizations. Numerical modeling of specific solar regions is hampered by uncertain coronal-field reconstructions and by poorly understood magnetic reconnection; these limitations result in uncertain estimates of field topology, energy, and helicity. The primary advances in understanding field destabilizations therefore come from the combination of generic numerical experiments with interpretation of sets of observations. These suggest a critical role for the emergence of twisted flux ropes into pre-existing strong field for many, if not all, of the active regions that produce M- or X-class flares. The flux and internal twist of the emerging ropes appear to play as important a role in determining whether an eruption will develop predominantly as flare, confined eruption, or CME, as do the properties of the embedding field. Based on reviewed literature, I outline a scenario for major flares and eruptions that combines flux-rope emergence, mass draining, near-surface reconnection, and the interaction with the surrounding field. Whether deterministic forecasting is in principle possible remains to be seen: to date no reliable such forecasts can be made. Large-sample studies based on long-duration, comprehensive observations of active regions from their emergence through their flaring phase are needed to help us better understand these complex phenomena.

Non-linear force-free field modeling of a solar active region around the time of a major flare and coronal mass ejection

C.J. **Schrijver**1, M.L. DeRosa1, T. Metcalf2, G. Barnes2, B. Lites3, T. Tarbell1, J. McTiernan4, G. Valori5, T. Wiegelmann6, M.S. Wheatland7, T. Amari8, G. Aulanier9, P. D´emoulin9, M. Fuhrmann10, K. Kusano11, S. R´egnier12, J.K. Thalmann6

E-print, Nov 2007, ApJ Vol. 675, No. 2: 1637-1644, **2008**.

http://www.journals.uchicago.edu/doi/pdf/10.1086/527413
13 Dec 2006
Solar flares and coronal mass ejections are associated with rapid changes in field connectivity and powered by the partial dissipation of electrical currents in the solar atmosphere. A critical unanswered question is whether the currents involved are induced by the motion of pre-existing atmospheric magnetic flux subject to surface plasma flows, or whether these currents are associated with the emergence of flux from within the solar convective zone. We address this problem by applying state-of-the-art nonlinear force-free field (NLFFF) modeling to the highest resolution and quality vector-magnetographic data observed by the recently launched **Hinode** satellite on NOAA Active Region 10930 around the time of a powerful X3.4 flare. We compute 14 NLFFF models with 4 different codes and a variety of boundary conditions. We find that the model fields differ markedly in geometry, energy content, and force-freeness. We discuss the relative merits of these models in a general critique of present abilities to model.

A characteristic magnetic field pattern associated with all major solar flares and its use in flare forecasting –

Carolus J. **Schrijver**
2007, ApJL, 655, L117, doi: 10.1086/511857
https://iopscience.iop.org/article/10.1086/511857/pdf
Solar flares result from some electromagnetic instability that occurs within regions of relatively strong magnetic field in the Sun's atmosphere. The processes that enable and trigger these flares remain topics of intense study and debate. I analyze observations of 289 X- and M-class flares and over 2500 active region magnetograms to discover (1) that large flares, without exception, are associated with pronounced high-gradient polarity-separation lines, while (2) the free energy that emerges with these fibrils is converted into flare energy in a broad spectrum of flare magnitudes that may well be selected at random from a power-law distribution up to a maximum value. This maximum is proportional to the total unsigned flux R within ~15 Mm of strong-field, high-gradient polarity-separation lines, which are a characteristic appearance of magnetic fibrils carrying electrical currents as they emerge through the photosphere. Measurement of R is readily automated, and R can therefore be used effectively for flare forecasting. The probability for major flares to occur within 24 hr of the measurement of R approaches unity for active regions with the highest values of R around 2×10^{21} Mx. For regions with $R \lesssim 10^{19}$ Mx, no M- or X-class flares occur within a day.

Soft X-Ray Observations of Quiescent Solar Active Regions using Novel Dual-zone Aperture X-ray Solar Spectrometer (DAXSS)

Bennet D. **Schwab**, Robert H. A. Sewell, Thomas N. Woods, Amir Caspi, James Paul Mason, Christopher Moore
ApJ **2020**
https://arxiv.org/pdf/2008.11313.pdf
The Dual-zone Aperture X-ray Solar Spectrometer (DAXSS) was flown on **2018 June18** on the NASA 36.336 sounding rocket flight and obtained the highest resolution to date for solar soft X-ray (SXR) spectra over a broad energy range. This observation was during a time with quiescent (non-flaring) small active regions on the solar disk and when the 10.7 cm radio flux (F10.7) was 75 solar flux units (1 sfu = 10-22 W/m^2/Hz). The DAXSS instrument consists of a LASP-developed dual-zone aperture and a commercial X-ray spectrometer from Amptek that measures solar full-disk irradiance from 0.5-20 keV with a resolving power of 20 near 1 keV. This paper discusses the novel design of the spectrometer and the instrument characterization techniques. Additionally,the solar measurements obtained from the 2018 sounding rocket flight are analyzed using CHIANTI spectral models to fit the temperatures, emission measures, and relative elemental abundances of the solar corona plasma. The abundance of iron was found to be 35 percent higher than expected in the quiescent sun's corona suggesting either that our spectral models require additional sophistication or that the underlying atomic database may require updates. Future long-term systematic observations of this spectral range are needed. DAXSS will fly on the INSPIRESat-1 CubeSat in late-2020, and its SXR spectral data could provide further insight into the sources of coronal heating through modeling the changes of relative elemental abundances during developments of active regions and solar flaring events.

A flare in the deep solar atmosphere

Richard **Schwartz**, Hugh Hudson
RHESSI Science Nugget No. 282, **2016**
http://sprg.ssl.berkeley.edu/~tohban/wiki/index.php/A_flare_in_the_deep_solar_atmosphere

In this Nugget we report a singular set of observations of a very short-lived GOES event, well-observed by RHESSI and Fermi at high temperatures, which we argue to have taken place in the deepest solar atmosphere. In fact the duration of the GOES event is only about 15 seconds (FWHM) in the soft channel (1-8 A), very unusual indeed. As noted, the X-ray data strongly suggest a compact, low-altitude source. These have a standard interpretation in terms of flux transfer between compact and large-scale fields.

DESAT: an SSW tool for SDO/AIA image de-saturation

Richard A **Schwartz**, Gabriele Torre, Anna Maria Massone, Michele Piana
Inverse Problems, **2015**
http://arxiv.org/pdf/1503.02302v1.pdf
Saturation affects a significant rate of images recorded by the Atmospheric Imaging Assembly on the Solar Dynamics Observatory. This paper describes a computational method and a technological pipeline for the de-saturation of such images, based on several mathematical ingredients like Expectation Maximization, image correlation and interpolation. An analysis of the computational properties and demands of the pipeline, together with an assessment of its reliability are performed against a set of data recorded from the **Feburary 25 2014** flaring event.

A Systematic Approach to the Reconstruction of Saturated SDO/AIA Images

Richard A **Schwartz**, Gabriele Torre, Michele Piana
ApJL, 793 L23 **2014**
http://arxiv.org/pdf/1407.7343v1.pdf
EUV images of solar flares provided by the Atmospheric Imaging Assembly onboard the Solar Dynamics Observatory (SDO/AIA) are often affected by saturation effects in their core, physically most interesting region. We introduce an image reconstruction procedure that allows recovering information in the primary saturation domain using the secondary images produced by the diffraction fringes as input data. Such a procedure is based on standard image-processing tools like correlation, convolution, and back-projection. Its effectiveness is tested in the case of SDO/AIA observations of the **July 8 2013** flaring event.

The Halloween Flares and Large-Scale Correlations

Richard **Schwartz** and Hugh Hudson
RHESSI Halloween Nugget, Oct **2013**
http://sprg.ssl.berkeley.edu/~tohban/wiki/index.php/The_Halloween_Flares_and_Large-Scale_Correlations
The celebrated phenomena of the "Halloween Flares" of 2003 have just reappeared, though more weakly, in **October 2013**. In the waning phase of the previous sunspot maximum, a remarkable group of apparently independent sunspot groups appeared within a few days of one another. Something like this has just happened, or is just happening, in the declining phase of our current sunspot maximum ([Cycle 24]). For reasons unknown in detail, and probably unknowable any time soon, the organization of solar activity visible at the surface has large-scale correlations in space and time, meaning that flares bunch up in a highly non-random manner:

Identification of Multiple Hard X-Ray Sources in Solar Flares: A Bayesian Analysis of the 2002 February 20 Event

Federica **Sciacchitano**1, Alberto Sorrentino1,2, A Gordon Emslie3, Anna Maria Massone2, and Michele Piana1,2
2018 ApJ 862 68
http://sci-hub.tw/http://iopscience.iop.org/article/10.3847/1538-4357/aacc27/meta
The hard X-ray emission in a solar flare is typically characterized by a number of discrete sources, each with its own spectral, temporal, and spatial variability. Establishing the relationship among these sources is critical to determining the role of each in the energy release and transport processes that occur within the flare. In this paper we present a novel method to identify and characterize each source of hard X-ray emission. The method permits a quantitative determination of the most likely number of subsources present, and of the relative probabilities that the hard X-ray emission in a given subregion of the flare is represented by a complicated multiple source structure or by a simpler single source. We apply the method to a well-studied flare on **2002 February 20** in order to assess competing claims as to the number of chromospheric footpoint sources present, and hence to the complexity of the underlying magnetic geometry/topology. Contrary to previous claims of the need for multiple sources to account for the chromospheric hard X-ray emission at different locations and times, we find that a simple two-footpoint-plus-coronal-source model is the most probable explanation for the data. We also find that one of the footpoint sources moves quite rapidly throughout the event, a factor that presumably complicated previous analyses. The inferred velocity of the footpoint corresponds to a very high induced electric field, compatible with the fields in thin reconnecting current sheets.

Using Flare Rates to Search for Stellar Activity Cycles

Matthew T. **Scoggins**1, James. R. A. Davenport2,3, and Kevin R. Covey1
2019 Res. Notes AAS 3 137
https://iopscience.iop.org/article/10.3847/2515-5172/ab45a0
Measuring the prevalence and duration of activity cycles gives insight into the origin of stellar magnetic dynamos. Traditional techniques for detecting activity cycles include: monitoring integrated flux measurements (Kopp et al. 2016), chromospheric emission lines (Duncan et al. 1991), and starspot tracking (Messina & Guinan 2002; Montet et al. 2017). However, these techniques face challenges such as photometric precision, or limited spectroscopic sample sizes. Flares, however, are easily detectable for stars even out to kpc distances, and can be surveyed for many stars simultaneously using wide-field photometric surveys. Encouragingly, *the Sun's flare rate varies by a factor of 10 between solar maximum and minimum* (e.g., Veronig et al. 2002; Aschwanden & Freeland 2012).

INFERRING THE MAGNETOHYDRODYNAMIC STRUCTURE OF SOLAR FLARE SUPRA-ARCADE PLASMAS FROM A DATA-ASSIMILATED FIELD TRANSPORT MODEL

Roger B. **Scott**, David E. McKenzie, and Dana W. Longcope
2016 ApJ 819 56
Supra-arcade fans are highly dynamic structures that form in the region above post-reconnection flare arcades. In these features the plasma density and temperature evolve on the scale of a few seconds, despite the much slower dynamics of the underlying arcade. Further, the motion of supra-arcade plasma plumes appears to be inconsistent with the low-beta conditions that are often assumed to exist in the solar corona. In order to understand the nature of these highly debated structures, it is, therefore, important to investigate the interplay of the magnetic field with the plasma. Here we present a technique for inferring the underlying magnetohydrodynamic processes that might lead to the types of motions seen in supra-arcade structures. Taking as a case study the **2011 October 22** event, we begin with extreme-ultraviolet observations and develop a time-dependent velocity field that is consistent with both continuity and local correlation tracking. We then assimilate this velocity field into a simplified magnetohydrodynamic simulation, which deals simultaneously with regions of high and low signal-to-noise ratio, thereby allowing the magnetic field to evolve self-consistently with the fluid. Ultimately, we extract the missing contributions from the momentum equation in order to estimate the relative strength of the various forcing terms. In this way we are able to make estimates of the plasma beta, as well as predict the spectral character and total power of Alfvén waves radiated from the supra-arcade region.

Observing the formation of flare-driven coronal rain

E. **Scullion**, L. Rouppe Van Der Voort, P. Antolin, S. Wedemeyer, G. Vissers, E. P. Kontar, P. Gallagher
ApJ **833** 184 **2016**
https://arxiv.org/pdf/1610.09255v1.pdf
Flare-driven coronal rain can manifest from rapidly cooled plasma condensations near coronal loop-tops in thermally unstable post-flare arcades. We detect 5 phases that characterise the post-flare decay: heating, evaporation, conductive cooling dominance for ~120 s, radiative / enthalpy cooling dominance for ~4700 s and finally catastrophic cooling occurring within 35-124 s leading to rain strands with s periodicity of 55-70 s. We find an excellent agreement between the observations and model predictions of the dominant cooling timescales and the onset of catastrophic cooling. At the rain formation site we detect co-moving, multi-thermal rain clumps that undergo catastrophic cooling from ~1 MK to ~22000 K. During catastrophic cooling the plasma cools at a maximum rate of 22700 K s-1 in multiple loop-top sources. We calculated the density of the EUV plasma from the DEM of the multi-thermal source employing regularised inversion. Assuming a pressure balance, we estimate the density of the chromospheric component of rain to be 9.21x10^11 +-1.76x10^11 cm-3 which is comparable with quiescent coronal rain densities. With up to 8 parallel strands in the EUV loop cross section, we calculate the mass loss rate from the post-flare arcade to be as much as 1.98x10^12 +/-4.95x10^11 g s-1. Finally, we reveal a close proximity between the model predictions of 10^5.8 K and the observed properties between 10^5.9 K and 10^6.2 K, that defines the temperature onset of catastrophic cooling. The close correspondence between the observations and numerical models suggests that indeed acoustic waves (with a sound travel time of 68 s) could play an important role in redistributing energy and sustaining the enthalpy-based radiative cooling. **01-07-2012**

Unresolved Fine-scale Structure in Solar Coronal Loop-tops

E. **Scullion**1,2, L. Rouppe van der Voort1, S. Wedemeyer1, and P. Antolin
2014 ApJ 797 36
http://arxiv.org/pdf/1409.1920v1.pdf
New and advanced space-based observing facilities continue to lower the resolution limit and detect solar coronal loops in greater detail. We continue to discover even finer substructures within coronal loop cross-sections, in order to understand the nature of the solar corona. Here, we push this lower limit further to search for the finest coronal loop

substructures, through taking advantage of the resolving power of the Swedish 1 m Solar Telescope/CRisp Imaging Spectro-Polarimeter (CRISP), together with co-observations from the Solar Dynamics Observatory/Atmospheric Image Assembly (AIA). High-resolution imaging of the chromospheric H? 656.28 nm spectral line core and wings can, under certain circumstances, allow one to deduce the topology of the local magnetic environment of the solar atmosphere where its observed. Here, we study post-flare coronal loops, which become filled with evaporated chromosphere that rapidly condenses into chromospheric clumps of plasma (detectable in H?) known as a coronal rain, to investigate their fine-scale structure. We identify, through analysis of three data sets, large-scale catastrophic cooling in coronal loop-tops and the existence of multi-thermal, multi-stranded substructures. Many cool strands even extend fully intact from loop-top to footpoint. We discover that coronal loop fine-scale strands can appear bunched with as many as eight parallel strands within an AIA coronal loop cross-section. The strand number density versus cross-sectional width distribution, as detected by CRISP within AIA-defined coronal loops, most likely peaks at well below 100 km, and currently, 69% of the substructure strands are statistically unresolved in AIA coronal loops. **1-2 July 2012, 24th Sept. 2011,**

Observations of an Eruptive Solar Flare in the Extended EUV Solar Corona

Daniel B. **Seaton**, Jonathan M. Darnel
2018 ApJL **852** L9
https://arxiv.org/pdf/1712.06003.pdf
http://iopscience.iop.org.sci-hub.tw/2041-8205/852/1/L9/
https://iopscience.iop.org/article/10.3847/2041-8213/aaa28e/pdf
We present observations of a powerful solar eruption, accompanied by an X8.2 solar flare, from NOAA Active Region 12673 on **2017 September 10** by the ***Solar Ultraviolet Imager (SUVI) on the GOES-16 spacecraft***. SUVI is noteworthy for its relatively large field of view, which allows it to image solar phenomena to heights approaching 2 solar radii. These observations include the detection of an apparent current sheet associated with magnetic reconnection in the wake of the eruption, and evidence of an extreme-ultraviolet wave at some of the largest heights ever reported. We discuss the acceleration of the nascent coronal mass ejection to approximately 2000 km s-1 at about 1.5 solar radii. We compare these observations with models of eruptions and eruption-related phenomena. We also describe the SUVI data and discuss how the scientific community can access SUVI observations of the event.

Observations of the Formation, Development, and Structure of a Current Sheet in an Eruptive Solar Flare

Daniel B. **Seaton**1,2, Allison E. Bartz3, and Jonathan M. Darnel
2017 ApJ 835 139
https://arxiv.org/pdf/1610.06905v1.pdf
We present Atmospheric Imaging Assembly observations of a structure we interpret as a current sheet associated with an X4.9 flare and coronal mass ejection that occurred on **2014 February 25** in NOAA Active Region 11990. We characterize the properties of the current sheet, finding that the sheet remains on the order of a few thousand kilometers thick for much of the duration of the event and that its temperature generally ranged between 8 and 10 MK. We also note the presence of other phenomena believed to be associated with magnetic reconnection in current sheets, including supra-arcade downflows and shrinking loops. We estimate that the rate of reconnection during the event was M A ≈ 0.004–0.007, a value consistent with model predictions. We conclude with a discussion of the implications of this event for reconnection-based eruption models.

Theoretical and Observational Evidence for Coriolis Effects in Coronal Magnetic Fields Via Direct Current Driven Flaring Events

Darryl Z. **Seligman**, Leslie A. Rogers, Adina D. Feinstein, Mark R. Krumholz, James R. Beattie, Christoph Federrath, Fred C. Adams, Marco Fatuzzo, Maximilian N. Günther
ApJ **929** 54 **2022**
https://arxiv.org/pdf/2201.03697.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ac5b69/pdf
All stars produce explosive surface events such as flares and coronal mass ejections. These events are driven by the release of energy stored in coronal magnetic fields, generated by the stellar dynamo. However, it remains unclear if the energy deposition in the magnetic fields is driven by direct or alternating currents. Recently, we presented observational measurements of the flare intensity distributions for a sample of ∼105 stars across the main sequence observed by TESS, all of which exhibited power-law distributions similar to those observed in the Sun, albeit with varying slopes. Here we investigate the mechanisms required to produce such a distribution of flaring events via direct current energy deposition, in which coronal magnetic fields braid, reconnect, and produce flares. We adopt a topological model for this process which produces a power-law distribution of energetic flaring events. We expand this model to include the Coriolis effect, which we demonstrate produces a shallower distribution of flare energies in stars that rotate more rapidly (corresponding to a weaker decline in occurrence rates toward increasing flare energies). We present tentative evidence for the predicted rotation-power-law index correlation in the observations. We advocate for future

observations of stellar flares that would improve our measurements of the power-law exponents, and yield key insights into the underlying dynamo mechanisms that underpin the self-similar flare intensity distributions.

Call and Response: A Time-Resolved Study of Chromospheric Evaporation in a Large Solar Flare

Sean G. **Sellers**, Ryan O. Milligan, R. T. James McAteer
ApJ **936** 85 **2022**
https://arxiv.org/pdf/2208.14347.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ac87a9/pdf
We studied an X1.6 solar flare produced by NOAA AR 12602 on **2014 October 22**. The entirety of this event was covered by RHESSI, IRIS, and Hinode/EIS, allowing analysis of the chromospheric response to a nonthermal electron driver. We derived the energy contained in nonthermal electrons via RHESSI spectral fitting, and linked the time-dependent parameters of this call to the response in Doppler velocity, density, and nonthermal width across a broad temperature range. The total energy injected was 4.8×1030 erg, and lasted 352 seconds. This energy drove explosive chromospheric evaporation, with a delineation in both Doppler and nonthermal velocities at the flow reversal temperature, between 1.35--1.82 MK. The time of peak electron injection (14:06 UT) corresponded to the time of highest velocities. At this time, we found 200 km s−1 blueshifts in the core of Fe XXIV, which is typically assumed to be at rest. Shortly before this time, the nonthermal electron population had the shallowest spectral index (≈ 6), corresponding to the peak nonthermal velocity in Si IV and Fe XXI. Nonthermal velocities in Fe XIV, formed near the flow reversal temperature were low, and not correlated with density or Doppler velocity. Nonthermal velocities in ions with similar temperatures were observed to increase and correlate with Doppler velocities, implying unresolved flows surrounding the flow reversal point. This study provides a comprehensive, time-resolved set of chromospheric diagnostics for a large X-class flare, along with a time-resolved energy injection profile, ideal for further modeling studies.

On the Distinct Periodicities of Sunspot Counts in Flaring and Non-flaring Active Regions

Stefano **Sello**
2017
https://arxiv.org/pdf/1707.01900.pdf
In a recent work, Kilcik et al. (2017), have detected the temporal and periodic behavior of sunspot counts (SSC) in flaring (i.e. C, M, or X class flares), and non-flaring active regions for the last two solar cycles, covering the period: 1996 - 2016. The main results obtained are: 1) The temporal behavior of monthly means of daily total SSC in flaring and non-flaring active regions are different and these differences are also varying from cycle to cycle; 2) The periodicities detected in SSC of flaring and non-flaring active regions are quite different and these variations are also different from one cycle to another; the highest detected period in the flaring active regions is 113 days, while there are much higher periodicities (327, 312, and 256 days) in non-flaring regions. The detection of typical different periodicities in flaring and non-flaring regions can suggests both important differences and physical interpretation in the magneto-hydrodynamic behavior of the Sun. For this reason in the present paper we show a further periodicity analysis of the sunspot counts in flaring and in non-flaring active regions using the same data source of that used by the above cited authors and applying a powerful wavelet analysis tool which is particularly useful to detect multiscale features of complex unsteady and unevenly sampled time series. In order to futher support the differences and similarities found in the time behavior of SSC in flaring and non-flaring regions, we also computed the behavior of the wavelet entropy, a proper time function which allow us to measure the degree of complexity in the dynamics of the related time series.

From eruption to post-flare rain: A 2.5D MHD model⋆

Samrat **Sen**1,2,3, Avijeet Prasad4,5, Valeriia Liakh3 and Rony Keppens3
A&A, 688, A64 (**2024**)
https://arxiv.org/pdf/2405.10688
https://www.aanda.org/articles/aa/pdf/2024/08/aa49767-24.pdf
Context. Erupting magnetic flux ropes play an important role in producing solar flares, whereas fine-scale condensed coronal rain is often found in post-flare loops. However, the formation of the MFRs in the pre-flare stage and how this leads to coronal rain in a post-eruption magnetic loop is not fully understood.
Aims. We explore the formation and eruption of MFRs, followed by the appearance of coronal rain in the post-flare loops to understand the magnetic and thermodynamic properties of eruptive events and their multi-thermal aspects in the solar atmosphere.
Methods. We performed a resistive-magnetohydrodynamic simulation with the open-source code MPI-AMRVAC to explore the evolution of sheared magnetic arcades that can lead to flux rope eruptions. The system was in mechanical imbalance at the initial state and evolved self-consistently in a nonadiabatic atmosphere under the influence of radiative losses, thermal conduction, and background heating. We used an additional level of adaptive mesh refinement to achieve the smallest cell size of ≈32.7 km in each direction to reveal the fine structures in the system.

Results. The system achieves a semi-equilibrium state after a short transient evolution from its initial mechanically imbalanced condition. A series of erupting MFRs is formed due to spontaneous magnetic reconnection across current sheets that are created underneath the erupting flux ropes. A gradual development of thermal imbalance is noted at a loop top in the post-eruption phase, which leads to catastrophic cooling and to the formation of condensations. We obtain plasma blobs that fall down along the magnetic loop in the form of coronal rain. The dynamical and thermodynamic properties of these cool condensations agree well with observations of post-flare coronal rain. Conclusions. Our simulation supports the development and eruption of multiple MFRs and the formation of coronal rain in post-flare loops. This is one of the key aspects required to reveal the mystery of coronal heating in the solar atmosphere.

Thermally enhanced tearing in solar current sheets: explosive reconnection with plasmoid-trapped condensations

Samrat **Sen**, Rony Keppens
A&A 666, A28 **2022**
https://arxiv.org/pdf/2208.04355.pdf
https://www.aanda.org/articles/aa/pdf/2022/10/aa44152-22.pdf
https://doi.org/10.1051/0004-6361/202244152
In flare-relevant current sheets, tearing instability may trigger explosive reconnection and plasmoid formation. We explore how the thermal and tearing modes reinforce each other in the fragmentation of a current sheet in the solar corona through an explosive reconnection process, characterized by the formation of plasmoids which interact and trap condensing plasma. We use a resistive magnetohydrodynamic (MHD) simulation of a 2D current layer, incorporating the non-adiabatic effects of optically thin radiative energy loss and background heating using \texttt{MPI-AMRVAC}. Our parametric survey explores different resistivities and plasma-β to quantify the instability growth rate in the linear and nonlinear regimes. We notice that for dimensionless resistivity values within 10−4−5×10−3, we get explosive behavior where thermal instability and tearing behavior reinforce each other. This is clearly below the usual critical Lundquist number range of pure resistive explosive plasmoid formation. The non-linear growth rates follow weak power-law dependency with resistivity. The fragmentation of the current sheet and the formation of the plasmoids in the nonlinear phase of the evolution due to the thermal and tearing instabilities are obtained. The formation of plasmoids is noticed for the Lundquist number (SL) range 4.6×103−2.34×105. We quantify the temporal variation of the plasmoid numbers and the density filling factor of the plasmoids for different physical conditions. We also find that the maximum plasmoid numbers scale as S0.223L. Within the nonlinearly coalescing plasmoid chains, localized cool condensations gather, realizing density and temperature contrasts similar to coronal rain or prominences.

Energy distribution of solar flare events

S. **Sen**, A. Mangalam, R. Ramesh (Indian Institute of Astrophysics)
Proceedings of IAU Symposium 340 **2018**
https://arxiv.org/pdf/1805.08431.pdf
Observational evidence of the braiding of magnetic field lines has been reported. The magnetic reconnection within the loop (nanoflares) and with other loops (microflares) disentangle the field. The coronal field then reorganizes itself to attain a force-free field configuration. We have evaluated the power law index of the energy distribution f(E)=f0E−α by using a model of relaxation incorporating different profile functions of winding number distribution f(w) based on braided topologies. We study the radio signatures that occur in the solar corona using the radio data obtained from the Gauribidanur Radio Observatory (IIA) and extract the power law index by using the Statistic-sensitive nonlinear iterative peak clipping (SNIP) algorithm. We see that the power law index obtained from the model is in good agreement with the calculated value from the radio data observation.

Proton Acceleration in Low-β Magnetic Reconnection with Energetic Particle Feedback

Jeongbhin **Seo**, Fan Guo, Xiaocan Li, and Hui Li
2024 ApJ 977 146
https://iopscience.iop.org/article/10.3847/1538-4357/ad8e64/pdf
Magnetic reconnection regions in space and astrophysics are known as active particle acceleration sites. There is ample evidence showing that energetic particles can take a substantial amount of converted energy during magnetic reconnection. However, there has been a lack of studies understanding the backreaction of energetic particles at magnetohydrodynamical scales in magnetic reconnection. To address this, we have developed a new computational method to explore the feedback by nonthermal energetic particles. This approach considers the backreaction from these energetic particles by incorporating their pressure into magnetohydrodynamics (MHD) equations. The pressure of the energetic particles is evaluated from their distribution evolved through Parker's transport equation, solved using stochastic differential equations (SDEs), so we coin the name MHD-SDE. Applying this method to low-β magnetic reconnection simulations, we find that reconnection is capable of accelerating a large fraction of energetic particles that contain a substantial amount of energy. When the feedback from these particles is included, their pressure suppresses the compression structures generated by magnetic reconnection, thereby mediating particle energization. Consequently,

the feedback from energetic particles results in a steeper power-law energy spectrum. These findings suggest that feedback from nonthermal energetic particles plays a crucial role in magnetic reconnection and particle acceleration.

Temporal and Spatial Characteristics of Hard X-Ray Sources in Flare Model with a Vertical Current Sheet

Alexander N. **Shabalin**, Evgeniia P. Ovchinnikova, Yuri E. Charikov
ApJ **954** 58 **2023**
https://arxiv.org/pdf/2308.05718.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/acea5e/pdf
We analyzed changes in the height of the coronal hard X-ray (HXR) source for flares SOL**2013-05-13**T01:50 and SOL**2013-05-13**T15:51. Analysis of the Reuven Ramaty High Energy Solar Spectroscopic Imager data revealed the downward motion of the HXR source and the separation of the sources by energy and height. In the early stages of the flares, a negative correlation was found between the HXR source area in the corona and HXR flux. For the SOL**2013-05-13**T15:51 event, an increasing trend in the time delay spectra at the footpoints was obtained. For both events, the spectra of the time delays in the coronal HXR source showed a decreasing trend across the energies in certain flare phases. To interpret the observed phenomena, we considered a flare model of collapsing traps and calculated the distribution functions of accelerated electrons along the magnetic loop using a nonstationary relativistic kinetic equation. This approach considers betatron and Fermi first-order acceleration mechanisms. The increasing trend of the time delay spectra at the footpoints was explained by the high mirror ratio in the magnetic loop and betatron acceleration mechanism. The observed features in the spatial and temporal behavior of the HXR sources, such as the negative correlation between the HXR source area and HXR flux, can be interpreted by the collapsing trap model.

A statistical study of CME-associated flare during the solar cycle 24

AMK **Shaltout**; Eid A Amin; M.M. Beheary; R. H. Hamid
Advances in Space Research Volume 63, Issue 7, 1 April **2019**, Pages 2300-2311
https://www.sciencedirect.com/science/article/pii/S0273117718309359?dgcid=raven_sd_via_email
We investigate on the relationship between flares and coronal mass ejections (CMEs) in which a flare started before and after the CME events which differ in their physical properties, indicating potentially different initiation mechanisms. The physical properties of two types flare-correlated CME remain an interesting and important question in space weather. We study the relationship between flares and CMEs using a different approach requiring both temporal and spatial constraints during the period from December 1, 2008 to April 30, 2017 in which the CMEs data were acquired by SOHO/LASCO (Solar and Heliospheric Observatory/Large Angle Spectrometric Coronagraph) over the solar cycle 24. The soft X-ray flare flux data, such as flare class, location, onset time and integrated flux, are collected from Geostationary Environmental satellite (GOES) \textbf{and XRT Flare catalogs}. We selected 301 CMEs-flares pairs applying simultaneously temporal and spatial constraints in all events for the distinguish between two associated CME-flare types. We study the correlated properties of coincident flares and CMEs during this period, specifically separating the sample into two types: flares that precede a CME and flares that follow a CME. We found an opposite correlation relationship between the acceleration and velocity of CMEs in the After- and Before-CMEs events. We found a log-log relation between the width and mass of CMEs in the two associated types. The CMEs and flares properties show that there were significant differences in all physical parameters such as (mass, angular width, kinetic energy, speed and acceleration) between two flare-associated CME types.

Spatial and Spectral Evolution of Microwave and X-Ray Sources During the Solar Limb Flare on February 5, 2023.

Shamsutdinova, J.N., Kashapova, L.K., Li, Z. et al.
Sol Phys 299, 80 (**2024**).
https://doi.org/10.1007/s11207-024-02331-w
We present an empirical scenario of the energy release process during a solar limb flare on **February 5, 2023**. This event was observed by the Siberian Radioheliograph (SRH) within the 3 – 12 GHz range and the Advanced Space-based Solar Observatory / Hard X-ray Imager (ASO-S/HXI) within 10 – 300 keV range. The combination of these data allowed us to use information not only about the spectral features but also about the spatial evolution of the flare. The main source of the energy released was a small compact loop which was revealed in both the X-ray and microwave ranges. During the early phases of the flare evolution, a spectral analysis of microwave emission showed that thermal gyrosynchrotron emission turned to gyrosynchrotron emission of nonthermal electrons. This indicated the transition from the heating process to the acceleration processes. Spectral indices derived from hard X-ray and microwave data closely agree with each other and show the classical soft–hard–soft scenario of acceleration. The hardening of the average microwave spectrum at the end of the impulsive phase was caused by the contribution of jet emission to microwaves rather than by peculiarities of the acceleration processes.

HARD–SOFT–HARD FLARE SPECTRA AND THEIR ENERGY DEPENDENCE IN SPECTRAL EVOLUTION OF A SOLAR HARD X-RAY FLARE
Chengwen **Shao**1,2 and Guangli Huang
Astrophysical Journal, 694:L162–L165, **2009**
http://www.iop.org/EJ/toc/-alert=43191/1538-4357/694/2
In this Letter, we studied the time evolution of the energy-dependent spectral indices for the **2004 November 3** solar hard X-ray flare observed by *RHESSI*. The common soft–hard–soft (SHS) pattern spectra were found at the lower energies, while a new feature, hard–soft–hard (HSH), was found at higher energies for each subpeak. As the energy increases, the SHS pattern is gradually converted into the HSH pattern. Some possible explanations for the spectral evolution and its energy dependence are discussed, such as the return current.

COMPARATIVE STUDY OF SOLAR HXR FLARE SPECTRA IN LOOPTOP AND FOOTPOINT SOURCES
Chengwen **Shao** et al **2009** ApJ 691 299-305
http://www.iop.org/EJ/abstract/0004-637X/691/1/299
In this paper, 28 peaks and subpeaks are selected in 13 RHESSI hard X-ray (HXR) flares with a single-loop structure. One looptop (LT) source is observed at lower energies, and two footpoint (FP) sources are observed at higher energies in these flares. The HXR flare spectra in the LT and FP sources are studied statistically. It is found that the LT spectral index (γLT) is well correlated with the FP spectral index (γFP) for larger values of γLT, while γLT is anticorrelated with γFP for smaller values of γLT. This new statistical result may be explained by the different relationships between the photon fluxes and spectral indices in the LT and FP sources, as well as by the nonthermal thin-target model with a larger low-cutoff energy.

Characteristics of Sustained >100 γ-ray Emission Associated with Solar Flares
G. H. **Share**, R. J. Murphy, A. K. Tolbert, B. R. Dennis, S. M. White, R. A. Schwartz, and A. J. Tylka
ApJ Supplement **2017**
http://www.astro.umd.edu/~share/publications/share_2017.pdf **File**
We characterize and provide a catalog of thirty >100 MeV sustained γ-ray emission (SGRE) events observed by Fermi LAT. These events are temporally and spectrally distinct from the associated solar flares. Their spectra are consistent with decay of pions produced by >300 MeV protons and are not consistent with electron bremsstrahlung. SGRE start times range from CME onset to two hours later. Their durations range from about four minutes to twenty hours and appear to be correlated with durations of >100 MeV SEP proton events. The >300 MeV protons producing SGRE have spectra that can be fit with power laws with a mean index of ∼4 and RMS spread of 1.8. γ-ray line measurements indicate that SGRE proton spectra are steeper above 300 MeV than they are below 300 MeV. The number of SGRE protons >500 MeV is on average about ten times more than the number in the associated flare and about fifty to one hundred times less than the number in the accompanying SEP. SGRE can extend tens of degrees from the flare site. Sustained bremsstrahlung from MeV electrons was observed in one SGRE event. Flare >100 keV X-ray emission appears to be associated with SGRE and with intense SEPs. From this observation, we provide arguments that lead us to propose that sub-MeV to MeV protons escaping from the flare contribute to the seed population that is accelerated by shocks onto open field lines to produce SEPs and onto field lines returning to the Sun to produce SGRE. **3 June 1983?, 2011-02-24, 2011 March 7, 2011-05-29, 2011-06-02, 2011-06-07, 2011-08-04, 2011-08-09, 2011-09-06, 2011-09-07, 2011-09-24, 22-Jan-12, 2012-01-23, 2012-01-27, 2012-03-04, 2012-03-05, 06-Mar-12, 2012 March 7, 2012-03-09, 2012-03-10, 2012-03-13, 2012-05-17, 2012-06-03, 2012-07-06, 2012-10-23, 2012-11-27, 2013-04-11, 2013-05-13, 2013-05-14, 2013-05-15, 2013-10-11, 2013-10-25, 2013-10-28, 2014 February 25, 2014-09-01, 2015-06-21**

Source-region characteristics of anemone active regions in the ascending phase of solar cycle 24

R. **Sharma** and C. Cid
A&A 642, A233 (2020)
https://www.aanda.org/articles/aa/pdf/2020/10/aa38927-20.pdf
https://doi.org/10.1051/0004-6361/202038927
https://sci-hub.st/https://www.aanda.org/articles/aa/abs/2020/10/aa38927-20/aa38927-20.html
Context. Active regions in close proximity to coronal holes, also known as anemone regions, are the best candidates for studying the interaction between closed and open magnetic field topologies at the Sun. Statistical investigation of their source-region characteristics can provide vital clues regarding their possible association with energetic events, relevant from space weather perspectives.
Aims. The main goal of our study is to understand the distinct properties of flaring and non-flaring anemone active regions and their host coronal holes, by examining spatial and magnetic field distributions during the rise phase of the solar cycle, in the years 2011–2014.
Methods. Anemone regions were identified from the minimum-distance threshold, estimated using the data available in the online catalogs for on-disk active regions and coronal holes. Along with the source-region area and magnetic field characteristics, associated filament and flare cases were also located. Regions with and without flare events were further selected for a detailed statistical examination to understand the major properties of the energetic events, both eruptive and confined, at the anemone-type active regions.
Results. Identified anemone regions showed weak asymmetry in their spatial distribution over the solar disk, with yearly average independent from mean sunspot number trend, during the rise phase of solar cycle 24. With the progression in solar cycle, the area and minimum-distance parameters indicated a decreasing trend in their magnitudes, while the magnetic field characteristics indicated an increase in their estimated magnitudes. More than half of the regions in our database had an association with a filament structure, and nearly a third were linked with a magnetic reconnection (flare) event. Anemone regions with and without flares had clear distinctions in their source-region characteristics evident from the distribution of their properties and density analysis. The key differences included larger area and magnetic field magnitudes for flaring anemone regions, along with smaller distances between the centers of the active region and its host coronal hole. **06 September 2011**

Radio and X-ray Observations of Short-lived Episodes of Electron Acceleration in a Solar Microflare

Rohit **Sharma**, Marina Battaglia, Yingjie Luo, Bin Chen, Sijie Yu
ApJ **904** 94 **2020**
https://arxiv.org/pdf/2009.14497.pdf
https://doi.org/10.3847/1538-4357/abbd96
Solar flares are sudden energy release events in the solar corona, resulting from magnetic reconnection, that accelerates particles and heats the ambient plasma. During a flare, there are often multiple, temporally and spatially separated individual energy release episodes that can be difficult to resolve depending on the observing instrument. We present multi-wavelength imaging and spectroscopy observations of multiple electron acceleration episodes during a GOES B1.7-class two-ribbon flare on **2012 February 25**, observed simultaneously with the Karl G. Jansky Very Large Array (VLA) at 1--2 GHz, the Reuven Ramatay High Energy Solar Spectroscopic Imager (RHESSI) in X-rays, and the Solar Dynamics Observatory in extreme ultraviolet (EUV). During the initial phase of the flare, five radio bursts were observed. A nonthermal X-ray source was seen co-temporal, but not co-spatial, with the first three radio bursts. Their radio spectra are interpreted as optically thick gyrosynchrotron emission. By fitting the radio spectra with a gyrosynchrotron model, we derive the magnetic field strength and nonthermal electron spectral parameters in each acceleration episode. Notably, the nonthermal parameters derived from X-rays differ considerably from the nonthermal parameters inferred from the radio. The observations are indicative of multiple, co-temporal acceleration episodes during the impulsive phase of a solar microflare. The X-ray and radio burst sources likely originate from separate electron distributions in different magnetic loops.
CESRA #2832 March **2021** http://www.astro.gla.ac.uk/users/eduard/cesra/?p=2832

On the Bright Loop Top Emission in Post Eruption Arcades

Rohit **Sharma**, Durgesh Tripathi, Hiroaki Isobe, Avyarthana Ghosh
ApJ **2016**
http://arxiv.org/pdf/1603.04959v1.pdf
The observations of post eruption arcades (PEAs) in X-rays and EUV reveal strong localised brightenings at the loop top regions. The origin of these brightenings and their dynamics is not well understood to date. Here, we study the dynamics of PEAs using one-dimensional hydrodynamic modelling with the focus on the the understanding of the formation of localised brightening.Our findings suggest that these brightenings are the result of collisions between the counter-streaming chromospheric evaporation from both the foot points. We further perform forward modelling of the emission observed in simulated results in various spectral lines observed by the Extreme-Ultraviolet Imaging Telescope

aboard Hinode. The forward modelled intensities in various spectral lines are in close agreement with a flare observed in **December 17, 2006** by EIS.

Sunquakes of Solar Cycle 24

I.N. **Sharykin**, A.G. Kosovichev
ApJ **2019**
https://arxiv.org/pdf/1911.04197.pdf
The paper presents results of a search for helioseismic events (sunquakes) produced by M-X class solar flares during Solar Cycle 24. The search is performed by analyzing photospheric Dopplergrams from Helioseismic Magnetic Imager (HMI). Among the total number of 500 M-X class flares, 82 helioseismic events were detected. This result is quite unexpected, since it was previously thought that sunquakes were very rare and observed mainly in strong flares. However, our analysis has shown that there many strong sunquakes were produced by solar flares of low M class, while in some powerful X-class flares helioseismic waves were not observed or were weak. Our analysis also revealed several active regions characterized by the most efficient generation of helioseismic waves during flares. We found that the sunquake power correlates with the maximum value of soft X-ray flux time derivative better than with the X-ray class, indicating that the sunquake mechanism is associated with high-energy particles. We also show that the seismically active flares are more impulsive than the flares without photospheric and helioseismic perturbations. We present a new catalog of helioseismic solar flares, which opens opportunities for performing statistical studies to better understand physics of sunquakes as well as flare energy release and transport. **October 23, 2012, November 5, 2013**

Flare Energy Release at the Magnetic Field Polarity Inversion Line During M1.2 Solar Flare of 2015 March 15.
II. Investigation of Photospheric Electric Current and Magnetic Field Variations Using HMI 135-second Vector Magnetograms

I.N. **Sharykin**, I.V. Zimovets, I.I.Myshyakov
2020 *ApJ* **893** 159
https://arxiv.org/pdf/1905.03352.pdf
https://doi.org/10.3847/1538-4357/ab84ef
This work is a continuation of Paper I (Sharykin et al. 2018) devoted to analysis of nonthermal electron dynamics and plasma heating in the confined M1.2 class solar flare SOL2015-03-15T22:43 revealing energy release in the highly sheared interacting magnetic loops in the low corona, above the polarity inversion line (PIL). The scope of the present work is to make the first extensive quantitative analysis of the photospheric magnetic field and photospheric vertical electric current (PVEC) dynamics in the PIL region using new vector magnetograms obtained with the Helioseismic and Magnetic Imager (HMI) onboard the Solar Dynamics Observatory (SDO) with high temporal resolution of 135 s. Data analysis revealed sharp changes of the magnetic structure and PVEC associated with the flare onset near the PIL. It was found that the strongest plasma heating and electron acceleration were associated with the largest increase of the magnetic reconnection rate, total PVEC and effective PVEC density in the flare ribbons. Observations and non-linear force-free field (NLFFF) extrapolations have shown that the magnetic field structure around the PIL is consistent with the tether-cutting magnetic reconnection (TCMR) geometry. We gave qualitative interpretation of the observed dynamics of the flare ribbons, magnetic field and PVEC, and electron acceleration, within the TCMR scenario.

Flare Energy Release in the Magnetic Field Polarity Inversion Line During M1.2 Solar Flare of March 15, 2015.
I. Onset of Plasma Heating and Electrons Acceleration

I.N. **Sharykin**, I.V. Zimovets, I.I. Myshyakov, N.S. Meshalkina
2018 *ApJ* **864** 156
https://arxiv.org/pdf/1805.05792.pdf
http://sci-hub.tw/http://iopscience.iop.org/article/10.3847/1538-4357/aada15/meta
We present the study of SOL**2015-03-15** M1.2 flare, revealing acceleration of electrons and plasma heating in the sheared twisted magnetic structure in the polarity inversion line (PIL). The scope is to make the analysis of nonthermal electrons dynamics and plasma heating in the highly stressed magnetic loops interacting in the PIL by using X-ray, microwave, ultraviolet, and optical observations. It is found that the most probable scenario for the energy release in the PIL is the tether-cutting magnetic reconnection between the low-lying (3 Mm above the photosphere) magnetic loops within a twisted magnetic flux rope. Energetic electrons with the hardest spectrum were appeared at the onset of plasma heating up to the super-hot temperature of 40 MK. These electrons are localized in a thin magnetic channel with width of around 0.5 Mm with high average magnetic field of about 1200 G. The plasma beta in the super-hot region is less than 0.01. The estimated density of accelerated electrons is about 10^9 cm^-3 that is much less than the super-hot plasma density. The energy density flux of non-thermal electrons is estimated up to 3x10^12 ergs cm^-2s^-1 that is much higher than in the currently available radiative hydrodynamic models. These results revealed that one need to

develop new self-consisting flare models reproducing 3D magnetic reconnection in the PIL with strong magnetic field, spatial filamentation of energy release, formation of high energy density populations of nonthermal electrons and appearance of the super-hot plasma.

Onset of Photospheric Impacts and Helioseismic Waves in X9.3 Solar Flare of September 6, 2017

Ivan N. **Sharykin**, Alexander G. Kosovichev
ApJ **864(1)** 86 **2018**
https://arxiv.org/pdf/1804.06565.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/aad558/pdf
The X9.3 flare of **September 6, 2017**, was the most powerful flare of Solar Cycle 24. It generated strong white-light emission and multiple helioseismic waves (sunquakes). By using data from Helioseismic and Magnetic Imager (HMI) onboard the Solar Dynamics Observatory (SDO) as well as hard X-ray data from KONUS instrument onboard WIND spacecraft, and Anti-Coincidence System (ACS) onboard the INTERGRAL space observatory, we investigate spatio-temporal dynamics of photospheric emission sources, identify sources of helioseismic waves and compare the flare photospheric dynamics with the hard X-ray (HXR) temporal profiles. The results show that the photospheric flare impacts started to develop in compact regions in close vicinity of the magnetic polarity inversion line (PIL) in the pre-impulsive phase before detection of the HXR emission. The initial photospheric disturbances were localized in the region of strong horizontal magnetic field of the PIL, and, thus, are likely associated with a compact sheared magnetic structure elongated along the PIL. The acoustic egression power maps revealed two primary sources of generation of sunquakes, which were associated with places of the strongest photospheric impacts in the pre-impulsive phase and the early impulsive phase. This can explain the two types of helioseismic waves observed in this flare. Analysis of the high-cadence HMI filtergrams suggests that the flare energy release developed in the form of sequential involvement of compact low-lying magnetic loops that were sheared along the PIL.
HMI Science Nuggets in September **2018** #110 hmi.stanford.edu/hminuggets/?p=2649

Investigation of Relationship Between High-Energy X-ray Sources and Photospheric Impact of X1.8 Solar Flare of October 23, 2012

Ivan N **Sharykin**, Alexander G Kosovichev, Viacheslav M Sadykov, Ivan V Zimovets, Ivan I Myshyakov
2017 *ApJ* **843** 67
https://arxiv.org/pdf/1703.03767.pdf
http://sci-hub.cc/10.3847/1538-4357/aa77f1
The X-class solar flare of **October 23, 2012,** generated continuum photospheric emission and a strong helioseismic wave ("**sunquake**") that points to an intensive energy release in the dense part of the solar atmosphere. We study properties of the energy release with high temporal and spatial resolutions, using photospheric data from Helioseismic Magnetic Imager (HMI) onboard Solar Dynamics Observatory (SDO), and hard X-ray observations made by Ramaty High-Energy Solar Spectroscopic Imager (RHESSI). For this analysis we use level-1 HMI data (filtergrams), obtained by scanning the Fe I line (6731 \AA) with time cadence of$\sim$3.6 s and spatial resolution of $\sim$0.5″ per pixel. It is found that the photospheric disturbances spatially coincide with the region of the hard X-ray emission but are delayed by $\lesssim$4seconds. This delay is consistent with predictions of the RADYN models. However, the models fail to explain the magnitude of the observed variations of the HMI lines. The data indicate that the photospheric impact might be caused by the electron energy flux substantially higher than that in the current flare radiative hydrodynamic models.

Solar flares with similar soft but different hard X-ray emissions: case and statistical studies

Ivan N. **Sharykin**, Alexei B. Struminsky, Ivan V. Zimovets, Wei-Qun Gan
Research in Astronomy and Astrophysics (RAA) Vol 16, No 1 (**2016**) paper 5
From the Reuven Ramaty High Energy Solar Spectroscopic Imager (RHESSI) catalog we select events which have approximately the same GOES class (high C - low M or 500–1200 counts s−1within the RHESSI 6–12 keV energy band), but with different maximal energies of detected hard X-rays. The selected events are subdivided into two groups: (1) flares with X-ray emissions observed by RHESSI up to only 50 keV and (2) flares with hard X-ray emission observed also above 50 keV. The main task is to understand observational peculiarities of these two flare groups. We use RHESSI X-ray data to obtain spectral and spatial information in order to find differences between selected groups. Spectra and images are analyzed in detail for six events (case study). For a larger number of samples (85 and 28 flares in the low-energy and high-energy groups respectively) we only make some generalizations. In spectral analysis we use the thick-target model for hard X-ray emission and one temperature assumption for thermal soft X-ray emission. RHESSI X-ray images are used for determination of flare region sizes. Although thermal and spatial properties of these two groups of flares are not easily distinguishable, power law indices of hard X-rays show significant differences. Events from the high-energy group generally have a harder spectrum. Therefore, the efficiency

of chromospheric evaporation is not sensitive to the hardness of nonthermal electron spectra but rather depends on the total energy flux of nonthermal electrons.

Flare Energy Release in the Lower Solar Atmosphere Near the Magnetic Field Polarity Inversion Line

I.N. **Sharykin**, V.M. Sadykov, A.G. Kosovichev, S. Vargas-Dominguez, I.V. Zimovets
Astrophysical Journal, Volume 840, Issue 2, article id. 84, 13 pp. (**2017**)
https://arxiv.org/abs/1801.04921

We study flare processes in the solar atmosphere using observational data for a M1-class flare of **June 12, 2014**, obtained by New Solar Telescope (NST/BBSO) and Helioseismic Magnetic Imager (HMI/SDO). The main goal is to understand triggers and manifestations of the flare energy release in the photosphere and chromosphere using high-resolution optical observations and magnetic field measurements. We analyze optical images, HMI Dopplergrams and vector magnetograms, and use Non-Linear Force-Free Field (NLFFF) extrapolations for reconstruction of the magnetic topology and electric currents. The NLFFF modelling reveals interaction of two magnetic flux ropes with oppositely directed magnetic field in the PIL. These flux ropes are observed as a compact sheared arcade along the PIL in the high-resolution broad-band continuum images from NST. In the vicinity of PIL, the NST H alpha observations reveal formation of a thin three-ribbon structure corresponding to a small-scale photospheric magnetic arcade. The observational results evidence in favor of location of the primary energy release site in the chromospheric plasma with strong electric currents concentrated near the polarity inversion line. In this case, magnetic reconnection is triggered by the interacting magnetic flux ropes forming a current sheet elongated along the PIL.

Observational Investigation of Energy Release in the Lower Solar Atmosphere of a Solar Flare

I. N. **Sharykin**, V. M. Sadykov, A. G. Kosovichev, S. Vargas-Dominguez, I. V. Zimovets
2017 ApJ 840 84
http://arxiv.org/pdf/1604.05380v1.pdf

We study flare processes in the lower solar atmosphere using observational data for a M1-class flare of **June 12, 2014**, obtained by New Solar Telescope (NST/BBSO) and Helioseismic Magnetic Imager (HMI/SDO). The main goal is to understand triggers and manifestations of the flare energy release in the lower layers of the solar atmosphere (the photosphere and chromosphere) using high-resolution optical observations and magnetic field measurements. We analyze optical images, HMI Dopplergrams and vector magnetograms, and use Non-Linear Force-Free Field (NLFFF) extrapolations for reconstruction of the magnetic topology. The NLFFF modelling reveals interaction of oppositely directed magnetic flux-tubes in the PIL. These two interacting magnetic flux tubes are observed as a compact sheared arcade along the PIL in the high-resolution broad-band continuum images from NST. In the vicinity of the PIL, the NST H alpha observations reveal formation of a thin three-ribbon structure corresponding to the small-scale photospheric magnetic arcade. Presented observational results evidence in favor of location of the primary energy release site in the dense chromosphere where plasma is partially ionized in the region of strong electric currents concentrated near the polarity inversion line. Magnetic reconnection may be triggered by two interacting magnetic flux tubes with forming current sheet elongated along the PIL.

Energy Release and Initiation of a Sunquake in a C-class Flare

I. N. **Sharykin**1,2, A. G. Kosovichev1,3,4, and I. V. Zimovets
2015 ApJ 807 102
http://arxiv.org/pdf/1405.5912v1.pdf
http://sci-hub.cc/10.3847/1538-4357/aa6dfd

We present an analysis of the C7.0 solar flare from **2013 February 17**, revealing a strong helioseismic response (sunquake) caused by a compact impact observed with the Helioseismic and Magnetic Imager on board the Solar Dynamics Observatory (SDO) in the low atmosphere. This is the weakest known C-class flare generating a sunquake event. To investigate the possible mechanisms of this event and understand the role of accelerated charged particles and photospheric electric currents, we use data from three space observatories: RHESSI, SDO, and Geostationary Operational Environmental Satellite. We find that the photospheric flare impact does not spatially correspond to the strongest hard X-ray emission source, but both of these events are parts of the same energy release. Our analysis reveals a close association of the flare energy release with a rapid increase in the electric currents and suggests that the sunquake initiation is unlikely to be caused by the impact of high-energy electrons, but may be associated with rapid current dissipation or a localized impulsive Lorentz force in the lower layers of the solar atmosphere.

Dynamics of Electric Currents, Magnetic Field Topology and Helioseismic Response of a Solar Flare

I. N. **Sharykin**, A. G. Kosovichev

2015 *ApJ* **808** 72

http://arxiv.org/pdf/1502.05190v1.pdf

The solar flare on **July 30, 2011** was of a modest X-ray class (M9.3), but it made a strong photospheric impact and produced a "sunquake," observed with the Helioseismic and Magnetic Imager (HMI) on NASA's Solar Dynamics Observatory (SDO). In addition to the helioseismic waves (also observed with the SDO/AIA instrument), the flare caused a large expanding area of white-light emission and was accompanied by substantial restructuring of magnetic fields, leading to the rapid formation of a sunspot structure in the flare region. The flare produced no significant hard X-ray emission and no coronal mass ejection. This indicates that the flare energy release was mostly confined to the lower atmosphere. The absence of significant coronal mass ejection rules out magnetic rope eruption as a mechanism of helioseismic waves. We discuss the connectivity of the flare energy release with the electric currents dynamics and show the potential importance of high-speed plasma flows in the lower solar atmosphere during the flare energy release.

Plasma Heating to Super-Hot Temperatures (>30 MK) in the August 9, 2011 Solar Flare

I.N. **Sharykin**, A.B. Struminsky, I.V. Zimovets

Astronomy Letters Volume 41, Issue 1-2, pp 53-66 **2015**

Pis'ma v Astronomicheskiĭ Zhurnal, **2015**, Vol. 41, Nos. 1–2, pp. 57–71.

http://arxiv.org/pdf/1502.03220v1.pdf

We investigate the August 9, 2011 solar flare of X-ray class X6.9, the "hottest" flare from 2000 to 2012, with a peak plasma temperature according to GOES data of 32.5 MK. Our goal is to determine the cause of such an anomalously high plasma temperature and to investigate the energy balance in the flare region with allowance made for the presence of a super-hot plasma (>30 MK). We analyze the RHESSI, GOES, AIA/SDO, and EVE/SDO data and discuss the spatial structure of the flare region and the results of our spectral analysis of its X-ray emission. Our analysis of the RHESSI X-ray spectra is performed in the one-temperature and two-temperature approximations by taking into account the emission of hot (20 MK) and super-hot (45 MK) plasmas. The hard X-ray spectrum in both models is fitted by power laws. The observed peculiarities of the flare are shown to be better explained in terms of the two-temperature model, in which the super-hot plasma is located at the flare loop tops (or in the magnetic cusp region). The formation of the super-hot plasma can be associated with its heating through primary energy release and with the suppression of thermal conduction. The anomalously high temperature (32.5 MK according to GOES) is most likely to be an artefact of the method for calculating the temperature based on two-channel GOES measurements in the one-temperature approximation applied to the emission of a multi-temperature flare plasma with a minor contribution from the low-temperature part of the differential emission measure.

August 9, 2011 (X6.9) and July 23, 2002

Onset of Electron Acceleration in a Flare Loop

I.N. **Sharykin**, S. Liu, L. Fletcher

2014 ApJ 793 25.

http://arxiv.org/pdf/1408.1413v1.pdf

We carried out detailed analysis of X-ray and radio observations of a simple flare loop that occurred on **12th August 2002**, with the impulsive hard X-ray (HXR) light curves dominated by a single pulse. The emission spectra of the early impulsive phase are consistent with an isothermal model in the coronal loop with a temperature reaching several keVs. A power-law high-energy spectral tail is evident near the HXR peak time, in accordance with the appearance of footpoints at high energies, and is well correlated with the radio emission. The energy content of the thermal component keeps increasing gradually after the disappearance of this nonthermal component. These results suggest that electron acceleration only covers a central period of a longer and more gradual energy dissipation process and that the electron transport within the loop plays a crucial role in the formation of the inferred power-law electron distribution. The spectral index of power-law photons shows a very gradual evolution indicating a quasi-steady state of the electron accelerator, which is confirmed by radio observations. These results are consistent with the theory of stochastic electron acceleration from a thermal background. Advanced modeling with coupled electron acceleration and spatial transport processes is needed to explain these observations more quantitatively, which may reveal the dependence of the electron acceleration on the spatial structure of the acceleration region.

Energy Release and Initiation of Sunquake in C-class Flare

I.N. **Sharykin**, A.G. Kosovichev, I.V. Zimovets

2014

http://arxiv.org/pdf/1405.5912v1.pdf

We present analysis of a C-class solar flare of **Febrary 17, 2013**, revealing a strong helioseismic response caused by a very compact impact in the photosphere. This is the first detection of sunquake in C-class flares. To investigate possible mechanisms of generation of this sunquake, and to understand the role of accelerated charged particles and photospheric electric currents, we use data from three space observatories: Ramaty High Energy Solar Spectroscopic Imager (RHESSI), Solar Dynamics Observatory (SDO) and Geostationary Operational Environmental Satellite (GOES). We find that the sunquake impulse does not spatially correspond to the HXR emission source, but both of these events are parts of the same energy release. Our analysis reveals a close association of the flare energy release with a rapid increase of the electric currents, and suggests that the sunquake initiation can be explained by a rapid current dissipation or by a localized impulsive Lorentz force.

Fine structure of flare ribbons and evolution of electric currents

I.N. **Sharykin**, A.G. Kosovichev
2014 ApJ 788 L18
http://arxiv.org/pdf/1404.5104v1.pdf
Emission of solar flares across the electromagnetic spectrum is often observed in the form of two expanding ribbons. The standard flare model explains the flare ribbons as footpoints of magnetic arcades, emitting due to interaction of energetic particles with the chromospheric plasma. However, the physics of this interaction and properties of the accelerated particles are still unknown. We present results of multiwavelength observations of C2.1 flare of **August 15, 2013**, observed with New Solar Telescope (NST) of Big Bear Solar Observatory, Solar Dynamics Observatory (SDO), GOES and FERMI spacecraft. The observations reveal previously unresolved sub-arcsecond structure of the flare ribbons in regions of strong magnetic field consisting from numerous small-scale bright knots. We observe red-blue asymmetry of H α flare ribbons with a width as small as 100 km. We discuss the relationship between the ribbons and vertical electric currents estimated from vector magnetograms, and show that Joule heating can be responsible for energization of H α knots in the ribbons.

Simulation Models for Exploring Magnetic Reconnection **Review**

Michael **Shay**, Subash Adhikari, Naoki Beesho, Joachim Birn, +++
Chapter 5.2 of ISSI Book on Magnetic Reconnection, Space Science Reviews **2024**
https://arxiv.org/pdf/2406.05901
Simulations have played a critical role in the advancement of our knowledge of magnetic reconnection. However, due to the inherently multiscale nature of reconnection, it is impossible to simulate all physics at all scales. For this reason, a wide range of simulation methods have been crafted to study particular aspects and consequences of magnetic reconnection. This chapter reviews many of these methods, laying out critical assumptions, numerical techniques, and giving examples of scientific results. Plasma models described include magnetohydrodynamics (MHD), Hall MHD, Hybrid, kinetic particle-in-cell (PIC), kinetic Vlasov, Fluid models with embedded PIC, Fluid models with direct feedback from energetic populations, and the Rice Convection Model (RCM).

Atmospheric Response to of an Active Region to new Small Flux Emergence

D.L. **Shelton**, L.K. Harra, L.M. Green
Solar Phys. Volume 290, Issue 3, pp 753-770 **2015**
http://arxiv.org/pdf/1412.5623v1.pdf
We investigate the atmospheric response to a small emerging flux region (EFR) that occurred in the positive polarity of Active Region 11236 on **23-24 June 2011**. Data from the \textit{Solar Dynamics Observatory's Atmopheric Imaging Assembly} (AIA), the \textit{Helioseismic and Magnetic Imager} (HMI) and Hinode's \textit{EUV imaging spectrometer} (EIS) are used to determine the atmospheric response to new flux emerging into a pre-existing active region.
Brightenings are seen forming in the upper photosphere, chromosphere, and corona over the EFR's location whilst flux cancellation is observed in the photosphere. The impact of the flux emergence is far reaching, with new large-scale coronal loops forming up to 43 Mm from the EFR and coronal upflow enhancements of approximately 10 km s−1 on the north side of the EFR. Jets are seen forming in the chromosphere and the corona over the emerging serpentine field. This is the first time that coronal jets have been seen over the serpentine field.

Flows and magnetic field structures in reconnection regions of simulations of the solar atmosphere: do flux pile-up models work?

S. **Shelyag**, Y. E. Litvinenko, V. Fedun, G. Verth, J.J. González-Avilés, F.S. Guzmán
A&A **2018**
https://arxiv.org/pdf/1809.00587.pdf
We study the process of magnetic field annihilation and reconnection in simulations of magnetised solar photosphere and chromosphere with magnetic fields of opposite polarities and constant numerical resistivity. Exact analytical

solutions for reconnective annihilations are used to interpret the features of magnetic reconnection in simulations of flux cancellation in the solar atmosphere. We use MURaM high-resolution photospheric radiative magneto-convection simulations to demonstrate the presence of magnetic field reconnection consistent with the magnetic flux pile-up models. Also, a simulated data-driven chromospheric magneto-hydrodynamic simulation is used to demonstrate magnetic field and flow structures, which are similar to the ones theoretically predicted. Both simulations demonstrate flow and magnetic field structures roughly consistent with accelerated reconnection with magnetic flux pile-up. The presence of standard Sweet-Parker type reconnection is also demonstrated in stronger photospheric magnetic fields.

Energy-releasing Process for the 2013 May 13 X1.7 Limb Flare: A Continued Study

Jinhua **Shen**1,2, Jianping Li3, Yu Huang3, Dong Li3, Yingna Su3, and Haisheng Ji3
2023 ApJ 950 71
https://iopscience.iop.org/article/10.3847/1538-4357/accc8c/pdf
In this paper, we reanalyze the X1.7 class limb flare that occurred on **2013 May 13** (SOL2013-05-13T01:56 UT), concentrating on the energy-releasing process using microwave observations mainly made by Nobeyama and X-ray observations made by RHESSI. The analysis was carried out in the context of EUV observations made by the Atmospheric Imaging Assembly on board Solar Dynamics Observatory. First, we complement the initiation process by showing that the initiation occurred together with material falling from a large-scale overlying prominence, a signature of drainage instability. The usual downward and upward motions of the microwave and X-ray sources are observed from their evolution. However, the microwave source's height shows a recurrent decrease and increase during its overall upward motion; it shows a kind of recurrent contraction and expansion. The time period of the recurrent contraction and expansion corresponds to the period of post-contraction oscillation of EUV loops, and the oscillatory motions are closely correlated with four microwave/hard X-ray peaks that unusually increased nonthermal emission levels by several times. X-ray spectra get hardened during the oscillation. In addition, the rapid contraction of magnetic loops located on the outside of the erupting flux rope occurs 5 minutes after the onset of the flare, showing that the contraction of the peripheral magnetic loops is more likely due to the vortex and sink flows generated by an upward erupting magnetic flux rope rather than a coronal implosion. The results can provide more insight into the physics of dynamic coronal magnetic field and particle acceleration during solar flares.

Non-thermal Broadening of IRIS Fe XXI Lines Caused by Turbulent Plasma Flows in the Magnetic Reconnection Region During Solar Eruptions

Chengcai **Shen**, Vanessa Polito, Katharine K. Reeves, Bin Chen, Sijie Yu, Xiaoyan Xie
2022
https://arxiv.org/pdf/2211.07428.pdf
Magnetic reconnection is the key mechanism for energy release in solar eruptions, where the high-temperature emission is the primary diagnostic for investigating the plasma properties during the reconnection process. Non-thermal broadening of high-temperature lines has been observed in both the reconnection current sheet (CS) and flare loop-top regions by UV spectrometers, but its origin remains unclear. In this work, we use a recently developed three-dimensional magnetohydrodynamic (MHD) simulation to model magnetic reconnection in the standard solar flare geometry and reveal highly dynamic plasma flows in the reconnection regions. We calculate the synthetic profiles of the Fe XXI 1354 Å~line observed by the Interface Region Imaging Spectrograph (IRIS) spacecraft by using parameters of the MHD model, including plasma density, temperature, and velocity. Our model shows that the turbulent bulk plasma flows in the CS and flare loop-top regions are responsible for the non-thermal broadening of the Fe XXI emission line. The modeled non-thermal velocity ranges from tens of km s−1 to more than two hundred km s−1, which is consistent with the IRIS observations. Simulated 2D spectral line maps around the reconnection region also reveal highly dynamic downwflow structures where the high non-thermal velocity is large, which is consistent with the observations as well. **2015-03-07-08**

Coronal Quasi-periodic Fast-mode Propagating Wave Trains **Review**

Yuandeng **Shen**, Xinping Zhou, Yadan Duan, Zehao Tang, Chengrui Zhou, Song Tan
Solar Phys. **2022**
https://arxiv.org/pdf/2112.14959.pdf **File**
QFP wave trains in the corona have been studied intensively in the past decade, thanks to the full-disk, high spatiotemporal resolution, and wide-temperature coverage observations taken by the SDO/AIA. In AIA observations, QFP wave trains are seen to consist of multiple coherent and concentric wavefronts emanating successively near the epicenter of the accompanying flares; they propagate outwardly either along or across coronal loops at fast-mode magnetosonic speeds from several hundred to more than 2000 km/s, and their periods are in the range of tens of seconds to several minutes. Based on the distinct different properties of QFP wave trains, they might be divided into two distinct categories including narrow and broad ones. For most QFP wave trains, some of their periods are similar to those of quasi-periodic pulsations (QPPs) in the accompanying flares, indicating that they are probably different manifestations of the same physical process. Currently, candidate generation mechanisms for QFP wave trains include two main categories: pulsed energy excitation mechanism in association with magnetic reconnection and dispersion evolution

mechanism related to the dispersive evolution of impulsively generated broadband perturbations. In addition, the generation of some QFP wave trains might be driven by the leakage of three and five minute oscillations from the lower atmosphere. As one of the new discoveries of SDO, QFP wave trains provide a new tool for coronal seismology to probe the corona parameters, and they are also useful for diagnosing the generation of QPPs, flare processes including energy release and particle accelerations. This review aims to summarize the main observational and theoretical results of the spatially-resolved QFP wave trains in extreme ultraviolet observations, and states briefly a number of questions that deserve further investigations. **2010 September 08, 2011 February 14, 2011 May 30, 2012 April 24, 2013 May 22, 2014 November 03, 2015 April 16**

Table 1. Physical parameters of the published QFP wave trains

The Origin of Underdense Plasma Downflows Associated with Magnetic Reconnection in Solar Flares

Chengcai **Shen**, Bin Chen, Katharine K. Reeves, Sijie Yu, Vanessa Polito, Xiaoyan Xie

Nature Astronomy **volume 6**, pages1–2 (**2022**)

https://arxiv.org/pdf/2111.11407.pdf

https://doi.org/10.1038/s41550-021-01570-2

Magnetic reconnection is a universal process that powers explosive energy release events such as solar flares, geomagnetic substorms, and some astrophysical jets. A characteristic feature of magnetic reconnection is the production of fast reconnection outflow jets near the plasma Alfvén speeds. In eruptive solar flares, dark, finger-shaped plasma downflows moving toward the flare arcade have been commonly regarded as the principal observational evidence for such reconnection-driven outflows. However, they often show a speed much slower than that expected in reconnection theories, challenging the reconnection-driven energy release scenario in standard flare models. Here, we present a three-dimensional magnetohydrodynamics model of solar flares. By comparing the model-predictions with the observed plasma downflow features, we conclude that these dark downflows are self-organized structures formed in a turbulent interface region below the flare termination shock where the outflows meet the flare arcade, a phenomenon analogous to the formation of similar structures in supernova remnants. This interface region hosts a myriad of turbulent flows, electron currents, and shocks, crucial for flare energy release and particle acceleration. **2015 June 28**

Round-Trip Slipping Magnetic Reconnection Observed in a Fan-Spine Jet

Yuandeng **Shen**, Zhining Qu, Chengrui Zhou, Yadan Duan, Zehao Tang, Ding Yuan

ApJL **885** L11 **2019**

https://arxiv.org/pdf/1910.05472.pdf

https://iopscience.iop.org/article/10.3847/2041-8213/ab4cf3/pdf

A solar jet on **2014 July 31**, which was accompanied by a GOES C1.3 flare and a mini-filament eruption at the jet base, was studied by using observations taken by the New Vacuum Solar Telescope and the Solar Dynamic Observatory. Magnetic field extrapolation revealed that the jet was confined in a fan-spine magnetic system that hosts a null point at the height of about 9 Mm from the solar surface. An inner flare ribbon surrounded by an outer circular ribbon and a remote ribbon were observed to be associated with the eruption, in which the inner and remote ribbons respectively located at the footprints of the inner and outer spines, while the circular one manifested the footprint of the fan structure. It is interesting that the circular ribbon's west part showed an interesting round-trip slipping motion, while the inner ribbon and the circular ribbon's east part displayed a northward slipping motion. Our analysis results indicate that the slipping motions of the inner and the circular flare ribbons reflected the slipping magnetic reconnection process in the fan quasi-separatrix layer, while the remote ribbon was associated with the magnetic reconnection at the null point. In addition, the filament eruption was probably triggered by the magnetic cancellation around its south end, which further drove the slipping reconnection in the fan quasi-separatrix layer and the reconnection at the null point.

The Dynamical Behavior of Reconnection-driven Termination Shocks in Solar Flares: Magnetohydrodynamic Simulations

Chengcai **Shen**, Xiangliang Kong, Fan Guo, John C. Raymond, Bin Chen

ApJ **869** 116 **2018**

https://arxiv.org/pdf/1812.01189.pdf

sci-hub.tw/10.3847/1538-4357/aaeed3

In eruptive solar flares, termination shocks (TSs), formed when high-speed reconnection outflows collide with closed dense flaring loops, are believed to be one of the possible candidates for plasma heating and particle acceleration. In this work, we perform resistive magnetohydrodynamic simulations in a classic Kopp-Pneuman flare configuration to study the formation and evolution of TSs, and analyze in detail the dynamic features of TSs and variations of the shock strength in space and time. This research focuses on the fast reconnection phase when plasmoids form and produce small-scale structures inside the flare current sheet. It is found that the TS emerges once the downward outflow colliding with closed magnetic loops becomes super-magnetosonic, and immediately becomes highly dynamical. The morphology of a TS can be flat, oblique, or curved depending on the detailed interactions between the outflows/plasmoids and the highly dynamic plasma in the looptop region. The TS becomes weaker when a plasmoid is

crossing through, or may even be destroyed by well developed plasmoids and then re-constructed above the plasmoids. We also perform detailed statistical analysis on important physical quantities along and across the shock front. The density and temperature ratios range from 1 to 3 across the TS front, and the pressure ratio typically has larger values up to 10. We show that weak guide fields do not strongly affect the Mach number and compression ratios, and the TS length becomes slightly larger in the case with thermal conduction.

INITIATION PROCESSES FOR THE 2013 MAY 13 X1.7 LIMB FLARE

Jinhua **Shen**1,2, Ya Wang3,4, Tuanhui Zhou3,5, and Haisheng Ji3,5
2017 ApJ 835 43
http://iopscience.iop.org.sci-hub.cc/0004-637X/835/1/43/
For the X1.7 class flare on **2013 May 13** (SOL2013-05-13T01:53), its initiation process was well observed by the Atmospheric Imaging Assembly (AIA) on board the Solar Dynamic Observatory and the Extreme UltraViolet Imager (EUVI) on board STEREO-B . The initiation process incorporates the following phenomena: an X-ray precursor that started ~9 minutes before flare onset, two hot magnetic loops (as seen with AIA hot channels) forming a sigmoidal core magnetic structure (as seen with the EUVI), a rapidly formed magnetic flux rope (MFR) that expands outward, and a flare loop that contracts inward. The two hot magnetic loops were activated after the occurrence of the X-ray precursor. After activation, magnetic reconnection occurred between the two hot magnetic loops (inside the sigmoid structure), which produced the expanding MFR and the contracting flare loop (CFL). The MFR and CFL can only be seen with AIA hot and cool channels, respectively. For this flare, the real initiation time can be regarded as being from the starting time of the precursor, and its impulsive phase started when the MFR began its fast expansion. In addition, the CFL and the growing postflare magnetic loops are different loop systems, and the CFL was the product of magnetic reconnection between sheared magnetic fields that also produced the MFR.

Well-observed Dynamics of Flaring and Peripheral Coronal Magnetic Loops during an M-class Limb Flare

Jinhua **Shen**1, Tuanhui Zhou2,3, Haisheng Ji2,3, Thomas Wiegelmann4, Bernd Inhester4, and Li Feng
2014 ApJ 791 83
In this paper, we present a variety of well-observed dynamic behaviors for the flaring and peripheral magnetic loops of the M6.6 class extreme limb flare that occurred on **2011 February 24** (SOL2011-02-24T07:20) from EUV observations by the Atmospheric Imaging Assembly on the Solar Dynamics Observatory and X-ray observations by RHESSI. The flaring loop motion confirms the earlier contraction-expansion picture. We find that the U-shaped trajectory delineated by the X-ray corona source of the flare roughly follows the direction of a filament eruption associated with the flare. Different temperature structures of the coronal source during the contraction and expansion phases strongly suggest different kinds of magnetic reconnection processes. For some peripheral loops, we discover that their dynamics are closely correlated with the filament eruption. During the slow rising to abrupt, fast rising of the filament, overlying peripheral magnetic loops display different responses. Two magnetic loops on the elbow of the active region had a slow descending motion followed by an abrupt successive fast contraction, while magnetic loops on the top of the filament were pushed outward, slowly being inflated for a while and then erupting as a moving front. We show that the filament activation and eruption play a dominant role in determining the dynamics of the overlying peripheral coronal magnetic loops.

OBSERVATIONAL STUDY OF THE QUASI-PERIODIC FAST-PROPAGATING MAGNETOSONIC WAVES AND THE ASSOCIATED FLARE ON 2011 MAY 30

Yuandeng **Shen**1,2 and Yu Liu
2012 ApJ 753 53
https://iopscience.iop.org/article/10.1088/0004-637X/753/1/53/pdf
On **2011 May 30**, quasi-periodic fast-propagating (QFP) magnetosonic waves accompanied by a C2.8 flare were directly imaged by the Atmospheric Imaging Assembly instrument on board the Solar Dynamics Observatory. The QFP waves successively emanated from the flare kernel, they propagated along a cluster of open coronal loops with a phase speed of ~834 km s–1 during the flare's rising phase, and the multiple arc-shaped wave trains can be fitted with a series of concentric circles. We generate the k - ω diagram of the Fourier power and find a straight ridge that represents the dispersion relation of the waves. Along the ridge, we find a lot of prominent nodes which represent the available frequencies of the QFP waves. On the other hand, the frequencies of the flare are also obtained by analyzing the flare light curves using the wavelet technique. The results indicate that almost all the main frequencies of the flare are consistent with those of the QFP waves. This suggests that the flare and the QFP waves were possibly excited by a common physical origin. On the other hand, a few low frequencies (e.g., 2.5 mHz (400 s) and 0.7 mHz (1428 s)) revealed by the k - ω diagram cannot be found in the accompanying flare. We propose that these low frequencies were

possibly due to the leakage of the pressure-driven p-mode oscillations from the photosphere into the low corona, which should be a noticeable mechanism for driving the QFP waves observed in the corona.

NUMERICAL EXPERIMENTS ON FINE STRUCTURE WITHIN RECONNECTING CURRENT SHEETS IN SOLAR FLARES

Chengcai **Shen**1,2, Jun Lin1,3 and Nicholas A. Murphy
2011 ApJ 737 14

We perform resistive magnetohydrodynamic simulations to study the internal structure of current sheets that form during solar eruptions. The simulations start with a vertical current sheet in mechanical and thermal equilibrium that separates two regions of the magnetic field with opposite polarity which are line-tied at the lower boundary representing the photosphere. Reconnection commences gradually due to an initially imposed perturbation, but becomes faster when plasmoids form and produce small-scale structures inside the current sheet. These structures include magnetic islands or plasma blobs flowing in both directions along the sheet, and X-points between pairs of adjacent islands. Among these X-points, a principal one exists at which the reconnection rate reaches maximum. A fluid stagnation point (S-point) in the sheet appeared where the reconnection outflow bifurcates. The S-point and the principal X-point (PX-point) are not co-located in space though they are very close to one another. Their relative positions alternate as reconnection progresses and determine the direction of motion of individual magnetic islands. Newly formed islands move upward if the S-point is located above the PX-point, and downward if the S-point is below the PX-point. Merging of magnetic islands was observed occasionally between islands moving in the same direction. Reconnected plasma flow was observed to move faster than blobs nearby.

KINEMATICS AND FINE STRUCTURE OF AN UNWINDING POLAR JET OBSERVED BY THE SOLAR DYNAMIC OBSERVATORY/ATMOSPHERIC IMAGING ASSEMBLY

Yuandeng **Shen**1,2,3, Yu Liu1,3, Jiangtao Su3,4 and Ahmed Ibrahim
2011 ApJ 735 L43

We present an observational study of the kinematics and fine structure of an unwinding polar jet, with high temporal and spatial observations taken by the Atmospheric Imaging Assembly on board the Solar Dynamic Observatory and the Solar Magnetic Activity Research Telescope. During the rising period, the shape of the jet resembled a cylinder with helical structures on the surface, while the mass of the jet was mainly distributed on the cylinder's shell. In the radial direction, the jet expanded successively at its western side and underwent three distinct phases: the gradually expanding phase, the fast expanding phase, and the steady phase. Each phase lasted for about 12 minutes. The angular speed of the unwinding motion of the jet and the twist transferred into the outer corona during the eruption are estimated to be 11.1 × 10–3 rad s–1 (period = 564 s) and 1.17-2.55 turns (or 2.34-5.1π), respectively. On the other hand, by calculating the azimuthal component of the magnetic field in the jet and comparing the free energy stored in the non-potential magnetic field with the jet's total energy, we find that the non-potential magnetic field in the jet is enough to supply the energy for the ejection. These new observational results strongly support the scenario that the jets are driven by the magnetic twist, which is stored in the twisted closed field of a small bipole, and released through magnetic reconnection between the bipole and its ambient open field.

EARLY ABNORMAL TEMPERATURE STRUCTURE OF X-RAY LOOP-TOP SOURCE OF SOLAR FLARES

Jinhua **Shen**,1,2 Tuanhui Zhou,2 Haisheng Ji,2,3 Na Wang,1 Wenda Cao,3 and Haimin Wang3
Astrophysical Journal, 686: L37–L40, **2008** October
http://www.journals.uchicago.edu/doi/pdf/10.1086/592835

This Letter is to investigate the physics of a newly discovered phenomenon—contracting flare loops in the early phase of solar flares. In classical flare models, which were constructed based on the phenomenon of the expansion of flare loops, an energy releasing site is put above flare loops. These models can predict that there is a vertical temperature gradient in the top of flare loops due to heat conduction and cooling effects. Therefore, the centroid of an X-ray loop-top source at higher energy bands will be higher in altitude, which we can define as the normal temperature distribution. With observations made by *RHESSI*, we analyzed 10 M- or X-class flares (9 limb flares). For all these flares, the movement of loop-top sources shows an obvious U-shaped trajectory, which we take as the signature of contraction-to-expansion of flare loops. We find that, for all these flares, a normal temperature distribution does exist, but only along the path of expansion. The temperature distribution along the path of contraction is abnormal, showing no spatial order at all. The result suggests that magnetic reconnection processes in the contraction and expansion phases of these solar flares are different.

Categorization model of moving small-scale intensity enhancements in solar active regions

B.M. **Shergelashvili**, E. Philishvili, S. Buitendag, S. Poedts, M. Khodachenko
A&A **2022**
https://arxiv.org/pdf/2203.06285.pdf
The small-scale moving intensity enhancements remotely observed in the extreme ultraviolet images of the solar active regions, which we refer to as active region moving campfires (ARMCs), are related to local plasma temperature and/or density enhancements. Their dynamics is driven by the physical processes in the entire coronal plasma. Our previous study of ARMCs indicates that they have characteristic velocities at around the background sound speed. The main goal of our work is to carry out a simultaneous analysis of EUV images from two observational missions, SDO/AIA and Hi-C 2.1. The aims of the performed cross-validating analysis of both SDO/AIA and Hi-C 2.1 data were to reveal how the observed moving features are distributed over the studied active region, **AR12712**, test the existence of different groups of ARMCs with distinct physical characteristics. We use the statistical model of intensity centroid convergence and tracking that was developed in our previous paper. Furthermore, a Gaussian mixture model fit of the observed complex of moving ARMCs is elaborated to reveal the existence of distinct ARMC groups and to study the physical characteristics of these different groups. In data from the 171Å, 193Å and 211Å channels of SDO/AIA, we identified several groups of ARMCs with respect to both blob intensity and velocity profiles. The existence of such groups is confirmed by the cross-validation of the 172Å data sets from Hi-C 2.1. The ARMCs studied in this paper have characteristic velocities in the range of the typical sound speeds in coronal loops. Hence, these moving objects differ from the well-known rapid Alfvénic velocity jets from magnetic reconnection sites. This is also proven by the fact that ARMCs propagate along the active region magnetic structure (strands). The nature of the discovered statistical grouping of the ARMC events is not known. **29 May 2018**

Extreme Ultraviolet Spectra of Solar Flares from the Extreme Ultraviolet Spectroheliograph SPIRIT Onboard the CORONAS-F Satellite

S. **Shestov**, A. Reva1, and S. Kuzin
2014 ApJ 780 15
http://arxiv.org/pdf/1510.03652v1.pdf
We present detailed extreme ultraviolet (EUV) spectra of four large solar flares: M5.6, X1.3, X3.4, and X17 classes in the spectral ranges 176-207 Å and 280-330 Å. These spectra were obtained by the slitless spectroheliograph SPIRIT onboard the CORONAS-F satellite. To our knowledge, these are the first detailed EUV spectra of large flares obtained with a spectral resolution of ~0.1 Å. We performed a comprehensive analysis of the obtained spectra and provide identification of the observed spectral lines. The identification was performed based on the calculation of synthetic spectra (the CHIANTI database was used), with simultaneous calculations of the differential emission measure (DEM) and density of the emitting plasma. More than 50 intense lines are present in the spectra that correspond to a temperature range of T = 0.5-16 MK; most of the lines belong to Fe, Ni, Ca, Mg, and Si ions. In all the considered flares, intense hot lines from Ca XVII, Ca XVIII, Fe XX, Fe XXII, and Fe XXIV are observed. The calculated DEMs have a peak at T ~ 10 MK. The densities were determined using Fe XI-Fe XIII lines and averaged 6.5 × 109 cm–3. We also discuss the identification, accuracy, and major discrepancies of the spectral line intensity prediction.

Asymmetric Hard X-ray Radiation of Two Ribbons in a Thermal-Dominated C-Class Flare

Guanglu **Shi**, Li Feng, Jun Chen, Beili Ying, Shuting Li, Qiao Li, Hui Li, Ying Li, Kaifan Ji, Yu Huang, Weiqun Gan, the LST team
Solar Phys. **299**, 104 **2024**
https://arxiv.org/pdf/2407.13099
https://doi.org/10.1007/s11207-024-02349-0
The asymmetry in hard X-ray (HXR) emission at the footpoints (FPs) of flare loops is a ubiquitous feature closely associated with nonthermal electron transport. We analyze the asymmetric HXR radiation at two flare ribbons which is thermal-dominated during a long-duration C4.4 flare that occurred on **March 20, 2023**, combining multi-view and multi-waveband observations from the ASO-S, SolO, and SDO spacecraft. We find that the H I Lyα emission captures similar features to the He II λ304 in both light curve and spatio-temporal evolution of a pair of conjugate flare ribbons. The spectra and imaging analysis of the HXR emission, detected by STIX in 4-18 keV, reveal that the two-ribbon flare radiation is thermal dominated by over 95%, and the radiation source mainly concentrates on the northern ribbon, leading to an asymmetric distribution. To understand the underlying reasons for the HXR radiation asymmetry, we extrapolate the magnetic field within the active region using the NLFFF model. For 78% of the magnetic field lines starting from the northern flare ribbon, their lengths from the loop-tops (LTs) to the northern FPs are shorter than those to the southern FPs. For 62% of the field lines, their magnetic field strengths at the southern FPs exceed those at the northern FPs. In addition, considering the larger density, ≈1.0×1010 cm−3, of the low-lying flare loops (< 32 Mm), we find the shorter path from the LT to the northern FP enables more electrons to reach the northern FP more easily after collisions with the surrounding plasma. Therefore, in this thermal-dominated C-class flare, the asymmetric location of the flare LT relative to its two FPs plays a dominant role in the HXR radiation asymmetry, while such asymmetry is

also slightly influenced by the magnetic mirror effect resulting in larger HXR radiation at the FPs with weaker magnetic strength.

Multiwavelength Observations of Quasiperiodic Pulsations in the Impulsive Phase of an Eruptive Flare with the Hard X-Ray Imager On Board ASO-S and Other Instruments.

Shi, F., Li, D., Ning, Z. et al.
Sol Phys 299, 30 (**2024**).
https://doi.org/10.1007/s11207-024-02272-4
We investigated the quasiperiodic pulsations (QPPs) of the X1.2 solar flare (SOL**2023-01-06**T00:57) based on multi-instrument observations, especially the Hard X-ray Imager (HXI) on board the Advanced Space-based Solar Observatory (ASO-S). The quasiperiod of ≈27 s was identified in hard X-rays (HXR) and microwaves using the Markov Chain Monte Carlo method, while no corresponding oscillation was found in soft X-rays. The HXI imaging demonstrates that HXR pulsations arise from the double-footpoint HXR sources. Moreover, the fluctuation of ≈27 s period was also present in the nonthermal electron power-law index derived from the X-ray spectra, which is the signature of periodic electron acceleration/precipitation during the impulsive phase. The electron spectral indices not only exhibited the well-known “soft–hard–soft” evolution, but also showed the negative correlation with the HXR pulsations. These results suggest that QPPs directly originate from quasiperiodic injections of accelerated electrons into flare-loop footpoints. We also discuss the possible generation mechanisms for QPPs.

Are Quasi-periodic Pulsations Independent of Loop Oscillations in Solar Flare?

Fanpeng **Shi** (**史帆鹏**)1,2, Dong Li (**李**东)1,2, Zongjun Ning (**宁宗**军)1,2, Yangfan Guo (**郭**杨帆)3, Song Feng (冯松)4, and Jun Xu (**徐俊**)1,2
2023 ApJ 958 39
https://iopscience.iop.org/article/10.3847/1538-4357/acf7c2/pdf
We investigated oscillations in an M8.7 solar flare (SOL**2014-10-22**), including quasi-periodic pulsations (QPPs) in light curves and Doppler shift oscillations in the flare loops. Using Bayesian-based Markov Chain Monte Carlo, Fast Fourier Transform, and wavelet analysis method, QPPs were identified at microwave and hard X-ray wave bands during the impulsive phase, and the dominant period is 40–50 s. They should be associated with a repetitive energy release process, which accelerates nonthermal electrons periodically. On the other hand, we cannot rule out the possibility of the modulation of external waves because of the lower temporal resolution of spectroscopic observation. However, almost immediately after QPPs, a minority of flare loops display their Doppler velocity oscillations with a significant period of ∼4 minutes, which are observed by the Interface Region Imaging Spectrograph at the coronal line Fe xxi 1354.08 Å (T ∼ 107 K), while its intensity and width show no similar oscillation. Our observations suggest that flare loop oscillations are most likely the fast kink mode waves with a phase speed of ∼840 km s−1. The magnetic field strength in flare loops was estimated to be 54–69 G via the coronal seismology. The QPPs and loop oscillation could be independent of each other in this event.

Excitation of Multi-periodic Kink Motions in Solar Flare Loops: Possible Application to Quasi-periodic Pulsations

Mijie **Shi**, Bo Li, Shao-Xia Chen, Mingzhe Guo, Shengju Yuan
ApJL **943** L19 **2023**
https://arxiv.org/pdf/2301.05382.pdf
https://iopscience.iop.org/article/10.3847/2041-8213/acb3c6/pdf
Magnetohydrodynamic (MHD) waves are often invoked to interpret quasi-periodic pulsations (QPPs) in solar flares. We study the response of a straight flare loop to a kink-like velocity perturbation using three-dimensional MHD simulations and forward model the microwave emissions using the fast gyrosynchrotron code. Kink motions with two periodicities are simultaneously generated,with the long-period component P_L = 57s being attributed to the radial fundamental kink mode and the short-period component P_S=5.8s to the first leaky kink mode. Forward modeling results show that the two-periodic oscillations are detectable in the microwave intensities for some lines of sight. Increasing the beam size to (1")^2 does not wipe out the microwave oscillations. We propose that the first leaky kink mode is a promising candidate mechanism to account for short-period QPPs. Radio telescopes with high spatial resolutions can help distinguish between this new mechanism with such customary interpretations as sausage modes.

Synthetic Emissions of the Fe XXI 1354 Å Line from Flare Loops Experiencing Fundamental Fast Sausage Oscillations

Mijie **Shi**, Bo Li, Zhenghua Huang, Shaoxia Chen
ApJ **2019**
https://arxiv.org/pdf/1902.06087.pdf

Inspired by recent IRIS observations, we forward model the response of the Fe XXI 1354 \AA\ line to fundamental, standing, linear fast sausage modes (FSMs) in flare loops. Starting with the fluid parameters for an FSM in a straight tube with equilibrium parameters largely compatible with the IRIS measurements, we synthesize the line profiles by incorporating the non-Equilibrium Ionization (NEI) effect in the computation of the contribution function. We find that both the intensity and Doppler shift oscillate at the wave period (P). The phase difference between the two differs from the expected value (90◦) only slightly because NEI plays only a marginal role in determining the ionic fraction of Fe XXI in the examined dense loop. The Doppler width modulations, however, posses an asymmetry in the first and second halves of a wave period, leading to a secondary periodicity at P/2 in addition to the primary one at P. This behavior results from the competition between the broadening due to bulk flow and that due to temperature variations, with the latter being stronger but not overwhelmingly so. These expected signatures, with the exception of the Doppler width, are largely consistent with the IRIS measurements, thereby corroborating the reported detection of a fundamental FSM. The forward modeled signatures are useful for identifying fundamental FSMs in flare loops from measurements of the Fe \MyRoman{21} 1354 \AA\ line with instruments similar to IRIS, even though a much higher cadence is required for the expected behavior in the Doppler widths to be detected.

The Kelvin Force and Loop-Top Concentration

Kiyoto **Shibasaki**

New physics can explain the perplexing overpressure at the flare looptop regions.

Numerical Study on Excitation of Turbulence and Oscillation in Above-the-loop-top Region of a Solar Flare

Kengo **Shibata**, Shinsuke Takasao, Katharine K. Reeves
ApJ **943** 106 **2023**
https://arxiv.org/pdf/2212.05802.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/acaa9c/pdf
Extreme ultraviolet imaging spectroscopic observations often show an increase in line width around the loop-top or above-loop-top (ALT) region of solar flares, suggestive of turbulence. In addition, recent spectroscopic observations found the oscillation in the Doppler velocity around the ALT region. We performed three-dimensional magnetohydrodynamic (MHD) simulations to investigate the dynamics in the ALT region, with a particular focus on the generation of turbulence and the excitation of the oscillatory motion. We found a rapid growth of MHD instabilities around the upper parts of the ALT region (arms of the magnetic tuning fork). The instabilities grow more rapidly than the magnetic Rayleigh-Taylor-type instabilities at the density interface beneath the reconnecting current sheet. Eventually, the ALT region is filled with turbulent flows. The arms of the magnetic tuning fork have bad-curvature and transonic flows. Therefore, we consider that the rapidly growing instabilities are combinations of pressure-driven and centrifugally driven Rayleigh-Taylor-type instabilities. Despite the presence of turbulent flows, the ALT region shows a coherent oscillation driven by the backflow of the reconnection jet. We examine the numerical results by re-analyzing the solar flare presented in Reeves et al. 2020. We find that the highest non-thermal velocity is always at the uppermost visible edge of the ALT region, where oscillations are present. This result is consistent with our models. We also argue that the turbulent magnetic field has a significant impact on the confinement of non-thermal electrons in the ALT region. **2017 10 September**

Fractal Reconnection in Solar and Stellar Environments

Kazunari **Shibata**, Shinsuke Takasao
2016 "Magnetic Reconnection: Concepts and Applications", Springer-Verlag, W. D. Gonzalez and E. N. Parker, eds.
http://arxiv.org/pdf/1606.09401v1.pdf
Recent space based observations of the Sun revealed that magnetic reconnection is ubiquitous in the solar atmosphere, ranging from small scale reconnection (observed as nanoflares) to large scale one (observed as long duration flares or giant arcades). Often the magnetic reconnection events are associated with mass ejections or jets, which seem to be closely related to multiple plasmoid ejections from fractal current sheet. The bursty radio and hard X-ray emissions from flares also suggest the fractal reconnection and associated particle acceleration. We shall discuss recent observations and theories related to the plasmoid-induced-reconnection and the fractal reconnection in solar flares, and their implication to reconnection physics and particle acceleration. Recent findings of many superflares on solar type stars that has extended the applicability of the fractal reconnection model of solar flares to much a wider parameter space suitable for stellar flares are also discussed.

Solar Flares: Magnetohydrodynamic Processes"

Review

Kazunari **Shibata** and Tetsuya Magara

Living **Reviews** in Solar Physics, 8, (**2011**), 6

http://www.livingreviews.org/lrsp-2011-6

This paper outlines the current understanding of solar flares, mainly focused on magnetohydrodynamic (MHD) processes responsible for producing a flare. Observations show that flares are one of the most explosive phenomena in the atmosphere of the Sun, releasing a huge amount of energy up to about 1032 erg on the timescale of hours. Flares involve the heating of plasma, mass ejection, and particle acceleration that generates high-energy particles. The key physical processes for producing a flare are: the emergence of magnetic field from the solar interior to the solar atmosphere (flux emergence), local enhancement of electric current in the corona (formation of a current sheet), and rapid dissipation of electric current (magnetic reconnection) that causes shock heating, mass ejection, and particle acceleration. The evolution toward the onset of a flare is rather quasi-static when free energy is accumulated in the form of coronal electric current (field-aligned current, more precisely), while the dissipation of coronal current proceeds rapidly, producing various dynamic events that affect lower atmospheres such as the chromosphere and photosphere. Flares manifest such rapid dissipation of coronal current, and their theoretical modeling has been developed in accordance with observations, in which numerical simulations proved to be a strong tool reproducing the time-dependent, nonlinear evolution of a flare. We review the models proposed to explain the physical mechanism of flares, giving an comprehensive explanation of the key processes mentioned above. We start with basic properties of flares, then go into the details of energy build-up, release and transport in flares where magnetic reconnection works as the central engine to produce a flare.

RHESSI OBSERVATIONS OF THE PROPORTIONAL ACCELERATION OF RELATIVISTIC >0.3 MeV ELECTRONS AND >30 MeV PROTONS IN SOLAR FLARES

A. Y. **Shih**1, R. P. Lin1, and D.M. Smith2

Astrophysical Journal, 698:L152–L157, **2009, File**

http://www.iop.org:80/EJ/toc/-alert=43191/1538-4357/698/2

We analyze all *RHESSI* measurements from 2002 to 2005 (29 flare events) of the 2.223 MeV neutroncapture γ -ray line and >0.3 MeV electron bremsstrahlung continuum emissions, produced by >30 MeV accelerated protons (depending on assumptions) and >0.3 MeV accelerated electrons, respectively. We find a close proportionality between the two emissions over >3 orders of magnitude in fluence, from the largest flares down to the limits of detectability. This implies that the processes in flares that accelerate electrons above 0.3 MeV and protons above 30 MeV are closely related, and that the relative acceleration of these two populations is roughly independent of flare size. We find an overall weak correlation between the 2.223 MeV fluence and the peak *GOES* 1–8 Å soft X-ray (SXR) flux, but with a close proportionality for flares with 2.223 MeV fluence above a threshold of 50 ph cm^{-2} (equivalent to ~2 Ч 10^{31} protons >30 MeV). Below this threshold the flares usually have large (M-class or higher) but generally uncorrelated excess SXR emission. Thus, above this threshold it appears that flares reach a maximum efficiency for >30 MeV proton and relativistic (>0.3 MeV) electron acceleration, with proportionate amounts of energy going to flare SXR thermal emission and to >50 keV electrons. Finally, we find that the electron-to-proton ratios—J_e(0.5 MeV)/J_p (10 MeV)—in these flares, obtained from the γ -ray observations, are about 2 orders of magnitude larger than the ratios in gradual solar energetic particle (SEP) events, but are comparable with ratios in impulsive SEP events.

Simultaneous ALMA-Hinode-IRIS observations on footpoint signatures of a soft X-ray loop-like microflare

Toshifumi **Shimizu**, Masumi Shimojo, Masashi Abe

ApJ **922** 113 **2021**

https://arxiv.org/pdf/2109.11215.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/ac27a4/pdf

https://doi.org/10.3847/1538-4357/ac27a4

Microflares have been considered to be among the major energy input sources to form active solar corona. To investigate the response of the low atmosphere to events, we conducted an ALMA observation at 3 mm coordinated with IRIS and Hinode observations, on **March 19, 2017**. During the observations, a soft X-ray loop-type microflare (active-region transient brightening) was captured using Hinode X-ray telescope in high temporal cadence. A brightening loop footpoint is located within narrow field of views ALMA, IRIS slit-jaw imager, and Hinode spectro-polarimeter. Counterparts of the microflare at the footpoint were detected in Si IV and ALMA images, while the counterparts were less apparent in C II and Mg II k images. Their impulsive time profiles exhibit the Neupert effect pertaining to soft X-ray intensity evolution. The magnitude of thermal energy measured using ALMA was approximately 100 times smaller than that measured in the corona. These results suggest that impulsive counterparts can

be detected in the transition region and upper chromosphere where the plasma is thermally heated via impinging non-thermal particles. Our energy evaluation indicates a deficit of accelerated particles that impinge the footpoints for a small class of soft X-ray microflares. The footpoint counterparts consist of several brightening kernels, all of which are located in weak (void) magnetic areas formed in patchy distribution of strong magnetic flux at the photospheric level. The kernels provide a conceptual image in which the transient energy release occurs at multiple locations on the sheaths of magnetic flux bundles in the corona.

3D magnetic field configuration of small-scale reconnection events in the solar plasma atmosphere **Review**

T. **Shimizu**
Physics of Plasmas **2015**
http://arxiv.org/ftp/arxiv/papers/1508/1508.05481.pdf
The outer solar atmosphere, i.e., the corona and the chromosphere, is replete with small energy-release events, which are accompanied by transient brightening and jet-like ejections. These events are considered to be magnetic reconnection events in the solar plasma, and their dynamics have been studied using recent advanced observations from the Hinode spacecraft and other observatories in space and on the ground. These events occur at different locations in the solar atmosphere, and vary in their morphology and amount of the released energy. The magnetic field configurations of these reconnection events are inferred based on observations of magnetic fields at the photospheric level. Observations suggest that these magnetic configurations can be classified into two groups. In the first group, two anti-parallel magnetic fields reconnect to each other, yielding a 2D emerging flux configuration. In the second group, helical or twisted magnetic flux tubes are parallel or at a relative angle to each other. Reconnection can occur only between anti-parallel components of the magnetic flux tubes and may be referred to as component reconnection. The latter configuration type may be more important for the larger class of small-scale reconnection events. The two types of magnetic configurations can be compared to counter-helicity and co-helicity configurations, respectively, in laboratory plasma collision experiments.

High speed photospheric material flow observed at the polarity inversion line of a delta-type sunspot producing an X5.4 flare on 7 March 2012

Shimizu, T., Lites, B.W., and Bamba, Y.
E-print, June **2014**; PASJ, Hinode special issue 66 (SP1), S14 (1–10) **2014**
http://arxiv.org/pdf/1406.1617v1.pdf
http://pasj.oxfordjournals.org/content/66/SP1/S14.full.pdf+html
Solar flares abruptly release the free energy stored as a non-potential magnetic field in the corona and may be accompanied by eruptions of the coronal plasma. Formation of a non-potential magnetic field and the mechanisms for triggering the onset of flares are still poorly understood. In particular, photospheric dynamics observed near those polarity inversion lines that are sites of major flare production have not been well observed with high spatial resolution spectro-polarimetry. This paper reports on a remarkable high-speed material flow observed along the polarity inversion line located between flare ribbons at the main energy release side of an X5.4 flare on **7 March 2012**. Observations were carried out by the spectro-polarimeter of the Solar Optical Telescope onboard Hinode. The high-speed material flow was observed in the horizontally-oriented magnetic field formed nearly parallel to the polarity inversion line. This flow persisted from at least 6 hours before the onset of the flare, and continued for at least several hours after the onset of the flare. Observations suggest that the observed material flow represents neither the emergence nor convergence of the magnetic flux. Rather, it may be considered to be material flow working both to increase the magnetic shear along the polarity inversion line and to develop magnetic structures favorable for the onset of the eruptive flare.

MAGNETOHYDRODYNAMICS STUDY OF THREE-DIMENSIONAL FAST MAGNETIC RECONNECTION FOR INTERMITTENT SNAKE-LIKE DOWNFLOWS IN SOLAR FLARES

T. **Shimizu**, K. Kondo1,4, M. Ugai2,5 and K. Shibata
ApJ 707 420-427, **2009**
Three-dimensional instability of the spontaneous fast magnetic reconnection is studied with magnetohydrodynamics (MHD) simulation, where the two-dimensional model of the spontaneous fast magnetic reconnection is destabilized in three dimensions. In two-dimensional models, every plasma condition is assumed to be uniform in the sheet current direction. In that case, it is well known that the two-dimensional fast magnetic reconnection can be caused by current-driven anomalous resistivity, when an initial resistive disturbance is locally put in a one-dimensional current sheet. In this paper, it is studied whether the two-dimensional fast magnetic reconnection can be destabilized or not when the

initial resistive disturbance is three dimensional, i.e., that which has weak fluctuations in the sheet current direction. According to our study, the two-dimensional fast magnetic reconnection is developed to the three-dimensional intermittent fast magnetic reconnection which is strongly localized in the sheet current direction. The resulting fast magnetic reconnection repeats to randomly eject three-dimensional magnetic loops which are very similar to the intermittent downflows observed in solar flares. In fact, in some observations of solar flares, the current sheet seems to be approximately one dimensional, but the fast magnetic reconnection is strongly localized in the sheet current direction, i.e., fully three dimensional. In addition, the observed plasma downflows as snake-like curves. It is shown that those observed features are consistent with our numerical MHD study.

HINODE **OBSERVATION OF THE MAGNETIC FIELDS IN A SUNSPOT LIGHT BRIDGE ACCOMPANIED BY LONG-LASTING CHROMOSPHERIC PLASMA EJECTIONS**

Toshifumi **Shimizu**1, Yukio Katsukawa2, Masahito Kubo3, Bruce W. Lites3, Kiyoshi Ichimoto4, Yoshinori Suematsu2, Saku Tsuneta2, Shin'ichi Nagata4, Richard A. Shine5, and Theodore D. Tarbell5
Astrophysical Journal, 696:L66–L69, 2009 May
http://www.iop.org/EJ/toc/-alert=43192/1538-4357/696/1

We present high-resolutionmagnetic fieldmeasurements of a sunspot light bridge (LB) that produced chromospheric plasma ejections intermittently and recurrently for more than 1 day. The observations were carried out with the *Hinode* Solar Optical Telescope on **2007 April 29 and 30**. The spectro-polarimeter reveals obliquely oriented magnetic fields with vertical electric current density higher than 100 mA m^{-2} along the LB. The observations suggest that current-carrying highly twisted magnetic flux tubes are trapped below a cusp-shaped magnetic structure along the LB. The presence of trapped current-carrying flux tubes is essential for causing longlasting chromospheric plasma ejections at the interface with pre-existing vertically oriented umbral fields. A bidirectional jet was clearly detected, suggesting magnetic reconnections occurring at very low altitudes, slightly above the height where the vector magnetic fields are measured. Moreover, we found another strong vertical electric current on the interface between the current-carrying flux tube and pre-existing umbral field, which might be a direct detection of the currents flowing in the current sheet formed at the magnetic reconnection sites.

THE CORRELATION AMONG THE RISE VELOCITY OF A SOFT X-RAY LOOP, THE EJECTION VELOCITY OF A PLASMOID, AND THE HEIGHT ABOVE THE LOOP TOP OF THE HARD X-RAY SOURCE IN MASUDA-TYPE FLARES, AND ITS INTERPRETATION BASED ON THE RECONNECTION MODEL OF FLARES

M. **Shimizu**,1 K. Nishida,2 H. Takasaki,3 D. Shiota,4 T. Magara,4 and K. Shibata2
Astrophysical Journal, 683: L203–L206, **2008**
http://www.journals.uchicago.edu/toc/apjl/2008/683/2

One of the most important results on solar flares obtained by *Yohkoh* is finding impulsive compact-loop flares associated with a hard X-ray (HXR) loop-top source well above a soft X-ray (SXR) loop, which are called Masuda-type flares. This finding supports the reconnection model of flares in which magnetic reconnection occurs above the closed loop observed in the soft X-ray during a flare. Although this model qualitatively explains the observed feature of Masuda-type flares, quantitative investigations into physical processes in these flares are still insufficient, which is the main subject of this Letter. We used 15 Masuda-type flares (seven are newly found and eight are previously reported) to examine the correlation among the rise velocity of an SXR loop, the ejection velocity of a plasmoid, and the height of the HXR source above the SXR loop (i.e., the difference in the apparent heights of the HXR and SXR sources). The main conclusion is that there is a positive correlation among these three quantities, and we explain the physical origin of this correlation using a reconnection model of flares.

FREQUENT OCCURRENCE OF HIGH-SPEED LOCAL MASS DOWNFLOWS ON THE SOLAR SURFACE

We report on new spectropolarimetric measurements with simultaneous filter imaging observation, revealing the frequent appearance of polarization signals indicating high-speed, probably supersonic, downflows that are associated with at least three different configurations of magnetic fields in the solar photosphere.

Development of Daily Maximum Flare-Flux Forecast Models for Strong Solar Flares

Seulki **Shin**, Jin-Yi Lee, Yong-Jae Moon , Hyoungseok Chu, Jongyeob Park

Solar Phys. Volume 291, Issue 3, pp 897-909 **2016**

We have developed a set of daily maximum flare-flux forecast models for strong flares (M- and X-class) using multiple linear regression (MLR) and artificial neural network (ANN) methods. Our input parameters are solar-activity data from January 1996 to December 2013 such as sunspot area, X-ray maximum, and weighted total flare flux of the previous day, as well as mean flare rates of McIntosh sunspot group (Zpc) and Mount Wilson magnetic classifications. For a training dataset, we used 61 events each of C-, M-, and X-class from January 1996 to December 2004. For a testing dataset, we used all events from January 2005 to November 2013. A comparison between our maximum flare-flux models and NOAA model based on true skill statistics (TSS) shows that the MLR model for X-class and the average of all flares (M+XM+X-class) are much better than the NOAA model. According to the hitting fraction (HF), which is defined as a fraction of events satisfying the condition that the absolute differences of predicted and observed flare flux on a logarithm scale are smaller than or equal to 0.5, our models successfully forecast the maximum flare flux of about two-thirds of the events for strong flares. Since all input parameters for our models are easily available, the models can be operated steadily and automatically on a daily basis for space-weather services.

PLASMA HEATING IN THE VERY EARLY PHASE OF SOLAR FLARES

M. **Siarkowski**1, R. Falewicz2, and P. Rudawy2

The Astrophysical Journal, 705:L143–L147, **2009**

In this Letter, we analyze soft X-ray (SXR) and hard X-ray (HXR) emission of the **2002 September 20** M1.8 *GOES* class solar flare observed by the *RHESSI* and *GOES* satellites. In this flare event, SXR emission precedes the onset of the main bulk HXR emission by ~5 minutes. This suggests that an additional heating mechanism may be at work at the early beginning of the flare. However, *RHESSI* spectra indicate a presence of the non-thermal electrons also before the impulsive phase. So, we assumed that a dominant energy transport mechanism during the rise phase of solar flares is electron-beam-driven evaporation. We used non-thermal electron beams derived from *RHESSI* spectra as the heating source in a hydrodynamic model of the analyzed flare. We showed that energy delivered by non-thermal electron beams is sufficient to heat the flare loop to temperatures in which it emits SXR closely following the *GOES* 1–8 Å light curve. We also analyze the number of non-thermal electrons, the low-energy cutoff, electron spectral indices, and the changes of these parameters with time.

Statistical analysis of the onset temperature of solar flares in 2010-2011

https://doi.org/10.1093/mnras/stad2244

Understanding the physical processes that trigger solar flares is paramount to help with forecasting space weather and mitigating the effects on our technological infrastructure. A previously unknown phenomenon was recently identified in solar flares: the plasma temperature, derived from soft X-ray (SXR) data, at the onset of four flares, was revealed to be in the range 10-15 MK, without evidence of gradual heating. To investigate how common the hot-onset phenomenon may be, we extend this investigation to solar flares of B1.2- X6.9 classes recorded by the X-ray Sensor (XRS) on-board the GOES-14 and GOES-15 satellites between 2010 and 2011. For this statistical study, we employed the same methodology as in recent work, where the pre-flare SXR flux of each flare is obtained manually, and the temperature and emission measure values are obtained by the flux ratio of the two GOES/XRS channels using the standard software. From 3224 events listed in the GOES flare catalog for 2010-2011, we have selected and analyzed 745 events for which the flare heliographic location was provided in the list, to investigate center-to-limb effects of the hot-onset phenomenon. Our results show that 559 out of 745 flares (75%) exhibit an onset temperature above 8.6 MK (the first quartile), with respective log10 of the emission measure values between 46.0 - 47.25 cm-3, indicating that small amounts of plasma are quickly heated to high temperatures. These results suggest that the hot-onset phenomenon is very common in solar flares. **20 Jan 2010, 14 Feb 2011, 3 Sep 2011**

Broken Power-law Energy Spectra of the Accelerated Electrons Detected in Radio and Hard X-Rays during the SOL2013-05-13 Event

Douglas Félix da **Silva**1,2 and Adriana Valio2

2021 ApJL 915 L1
https://doi.org/10.3847/2041-8213/ac0726

https://iopscience.iop.org/article/10.3847/2041-8213/ac0726/pdf
Solar flares, resulting from magnetic activity of the Sun, are among the most energetic events in the solar system and in extreme cases directly affect our highly technological society. In this work, we analyze a solar flare detected at millimeter and centimeter wavelengths, as well as X-rays above 1 MeV. Observations of solar flares at these energy bands provide diagnostics of the energetic accelerated electrons and the magnetic fields where the emission is produced. During the SOL**2013-05-13** solar flare, radio data were obtained by the telescope system POlarisation Emission of Millimeter Activity at the Sun, which observes the Sun at 45 and 90 GHz with polarization measurements, and at microwaves (1–15 GHz) by the Radio Solar Telescope Network. For the same event, X-ray emission was detected by the RHESSI and Fermi satellites. Spectra at both wavelengths were constructed and fit separately to yield the accelerated electron energy distribution that produced the emission. The optically thin radio spectral index was calculated by fitting the Ramaty model of gyrosynchrotron emission to the observed radio spectrum, whereas the hard X-ray spectral index was obtained from the spectral fit assuming a thermal emission model plus a nonthermal broken power-law distribution. Finally, both spectral indexes were compared and confirmed that the index obtained from the radio spectrum agrees with the index of the X-ray spectrum for energies above the break energy of ~600 keV. Thus, the hard X-rays more energetic than 600 keV and high radio frequencies of solar flares are emitted by the same population of high-energy accelerated electrons. This result indicates that the accelerated electrons have an energy distribution best represented by a broken power law, with a breakup above energies around 1 MeV.

Submillimeter radiation as the thermal component of the Neupert Effect

Jorge Fernando Valle **Silva**, C. Guillermo Giménez de Castro, Paulo José de Aguiar Simões, Jean-Pierre Raulin
Solar Phys. **2019**
https://arxiv.org/pdf/1909.01435.pdf
The Neupert effect is the empirical observation that the time evolution of non-thermal emission (e.g. hard X-rays) is frequently proportional to the time derivative of the thermal emission flux (soft X-rays), or, vice versa, that time integrated non-thermal flux is proportional to thermal flux. We analyzed the GOES M2.2 event SOL**2011-02-14**T17:25, and found that the 212 GHz emission plays quite well the role of the thermal component of the Neupert effect. We show that the maximum of the hard X-ray flux for energies above 50 keV is coincident in time with the time-derivative of the 212 GHz flux, within the uncertainties. The microwave flux density at 15.4 GHz, produced by optically thin gyrosynchrotron mechanism, and hard-X rays above 25 keV mark the typical impulsive phase, and have similar time evolution. On the other hand, the 12 GHz emission is delayed by about 25 seconds with respect of the microwave and hard X-ray peak. We argue that this delay cannot be explained by magnetic trapping of non-thermal electrons. With all the observational evidence, we suggest that the 212 GHz emission is produced by thermal bremsstrahlung, initially in the chromosphere, and shifting to optically thin emission from thehot coronal loops at the end of the gradual phase.

The behavior of the spotless active regions during the solar minimum 23-24

Alexandre J. Oliveira e **Silva**, Caius L. Selhorst
Living Around Active Stars Proceedings IAU Symposium No. 328, 2016 **2017**
https://arxiv.org/pdf/1703.00926.pdf
In this work, we analysed the physical parameters of the spotless actives regions observed during solar minimum 23 - 24 (2007 - 2010). The study was based on radio maps at 17~GHz obtained by Imager (MDI) on board the Solar and Heliospheric Observatory (SOHO). The results shows that the spotless active regions presents the same radio characteristics of a ordinary one, they can live in the solar surface for long periods (>10 days), and also can present small flares.

Millimeter Observation of Solar Flares with Polarization

Silva, D. F.; Valio, A. B. M.
Ground-based Solar Observations in the Space Instrumentation Era
ASP Conference Series, Vol. 504, p. 55, **2016**
http://aspbooks.org/publications/504/055.pdf
We present the investigation of two solar flares on **February 17 and May 13, 2013**, studied in radio from 5 to 405 GHz (RSTN, POEMAS, SST), and in X-rays up to 300 keV (FERMI and RHESSI). The objective of this work is to study the evolution and energy distribution of the population of accelerated electrons and the magnetic field configuration. For this we constructed and fit the radio spectrum by a gyro synchrotron model. The optically thin spectral indices from radio observations were compared to that of the hard X-rays, showing that the radio spectral index is harder than the latter by 2. These flares also presented 10-15 % circular polarized emission at 45 and 90 GHz that suggests that the sources are located at different legs of an asymmetric loop.

Precise timing of solar flare footpoint sources from mid-infrared observations

Paulo J. A. **Simões**, Lyndsay Fletcher, Hugh S. Hudson, Graham S. Kerr, Matt Penn, Karla F. Lopez
MNRAS **2024**

https://arxiv.org/pdf/2406.11361
Solar flares are powerful particle accelerators, and in the accepted standard flare model most of the flare energy is transported from a coronal energy-release region by accelerated electrons which stop collisionally in the chromosphere, heating and ionising the plasma, producing a broadband enhancement to the solar radiative output. We present a time-delay analysis of the infrared emission from two chromospheric sources in the flare SOL**2014-09-24**T17:50 taken at the McMath-Pierce telescope. By cross-correlating the intensity signals, measured with 1s cadence, from the two spatially resolved infrared sources we find a delay of 0.75 ± 0.07 s at 8.2 μm, where the uncertainties are quantified by a Monte Carlo analysis. The sources correlate well in brightness but have a time lag larger than can be reasonably explained by the energy transport dominated by non-thermal electrons precipitating from a single acceleration site in the corona. If interpreted as a time-of-flight difference between electrons traveling to each footpoint, we estimate time delays between 0.14 s and 0.42 s, for a reconnection site at the interior quasi-separatrix layer or at the null-point of the spine-fan topology inferred for this event. We employed modelling of electron transport via time-dependent Fokker-Planck and radiative hydrodynamic simulations to evaluate other possible sources of time-delay in the generation of the IR emission, such as differing ionisation timescales under different chromospheric conditions. Our results demonstrate that they are also unable to account for this discrepancy. This flare appears to require energy transport by some means other than electron beams originating in the corona.

The spectral content of SDO/AIA 1600 and 1700 Å filters from flare and plage observations

Paulo J. A. **Simões**, Hamish A. S. Reid, Ryan O. Milligan, Lyndsay Fletcher
ApJ 870 114 **2019**
https://arxiv.org/pdf/1808.01488.pdf
sci-hub.tw/10.3847/1538-4357/aaf28d
The strong enhancement of the ultraviolet emission during solar flares is usually taken as an indication of plasma heating in the low solar atmosphere caused by the deposition of the energy released during these events. Images taken with broadband ultraviolet filters by the Transition Region and Coronal Explorer (TRACE) and Atmospheric Imaging Assembly (AIA 1600 and 1700 \AA) have revealed the morphology and evolution of flare ribbons in great detail. However, the spectral content of these images is still largely unknown. Without the knowledge of the spectral contribution to these UV filters, the use of these rich imaging datasets is severely limited. Aiming to solve this issue, we estimate the spectral contributions of the AIA UV flare and plage images using high-resolution spectra in the range 1300 to 1900 \AA\ from the Skylab NRL SO82B spectrograph. We find that the flare excess emission in AIA 1600 \AA\ is composed of the C IV 1550 \AA\ doublet (26\%), Si I continua (20\%), with smaller contributions from many other chromospheric lines such as C I 1561 and 1656 \AA\ multiplets, He II 1640 \AA, Si ii 1526 and 1533 \AA. For the AIA 1700 \AA\ band, C I 1656 \AA\ multiplet is the main contributor (38\%), followed by He II 1640 (17\%), and accompanied by a multitude of other chromospheric lines, with minimal contribution from the continuum. Our results can be generalized to state that the AIA UV flare excess emission is of chromospheric origin, while plage emission is dominated by photospheric continuum emission in both channels. **1973-09-07**

Formation of the thermal infrared continuum in solar flares

Aims. Observations of the Sun with the Atacama Large Millimeter Array have now started, and the thermal infrared will regularly be accessible from the NSF's Daniel K. Inouye Solar Telescope. Motivated by the prospect of these new data, and by recent flare observations in the mid infrared, we set out here to model and understand the source of the infrared continuum in flares, and to explore its diagnostic capability for the physical conditions in the flare atmosphere. Methods. We use the one-dimensional (1D) radiation hydrodynamics code RADYN to calculate mid-infrared continuum emission from model atmospheres undergoing sudden deposition of energy by non-thermal electrons. Results. We identify and characterise the main continuum thermal emission processes relevant to flare intensity enhancement in the mid- to far-infrared (2–200 μm) spectral range as free-free emission on neutrals and ions. We find that the infrared intensity evolution tracks the energy input to within a second, albeit with a lingering intensity

enhancement, and provides a very direct indication of the evolution of the atmospheric ionisation. The prediction of highly impulsive emission means that, on these timescales, the atmospheric hydrodynamics need not be considered in analysing the mid-IR signatures. **24−Sep−14**

Tracking flare chromospheric ionisation in the infrared

Paulo **Simões**, Lyndsay Fletcher, Hugh Hudson …
UKSP Nuggets # 78, **2017.**
http://www.uksolphys.org/uksp-nugget/78-tracking-flare-chromospheric-ionisation-in-the-infrared/
Infrared observations of solar flare chromospheric sources look like they will provide useful flare diagnostics, being both a prompt response to the energy input, and directly related to the evolution of ionisation in the chromosphere. We have also been able to show [3] that as the flare rises to its peak IR intensity, the brightness temperature maps very closely the evolution of electron density where the contribution function peaks, offering the possibility that the IR brightness temperature can be used to track something like the chromospheric 'total electron content'. Flare observations in the infrared continuum are rare at present, but this will change with the Daniel K. Inouye Solar Telescope which will be able to observe parts of the IR continuum between 1 and 5 μm, initially, though with capability to go out to 10μm in the future.

Observations and modelling of Helium lines in solar flares

Paulo J. A. **Simões**, Lyndsay Fletcher, Nicolas Labrosse, Graham S. Kerr
Proceedings of the Coimbra Solar Physics Meeting 2015: Ground-based Solar Observations in the Space Instrumentation Era; Astronomical Society of the Pacific Conference Series **201**5
http://arxiv.org/pdf/1512.03477v1.pdf
We explore the response of the He II 304 {\AA} and He I 584 {\AA} line intensities to electron beam heating in solar flares using radiative hydrodynamic simulations. Comparing different electron beams parameters, we found that the intensities of both He lines are very sensitive to the energy flux deposited in the chromosphere, or more specifically to the heating rate, with He II 304 {\AA} being more sensitive to the heating than He I 584 {\AA}. Therefore, the He line ratio increases for larger heating rates in the chromosphere. A similar trend is found in observations, using SDO/EVE He irradiance ratios and estimates of the electron beam energy rate obtained from hard X-ray data. From the simulations, we also found that spectral index of the electrons can affect the He ratio but a similar effect was not found in the observations. **2011-02-15, 2011-07-30, 2011-08-04, 2014-01-01**

Impulsive Heating of Solar Flare Ribbons Above 10 MK

Paulo J. A. **Simões**, David R. Graham, Lyndsay Fletcher
Solar Phys. Volume 290, Issue 12, pp 3573-3591 **2015**
http://arxiv.org/pdf/1505.03384v1.pdf
The chromospheric response to the input of flare energy is marked by extended extreme ultraviolet (EUV) ribbons and hard X-ray (HXR) footpoints. These are usually explained as the result of heating and bremsstrahlung emission from accelerated electrons colliding in the dense chromospheric plasma. We present evidence of impulsive heating of flare ribbons above 10 MK in a two-ribbon flare. We analyse the impulsive phase of **SOL2013-11-09**T06:38, a C2.6 class

event using data from Atmospheric Imaging Assembly (AIA) on board of Solar Dynamics Observatory (SDO) and the Reuven Ramaty High Energy Solar Spectroscopic Imager (RHESSI) to derive the temperature, emission measure and differential emission measure of the flaring regions and investigate the evolution of the plasma in the flaring ribbons. The ribbons were visible at all SDO/AIA EUV/UV wavelengths, in particular, at 94 and 131 \AA\ filters, sensitive to temperatures of 8 MK and 12 MK. Time evolution of the emission measure of the plasma above 10 MK at the ribbons has a peak near the HXR peak time. The presence of hot plasma in the lower atmosphere is further confirmed by RHESSI imaging spectroscopy analysis, which shows resolved sources at 11-13 MK associated with at least one ribbon. We found that collisional beam heating can only marginally explain the necessary power to heat the 10 MK plasma at the ribbons.

Direct observation of the energy release site in a solar flare by SDO/AIA, Hinode/EIS and RHESSI

Paulo J. A. **Simões**, David R. Graham, Lyndsay Fletcher
A&A 577, A68 **2015**
http://arxiv.org/pdf/1503.01491v1.pdf
We present direct evidence for the detection of the main energy release site in a non-eruptive solar flare, **SOL2013-11-09**T06:38UT. This GOES C2.7 event was characterised by two flaring ribbons and a compact, bright coronal source located between them, which is the focus of our study. We use imaging from SDO/AIA, and imaging spectroscopy from RHESSI to characterise the thermal and non-thermal emission from the coronal source, and EUV spectroscopy from the Hinode/EIS, which scanned the coronal source during the impulsive peak, to analyse Doppler shifts in Fe XII and Fe XXIV emission lines, and determine the source density. The coronal source exhibited an impulsive emission lightcurve in all AIA filters during the impulsive phase. RHESSI hard X-ray images indicate both thermal and non-thermal emission at the coronal source, and its plasma temperature derived from RHESSI imaging spectroscopy shows an impulsive rise, reaching a maximum at 12-13 MK about 10 seconds prior to the hard X-ray peak. High redshifts associated with this bright source indicate downflows of 40-250 km/s at a broad range of temperatures, interpreted as loop shrinkage and/or outflows along the magnetic field. Outflows from the coronal source towards each ribbon are also observed by AIA images at 171, 193, 211, 304 and 1600 A. The electron density of the source obtained from a Fe XIV line pair is 1011.50which is collisionally thick to electrons with energy up to 45-65 keV, responsible for the source's non-thermal X-ray emission. We conclude that the bright coronal source is the location of the main release of magnetic energy in this flare, with a geometry consistent with component reconnection between crossing, current-carrying loops. We argue that the energy that can be released via reconnection, based on observational estimates, can plausibly account for the non-thermal energetics of the flare.

Soft X-ray Pulsations in Solar Flares

Paulo J. A. **Simões**, Hugh S. Hudson, Lyndsay Fletcher
Solar Phys. Volume 290, Issue 12, pp 3625-3639 **2015**
http://arxiv.org/pdf/1412.3045v1.pdf
https://sci-hub.ru/10.1007/s11207-015-0691-2
The soft X-ray emissions of solar flares come mainly from the bright coronal loops at the highest temperatures normally achieved in the flare process. Their ubiquity has led to their use as a standard measure of flare occurrence and energy, although the bulk of the total flare energy goes elsewhere. Recently Dolla et al. (2012) noted quasi-periodic pulsations (QPP) in the soft X-ray signature of the X-class flare SOL**2011-02-15**, as observed by the standard photometric data from the GOES (Geostationary Operational Environmental Satellite) spacecraft. We analyze the suitability of the GOES data for this kind of analysis and find them to be generally valuable after Sept. 2010 (GOES-15). We then extend Dolla et al. results to a list of X-class flares from Cycle 24, and show that most of them display QPP in the impulsive phase. During the impulsive phase the footpoints of the newly-forming flare loops may also contribute to the observed soft X-ray variations. The QPP show up cleanly in both channels of the GOES data, making use of time-series of irradiance differences (the digital time derivative on the 2-s sampling). We show that there is minimal phase difference between the differenced GOES energy channels, nor between them and the hard X-ray variations on short time scales. We deploy different techniques to characterize the GOES QPP, finding no systematic patterns in spite of their general prevalence and usually no strong signature of a strict periodicity. The QPP may also appear on somewhat longer time scales during the later gradual phase, possibly with a greater tendency towards coherence, but the sampling noise in GOES difference data for large irradiance values makes these more uncertain. We note that the QPP of the impulsive phase can result from broadband variations, for example in red-noise power law distribution, in the flare development from its basic plasma instability. **2011-09-07, 14−May−13, 15−May−13, 28−Oct−13, 10−Nov−13, 25−Feb−14, 25−Apr−14**

SDO observations of a flare’s coronal “implosion”

Paulo **Simões**, L. Fletcher, H. Hudson & A. Russell
UKSP Nugget: 42, Dec **2013**.
http://www.uksolphys.org/?p=7616
The corona collapses at the start of a flare.
The diffusion timescale for magnetic field in the corona is long but the impulsive phase of a flare is short, so most of the energy must come from a reduction in volume (i.e. from the shortening of the current-carrying field) somewhere in the configuration [2], referred to as the 'implosion'.

Implosion of Coronal Loops during the Impulsive Phase of a Solar Flare

P. J. A. **Simões**1, L. Fletcher1, H. S. Hudson1,2, and A. J. B. Russell
2013 ApJ 777 152
We study the relationship between implosive motions in a solar flare, and the energy redistribution in the form of oscillatory structures and particle acceleration. The flare **SOL2012-03-09**T03:53 (M6.4) shows clear evidence for an irreversible (stepwise) coronal implosion. Extreme-ultraviolet (EUV) images show at least four groups of coronal loops at different heights overlying the flaring core undergoing fast contraction during the impulsive phase of the flare. These contractions start around a minute after the flare onset, and the rate of contraction is closely associated with the intensity of the hard X-ray and microwave emissions. They also seem to have a close relationship with the dimming associated with the formation of the coronal mass ejection and a global EUV wave. Several studies now have detected contracting motions in the corona during solar flares that can be interpreted as the implosion necessary to release energy. Our results confirm this, and tighten the association with the flare impulsive phase. We add to the phenomenology by noting the presence of oscillatory variations revealed by Geostationary Operational Environmental Satellite soft X-rays (SXR) and spatially integrated EUV emission at 94 and 335 Å. We identify pulsations of 60 s in SXR and EUV data, which we interpret as persistent, semi-regular compressions of the flaring core region which modulate the plasma temperature and emission measure. The loop oscillations, observed over a large region, also allow us to provide rough estimates of the energy temporarily stored in the eigenmodes of the active-region structure as it approaches its new equilibrium.

The Flare that Time Forgot

Paulo **Simoes** and Hugh Hudson
RHESSI Science Nuggets, October **2013**, No. 209
http://sprg.ssl.berkeley.edu/~tohban/wiki/index.php/The_Flare_that_Time_Forgot
The Masuda flare. But, there was only really the one event, and many have commented how unusual it was. Was this type of event worth the fuss?

Implosion and Oscillation

Too few? Too many?

Simoes, P. J. A. and Kontar, E. P.
RHESSI Science Nugget, No. 200, **2013**
We analysed four well-observed events in which the common loop structure could be identified in HXR: two footpoint sources at higher photon energies and a looptop source at lower energies.
Our conclusion is that the accelerated electrons must be subject to magnetic trapping and/or pitch-angle scattering, keeping a fraction of the population trapped inside the coronal loops.
2002 July 23, 2003 Nov 02, 2011 Feb 24, 2011 Sept 24

Implications for electron acceleration and transport from non-thermal electron rates at looptop and footpoint sources in solar flares

Simoes, P. J. A. and Kontar, E. P.
E-print, Feb **2013**; A&A, 551, A135 (**2013**)
The interrelation of hard X-ray (HXR) emitting sources and the underlying physics of electron acceleration and transport presents one of the major questions in high-energy solar flare physics. Spatially resolved observations of solar

flares often demonstrate the presence of well-separated sources of bremsstrahlung emission, so-called coronal and footpoint sources. Using spatially resolved X-ray observations by the Reuven Ramaty High Energy Solar Spectroscopic Imager (RHESSI) and recently improved imaging techniques, we investigate in detail the spatially resolved electron distributions in a few well-observed solar flares. The selected flares can be interpreted as having a standard geometry with chromospheric HXR footpoint sources related to thick-target X-ray emission and the coronal sources characterised by a combination of thermal and thin-target bremsstrahlung. Using imaging spectroscopy techniques, we deduce the characteristic electron rates and spectral indices required to explain the coronal and footpoint X-ray sources. We found that, during the impulsive phase, the electron rate at the looptop is several times (a factor of 1.7-8) higher than at the footpoints. The results suggest that a sufficient number of electrons accelerated in the looptop explain the precipitation into the footpoints and imply that electrons accumulate in the looptop. We discuss these results in terms of magnetic trapping, pitch-angle scattering, and injection properties. Our conclusion is that the accelerated electrons must be subject to magnetic trapping and/or pitch-angle scattering, keeping a fraction of the population trapped inside the coronal loops. These findings put strong constraints on the particle transport in the coronal source and provide quantitative limits on deka-keV electron trapping/scattering in the coronal source.

Study of reconnection rates and light curves in solar flares from low and mid chromosphere

G **Sindhuja** Nandita Srivastava A M Veronig W Pötzi
Monthly Notices of the Royal Astronomical Society, Volume 482, Issue 3, 21 January **2019**, Pages 3744–3756
sci-hub.tw/10.1093/mnras/sty2887
We study the flare evolution process using both H α and Ca–K data sets to understand the variations between the two. The reconnection rates and fluxes from low and mid chromosphere using the high cadence Ca–K and H α time lapse images and low-noise 720-s Helioseismic Magnetic Imager line-of-sight magnetograms, respectively, are studied. From the past studies it is understood that the surface magnetic flux swept by the flare ribbons relates to a global reconnection rate. Therefore in order to measure the abovesaid parameters, the observables like the newly brightened area and magnetic field of the area are calculated. We report the results of the analysis carried out for nine flare events observed during 2010–2015 from Kanzelhöhe Solar Observatory for Solar and Environmental Research. The parameters like reconnection flux and reconnection rate estimated using Ca–K and H α images are compared. We infer that the reconnection flux parameter estimated from Ca–K and H α follow a similar trend and shows a linear relation in the log–log plot. Further our study also reveals that Ca–K light curve during the course of the flare is dominated by impulsive and gradual components and follows the trend of the non-thermally dominated Reuven Ramaty High Energy Solar Spectroscopic Imager (RHESSI) (25–50 keV) light curves. Whereas, H α light curve is dominated by a gradual component and follows the trend and shape of the thermally dominated RHESSI HXR (6-12 keV) light curves. **2014 Feb 13-14,2014 May 10, 22 Oct 14, 2015 Apr 9**

The Missing Cool Corona in the Flat Magnetic Field around Solar Active Regions

Talwinder **Singh**, Alphonse C. Sterling, Ronald L. Moore
ApJ **909** 57 **2021**
https://arxiv.org/pdf/2012.15406.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/abd7f2/pdf
https://doi.org/10.3847/1538-4357/abd7f2
SDO/AIA images the full solar disk in several EUV bands that are each sensitive to coronal plasma emissions of one or more specific temperatures. We observe that when isolated active regions (ARs) are on the disk, full-disk images in some of the coronal EUV channels show the outskirts of the AR as a dark moat surrounding the AR. Here we present seven specific examples, selected from time periods when there was only a single AR present on the disk. Visually, we observe the moat to be most prominent in the AIA 171 Angstrom band, which has the most sensitivity to emission from plasma at log10 T = 5.8. By examining the 1D line-of-sight emission measure temperature distribution found from six AIA EUV channels, we find the intensity of the moat to be most depressed over the temperature range log10 T ~ 5.7 - 6.2 for most of the cases. We argue that the dark moat exists because the pressure from the strong magnetic field that splays out from the AR presses down on underlying magnetic loops, flattening those loops -- along with the lowest of the AR's own loops over the moat -- to a low altitude. Those loops, which would normally emit the bulk of the 171 Angstrom emission, are restricted to heights above the surface that are too low to have 171 Angstrom-emitting plasmas sustained in them, according to Antiochos & Noci (1986), while hotter EUV-emitting plasmas are sustained in the overlying higher-altitude long AR-rooted coronal loops. This potentially explains the low-coronal-temperature dark moats surrounding the ARs. **2014 Dec 17, 2018 Feb 11, 2018 Apr 25, 2018 May 30, 2018 Jun 17, 2018 Jul 14, 2019 Feb 20, 2019 Apr 15**

Dynamic Evolution of Current Sheets, Ideal Tearing, Plasmoid Formation and Generalized Fractal Reconnection Scaling Relations

K. A. P. **Singh**1,2, Fulvia Pucci3,4, Anna Tenerani5, Kazunari Shibata2, Andrew Hillier6, and Marco Velli7
2019 ApJ 881 52
sci-hub.se/10.3847/1538-4357/ab2b99
Magnetic reconnection may be the fundamental process allowing energy stored in magnetic fields to be released abruptly, with solar flares and coronal mass ejection being archetypal natural plasma examples. Magnetic reconnection is much too slow of a process to be efficient on the large scales, but accelerates once small enough scales are formed in the system. For this reason, the fractal reconnection scenario was introduced to explain explosive events in the solar atmosphere; it was based on the recursive triggering and collapse via tearing instability of a current sheet originally thinned during the rise of a filament in the solar corona. Here we compare the different fractal reconnection scenarios that have been proposed, and derive generalized scaling relations for the recursive triggering of fast, "ideal" —i.e., Lundquist number independent—tearing in collapsing current sheet configurations with arbitrary current profile shapes. An important result is that the Sweet–Parker scaling with Lundquist number, if interpreted as the aspect ratio of the singular layer in an ideally unstable sheet, is universal and does not depend on the details of the current profile in the sheet. Such a scaling, however, must not be interpreted in terms of stationary reconnection, rather it defines a step in the accelerating sequence of events of the ideal tearing mediated fractal cascade. We calculate scalings for the expected number of plasmoids for such generic profiles and realistic Lundquist numbers, showing that in ideal tearing scenarios a smaller number of plasmoids, by orders of magnitude, is generated compared to the original fractal model.

GPS as a solar observational instrument: Real-time estimation of EUV photons flux rate during strong, medium, and weak solar flares

Talwinder **Singh**, Manuel Hernandez-Pajares, Enric Monte, Alberto Garcia-Rigo, Germán Olivares-Pulido
JGR December **2015** Vol: 120, Pages: 10,840–10,850
http://onlinelibrary.wiley.com/doi/10.1002/2015JA021824/pdf
In this manuscript, the authors show how the Global Navigation Satellite Systems, GNSS (exemplified in the Global Positioning System, GPS), can be efficiently used for a very different purpose from that for which it was designed as an accurate Solar observational tool, already operational from the open global GPS measurements available in real-time, and with some advantages regarding dedicated instruments onboard spacecraft. The very high correlation of the solar extreme ultraviolet (EUV) photon flux rate in the 26–34 mm spectral band, obtained from the solar EUV monitor instrument onboard the SOHO spacecraft during Solar flares, is shown with the GNSS solar flare activity indicator (GSFLAI). The GSFLAI is defined as the gradient of the ionospheric vertical total electron content rate versus the cosine of the Solar zenith angle in the day hemisphere (which filters out nonsolar over ionization), and it is measured from data collected by a global network of dual frequency GPS receivers (giving in this way continuous coverage). GSFLAI for 60 X class flares, 320 M class flares, and 300 C class flares, occurred since 2001, were directly compared with the EUV solar flux rate data to show existing correlations. It was found that the GSFLAI and EUV flux rate present the same linear relationship for all classes of flares, not only the strong and medium intensity ones, X and M class, as in previous works, but also for the weakest C class solar flares, which is a remarkable result.

Nonlinear Instability and Intermittent Nature of Magnetic Reconnection in Solar Chromosphere

K.A.P. **Singh**, Andrew Hillier, H. Isobe, K. Shibata
PASJ 10 **2015**
http://arxiv.org/pdf/1602.01999v1.pdf
The recent observations of Singh et al. (2012) have shown multiple plasma ejections and the intermittent nature of magnetic reconnection in the solar chromosphere, highlighting the need for fast reconnection to occur in highly collisional plasma. However, the physical process through which fast magnetic reconnection occurs in partially ionized plasma, like the solar chromosphere, is still poorly understood. It has been shown that for sufficiently high magnetic Reynolds numbers, Sweet-Parker current sheets can become unstable leading to tearing mode instability and plasmoid formation, but when dealing with a partially ionized plasma the strength of coupling between the ions and neutrals plays a fundamental role in determining the dynamics of the system. We propose that as the reconnecting current sheet thins and the tearing instability develops, plasmoid formation passes through strongly, intermediately, and weakly coupled (or decoupled) regimes, with the time scale for the tearing mode instability depending on the frictional coupling between ions and neutrals. We present calculations for the relevant time scales for fractal tearing in all three regimes. We show that as a result of the tearing mode instability and the subsequent non-linear instability due to the plasmoid-dominated reconnection, the Sweet-Parker current sheet tends to have a fractal-like structure, and when the chromospheric magnetic field is sufficiently strong the tearing instability can reach down to kinetic scales, which are hypothesized to be necessary for fast reconnection.

Chromospheric Anemone Jets and Magnetic Reconnection in Partially Ionized Solar Atmosphere

K.A.P **Singh**, K. Shibata, N. Nishizuka, and H. Isobe
Physics of Plasmas, Volume 18, 111210 (**2011**)
The solar optical telescope onboard Hinode with temporal resolution of less than 5 s and spatial resolution of 150 km has observed the lower solar atmosphere with an unprecedented detail. This has led to many important findings, one of them is the discovery of chromospheric anemone jets in the solar chromosphere. The chromospheric anemone jets are ubiquitous in solar chromosphere and statistical studies show that the typical length, life time and energy of the chromospheric anemone jets are much smaller than the coronal events (e.g., jets/flares/CMEs). Among various observational parameters, the apparent length and maximum velocity shows good correlation. The velocity of chromospheric anemone jets is comparable to the local Alfvén speed in the lower solar chromosphere. Since the discovery of chromospheric anemone jets by Hinode, several evidences of magnetic reconnection in chromospheric anemone jets have been found and these observations are summarized in this paper. These observations clearly suggest that reconnection occurs quite rapidly as well as intermittently in the solar chromosphere. In the solar corona, anomalous resistivity arises due to various collisionless processes. Previous MHD simulations show that reconnection becomes fast as well as strongly time-dependent due to anomalous resistivity. Such processes would not arise in the solar chromosphere which is fully collisional and partially-ionized. So, it is unclear how the rapid and strongly time-dependent reconnection would occur in the solar chromosphere. It is quite likely that the Hall and ambipolar diffusion are present in the solar chromosphere and they could play an important role in driving such rapid, strongly time-dependent reconnection in the solar chromosphere.

A Comparative Analysis of Machine Learning Models for Solar Flare Forecasting: Identifying High Performing Active Region Flare Indicators

Suvadip **Sinha**, Om Gupta, Vishal Singh, B. Lekshmi, Dibyendu Nandy, Dhrubaditya Mitra, Saikat Chatterjee, Sourangshu Bhattacharya, Saptarshi Chatterjee, Nandita Srivastava, Axel Brandenburg
ApJ **935** 45 **2022**
https://arxiv.org/pdf/2204.05910.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ac7955/pdf
Solar flares create adverse space weather impacting space and Earth-based technologies. However, the difficulty of forecasting flares, and by extension severe space weather, is accentuated by the lack of any unique flare trigger or a single physical pathway. Studies indicate that multiple physical properties contribute to active region flare potential, compounding the challenge. Recent developments in Machine Learning (ML) have enabled analysis of higher dimensional data leading to increasingly better flare forecasting techniques. However, consensus on high-performing flare predictors remains elusive. In the most comprehensive study till date, we conduct a comparative analysis of four popular ML techniques (K-Nearest Neighbor, Logistic Regression, Random Forest Classifier, and Support Vector Machine) by training these on magnetic parameters obtained from the Helioseismic Magnetic Imager (HMI) onboard the Solar Dynamics Observatory (SDO) during the entirety of solar cycle 24. We demonstrate that Logistic Regression and Support Vector Machine algorithms perform extremely well in forecasting active region flaring potential. The logistic regression algorithm returns the highest true skill score of 0.967±0.018, possibly the highest classification performance achieved with any parametric study alone. From a comparative assessment, we establish that the magnetic properties like total current helicity, total vertical current density, total unsigned flux, R_value, and total absolute twist are the top-performing flare indicators. We also introduce and analyze two new performance metrics, namely, Severe and Clear Space Weather indicators. Our analysis constrains the most successful ML algorithms and identifies physical parameters that contribute most to active region flare productivity.

Particle heating and acceleration by reconnecting and nonreconnecting current sheets

Nikos **Sioulas**1,2, Heinz Isliker1 and Loukas Vlahos1
A&A 657, A8 (**2022**)
https://www.aanda.org/articles/aa/pdf/2022/01/aa41361-21.pdf
https://doi.org/10.1051/0004-6361/202141361
In this article, we study the physics of charged particle energization inside a strongly turbulent plasma, where current sheets naturally appear in evolving large-scale magnetic topologies, but they are split into two populations of fractally distributed reconnecting and nonreconnecting current sheets (CS). In particular, we implemented a Monte Carlo simulation to analyze the effects of the fractality and we study how the synergy of energization at reconnecting CSs and at nonreconnecting CSs affects the heating, the power-law high energy tail, the escape time, and the acceleration time of electrons and ions. The reconnecting current sheets systematically accelerate particles and play a key role in the formation of the power-law tail in energy distributions. On the other hand, the stochastic energization of particles through their interaction with nonreconnecting CSs can account for the heating of the solar corona and the impulsive heating during solar flares. The combination of the two acceleration mechanisms (stochastic and systematic), commonly present in many explosive events of various sizes, influences the steady-state energy distribution, as well as the transport properties of the particles in position- and energy-space. Our results also suggest that the heating and acceleration characteristics of ions and electrons are similar, the only difference being the time scales required to reach a steady state.

Stationary and impulsive injection of electron beams in converging magnetic field:

T. V. **Siversky** and V. V. Zharkova
A&A 504 (**2009**) 1057-1070
http://www.aanda.org/10.1051/0004-6361/200912341
Aims. We study time-dependent precipitation of an electron beam injected into a flaring atmosphere with a converging magnetic field by considering collisional and Ohmic losses with anisotropic scattering and pitch angle diffusion. Two injection regimes are investigated: short impulse and stationary injection. The effects of converging magnetic fields with different spatial profiles are compared and the energy deposition produced by the precipitating electrons at different depths and regimes is calculated.
Methods. The time dependent Fokker-Planck equation for electron distribution in depth, energy and pitch angle was solved numerically by using the summary approximation method.
Results. Steady state injection was found to be established for beam electrons 0.07–0.2 s after the injection onset depending on the initial beam parameters. Energy deposition by a stationary beam is strongly dependent on a self-induced electric field but more weakly dependent on a magnetic field convergence. Energy depositions by short electron impulses are found to be insensitive to the self-induced electric field but are strongly affected by magnetic convergence. Short beam impulses are shown to produce sharp asymmetric hard X-ray bursts on a timescale of the order of tens of milliseconds, often observed in solar flares.

Pulsations of microwave emission from a solar flare in a twisted loop caused by intrinsic MHD oscillations

C. **Smith**, M. Gordovskyy, P.K. Browning
MNRAS **2022**
https://arxiv.org/pdf/2201.08419.pdf
We present results revealing microwave pulsations produced in a model of a flaring twisted solar coronal loop, without any external oscillatory driver. Two types of oscillations are identified: slowly-decaying oscillations with a period of about 70-75s and amplitude of about 5-10% seen in loops both with and without energetic electrons, and oscillations with period of about 40s and amplitude of a few tens of percent observed only in loops with energetic electrons for about 100s after onset of fast energy release. We interpret the longer-period oscillations as the result of a standing kink mode modulating the average magnetic field strength in the loop, whilst the short-period intermittent oscillations associated with energetic electrons are likely to be produced by fast variations of the electric field which produces energetic electrons in this scenario. The slowly-decaying oscillations can explain the quasi-periodic pulsations often observed in the flaring corona.

Information Theoretical Approach to Understanding Flare Waiting Times

Jesse M. **Snelling**, Jay R. Johnson, Jake Willard, Yosia Nurhan, Jonathan Homan, and Simon Wing
2020 ApJ 899 148
https://doi.org/10.3847/1538-4357/aba7b9
There is not currently a consensus on the process responsible for producing the waiting time distribution of solar flares. This study presents an information theoretical approach to determining whether solar flare data are significantly distinguishable from a nonstationary Poisson process. A study of solar flares stronger than C1 class detected by the Geostationary Operational Environmental Satellite from 1975 to 2017 was performed. A sequence of waiting times (time elapsed between adjacent X-ray flare peaks) was constructed from the data. Surrogate waiting time sequences were produced using a time-varying Poisson firing rate from the Bayesian block procedure. Utilizing Shannon entropy, the mutual information of time-lagged waiting time distributions was computed for both the original data and the surrogates using a method of discretization by binning. When the entire period is considered, we see that when compared to carefully constructed surrogates, there is a significant elevation of mutual information on a timescale of approximately 30 hr, demonstrating that flares are confidently related to subsequent flares, contradicting the null hypothesis that flares are produced by a nonstationary Poisson process. When only 4 yr subsets of the data are considered, we see that at relatively small timescales (on the order of 10–30 hr), solar flare waiting times have a significant impact on subsequent flares. When corrected for the number of points in each considered time window, there is no correlation between the magnitude of significance and position in the solar cycle.

Onset of 2D magnetic reconnection in the solar photosphere, chromosphere and corona

B. **Snow**, G. J.J. Botha, J. A. McLaughlin, A. Hillier
2017 A&A
https://arxiv.org/pdf/1711.00683.pdf
We investigate the onset of 2D time-dependent magnetic reconnection that is triggered using an external velocity driver located away from, and perpendicular to, an equilibrium Harris current sheet. Previous studies have typically utilised an internal trigger to initiate reconnection, e.g. initial conditions centred on the current sheet. Numerical simulations

solving the compressible, resistive magnetohydrodynamics equations were performed to investigate the reconnection onset within different atmospheric layers of the Sun, namely the corona, chromosphere and photosphere. A reconnecting state is reached for all atmospheric heights considered, with the dominant physics being highly dependent on atmospheric conditions. The coronal case achieves a sharp rise in electric field for a range of velocity drivers. For the chromosphere, we find a larger velocity amplitude is required to trigger reconnection. For the photospheric environment, the electric field is highly dependent on the inflow speed; a sharp increase in electric field is obtained only as the velocity entering the reconnection region approaches the Alfven speed. Additionally, the role of ambipolar diffusion is investigated for the chromospheric case and we find that the ambipolar diffusion alters the structure of the current density in the inflow region. The rate at which flux enters the reconnection region is controlled by the inflow velocity. This determines all aspects of the reconnection start-up process, i.e. the early onset of reconnection is dominated by the advection term in Ohms law in all atmospheric layers. A lower plasma-β enhances reconnection and creates a large change in the electric field. A high plasma-β hinders the reconnection, yielding a sharp rise in the electric field only when the velocity flowing into the reconnection region approaches the local Alfven speed.

Effects of flares on solar high-degree helioseismic acoustic mode amplitudes

M. Cristina Rabello **Soares**, Frederic Baudin, Vanessa G. Teixeira
MNRAS Volume 505, Issue 1, Pages 293–303, **2021**
https://arxiv.org/pdf/2102.13181.pdf
https://doi.org/10.1093/mnras/stab1277
Several attempts have been made to observe whether solar flares excite acoustic modes since Wolff (1972) suggested this possibility. Moreover, the rapid progress of asteroseismology and the study of stellar flares makes the study of these phenomena in the Sun important to inform our study of the influence of the more energetic stellar flares on asteroseismic acoustic modes.
We look for the impact of flares on the amplitude of solar acoustic modes and other effects that are also affecting the mode amplitude. Solar acoustic mode amplitudes are known to be sensitive to magnetic fields. As flares usually occur in the presence of strong magnetic fields and most likely are the by-product of magnetic reconnection, we show how the magnetic field in and around the flaring region affects the mode amplitude. The mode amplitudes were obtained using ring-diagram analysis, which was first applied to a single event, the largest flare in the space age (the `Halloween Flare', SOL**2003-10-28**T11:00), using MDI data. Then, using HMI data, the analysis was applied to the regions corresponding to the flares observed during the high activity phase of cycle 24 and that fall into two groups. These two groups consist of small (10-60 erg cm−2 s−1) and large (>1200 erg cm−2 s−1) peak-flux flares, based on the Heliophysics Event Knowledgebase (HEK).
After applying several corrections in order to take into account several sources of bias, we did not find any amplification in the inferred mode amplitude due to flaring activity, within a 10% uncertainty.

Slipping reconnection in a solar flare observed in high resolution with the GREGOR solar telescope

M. **Sobotka**, J. Dudík, C. Denker, H. Balthasar, J. Jurčák, W. Liu, T. Berkefeld, M. Collados Vera, A. Feller, A. Hofmann, F. Kneer, C. Kuckein, A. Lagg, R. E. Louis, O. von der Lühe, H. Nicklas, R. Schlichenmaier, D. Schmidt, W. Schmidt, M. Sigwarth, S. K. Solanki, D. Soltau, J. Staude, K. G. Strassmeier, R. Volkmer, T. Waldmann
A&A **2016**
http://arxiv.org/pdf/1605.00464v1.pdf
A small flare ribbon above a sunspot umbra in active region 12205 was observed on **November 7, 2014**, at 12:00 UT in the blue imaging channel of the 1.5 m GREGOR telescope, using a 1 A Ca II H interference filter. Context observations from the Atmospheric Imaging Assembly (AIA) onboard the Solar Dynamics Observatory (SDO), the Solar Optical Telescope (SOT) onboard Hinode, and the Interface Region Imaging Spectrograph (IRIS) show that this ribbon is part of a larger one that extends through the neighboring positive polarities and also participates in several other flares within the active region. We reconstructed a time series of 140 seconds of Ca II H images by means of the multiframe blind deconvolution method, which resulted in spatial and temporal resolutions of 0.1 arcsec and 1 s. Light curves and horizontal velocities of small-scale bright knots in the observed flare ribbon were measured. Some knots are stationary, but three move along the ribbon with speeds of 7-11 km/s. Two of them move in the opposite direction and exhibit highly correlated intensity changes, which provides evidence of a slipping reconnection at small spatial scales.

DIRECT IMAGING OF FINE STRUCTURE IN THE CHROMOSPHERE OF A SUNSPOT UMBRA

H. Socas-Navarro1, S. W. McIntosh2, R. Centeno2, A. G. de Wijn2 and B. W. Lites2
ApJ 696 1683-1688 doi: 10.1088/0004-637X/696/2/1683, **2009**
High-resolution imaging observations from the Hinode spacecraft in the Ca II H line are employed to study the dynamics of the chromosphere above a sunspot. We find that umbral flashes and other brightenings produced by the oscillation are extremely rich in fine structure, even beyond the resolving limit of our observations (0.″22). The umbra is tremendously dynamic to the point that our time cadence of 20 s does not suffice to resolve the fast lateral (probably apparent) motion of the emission source. Some bright elements in our data set move with horizontal propagation speeds of 30 km s–1. We have detected filamentary structures inside the umbra (some of which have a horizontal extension of ~1500 km) which, to our best knowledge, had not been reported before. The power spectra of the intensity fluctuations reveal a few distinct areas with different properties within the umbra that seem to correspond with the umbral cores that form it. Inside each one of these areas the dominant frequencies of the oscillation are coherent, but they vary considerably from one core to another.

String confinement of super-strong magnetic fields

A A **Solov'ev**
Monthly Notices of the Royal Astronomical Society, Volume 515, Issue 4, **2022**, Pages 4981–4989,
https://doi.org/10.1093/mnras/stac1818
A new class of force-free solutions for a horizontal magnetic filament with a circular cross-section is found, in which the magnetic field strength on the axis significantly (up to 2–3 orders of magnitude and more) exceeds the strength of the longitudinal external field that keeps the rope from lateral expansion. A weak transverse field leads to a small deviation from the force-free field structure and results in a density deficit and an increase in temperature on the rope axis. The possibility of a flare release of magnetic energy is shown when critical values of the longitudinal electric current density in the filament are reached at which ‘anomalous resistance’ occurs, caused by the development of the current ion-sound plasma instability. It turns out to be much larger than the usual Coulomb resistance. The following values are determined: the scale of the current dissipation region, the electric field strength in it, which significantly exceeds the Dreicer value, and the possible energy of accelerated charged particles (up to hundreds of MeV). The critical density of the longitudinal current at which the plasma turbulence is excited does not depend on the presence of a super-strong field on the flux-rope axis, so that the current density depends only on the electron concentration, temperature, and anomalous conductivity. However, super-strong magnetic fields can manifest themselves in the fact that, in their presence, the excitation of plasma instabilities can occur at sufficiently high electron concentrations. This effect may explain the large number of accelerated particles sometimes observed in solar flares.

FLARE ENERGY RELEASE IN MAGNETIC FLUX ROPE COMPRESSED BY THE CONVERGENT SUNSPOTS

Solov’ev1,2 A.A., Kirichek1 E.A.
Астрономия-**2018** Том 2 Солнечно-земная физика – современное состояние и перспективы С.230
http://www.izmiran.ru/library/eaas2018/eaas-2018-2.pdf
In paper [1] a new mechanism of solar flares caused by the convergence of two magnetic centers (sunspots) was suggested. According to [1], the strong X-class flare does not occur at the moment of closest approach of spots, but arises at the stage of their divergence. The authors obtained a number of empirical regularities typical for this mechanism. We propose the theoretical MHD model of the accumulation of free magnetic energy in the flux rope compressed between two approaching sunspots. This energy is released later as a power flare at the stage of their divergence.

Does the region of flare-energy release work as a vacuum-cleaner?,

Solov'ev, A., Murawski, K.,
Astrophysics and Space Science 350, 11, **2014**,
We aim to explore the unusual flare event which took place in the solar atmosphere on **September 22, 2011** and propose its theoretical interpretation. We analyze the process of energy release in the twisted magnetic flux-rope associated with the event, assuming the excitation of anomalous resistivity of turbulent plasma in the rope, and solve numerically nonlinear two-dimensional (2D) magnetohydrodynamic (MHD) equations. The analytical approach to the problem of flare-energy release show that the conditions of excitation of anomalous resistivity can be satisfied in the twisted magnetic flux-rope whose parameters fits well the SDO observational findings. One of the most remarkable properties of the flare phenomenon under the present consideration was the permanent sucking of the coronal/chromospheric gas from the very remote points to the flare filament, i.e. into the low-lying hot region of the flare energy release. This unusual phenomenon has been simulated by numerical methods in terms of ideal MHD. The numerical results reveal that siphon back-flow exhibits characteristic spatial signatures which mimic the observational

findings. The flare-energy release region, as a part of strongly twisted magnetic flux-rope, is able to work as a vacuum-cleaner.

On the magnetic reconnection of electric currents in solar flares

B. V. **Somov**
Astronomy Letters, Volume 38, Number 2, 128-138, **2012**
Astronomicheskiĭ Zhurnal, **2012**, Vol. 38, No. 2, pp. 149–160.
The role of the electric currents distributed over the volume of an active region on the Sun is considered from the standpoint of solar flare physics. We suggest including the electric currents in a topological model of the magnetic field in an active region. Typical values of the mutual inductance and the interaction energy of the coronal electric currents flowing along magnetic loops have been estimated for the M7/1N flare on **April 27, 2006**. We show that if these currents actually make a significant contribution to the flare energetics, then they must manifest themselves in the photosphericmagnetic fields. Depending on their orientation, the distributed currents can both help and hinder reconnection in the current layer at the separator during the flare. Asymmetric reconnection of the currents is accompanied by their interruption and an inductive change in energy. The reconnection of currents in flares differs significantly from the ordinary coalescence instability of magnetic islands in current layers. Highly accurate measurements of the magnetic fields in active regions are needed for a quantitative analysis of the role of distributed currents in solar flares.

Overview of open issues in the physics of large solar flares

B. V. **SOMOV,** S. I. BEZRODNYKH, L. S. LEDENTSOV
Astronomical and Astrophysical Transactions (*AApTr*), 2010/**2011**, Vol. 27, Issue 1, pp. 69–81, **File**
A broad variety of observational methods allows us to see the effect of magnetic reconnection in high-temperature strongly-magnetized plasma of the solar corona. Some specific features of the large-scale reconnection in large solar flares are summarized in this **review** but they are not investigated in detail yet. For example, an analysis of the topological peculiarities of magnetic field in active regions clearly shows that the so-called topological trigger phenomenon is necessary to allow for in order to construct realistic models for large solar flares and Coronal Mass Ejections (CMEs). However this is not a simple task. We discuss also some new analytical models of magnetic reconnection in a current layer with attached MHD discontinuities. In the context of the numerical simulations on reconnection, a question on their interpretation is considered. Some new results obtained recently are briefly reviewed together with new questions of the solar flare physics to be studied.

Magnetic reconnection and topological trigger in physics of large solar flares

Somov B.V.
Asian Journal of Physics, Vol. 17, Nos. 2-3, 421-454, **2008; File**
Solar flares are accessible to a broad variety of observational methods to see and investigate the {\em magnetic reconnection} phenomenon in high-temperature strongly-magnetized plasma of the solar corona. An analysis of the topological peculiarities of magnetic field in active regions shows that the {\em topological trigger} effect is necessary to allow for in order to construct models for large eruptive flares. The topological trigger is not a resistive instability which leads to a change of the topology of the field configuration from pre- to post reconnection state. On the contrary, the topological trigger is a quick change of the global topology, which dictates the fast reconnection of collisional or collisionless nature. The current state of the art and development potential of the theory of collisionless reconnection in

the strong magnetic fields related to large flares are briefly reviewed. Particle acceleration is considered in collapsing magnetic traps created by reconnection. In order to explain the formation of coronal X-ray sources, the Fermi acceleration and betatron mechanism are simultaneously taken into account analytically in a collisionless approximation. Finally, the emphasis is on urgent unsolved problems of solar flare physics.

Plasma Astrophysics, Part II

Reconnection and Flares

Series: Astrophysics and Space Science Library, Vol. 392, **2012**

This two-part book is devoted to classic fundamentals and current practices and perspectives of modern plasma astrophysics. This first part uniquely covers all the basic principles and practical tools required for understanding and work in plasma astrophysics. More than 25% of the text is updated from the first edition, including new figures, equations and entire sections on topics such as magnetic reconnection and the Grad-Shafranov equation.

The book is aimed at professional researchers in astrophysics, but it will also be useful to graduate students in space sciences, geophysics, applied physics and mathematics, especially those seeking a unified view of plasma physics and fluid mechanics.

The triggering process of an X-class solar flare on a small quadrupolar active region

Qiao **Song**, Jing-Song Wang, Xiaoxin Zhang, Hechao Chen, Shuhong Yang, Zhenyong Hou, Yijun Hou, Qian Ye, Peng Zhang, Xiuqing Hu, Jinping Dun, Weiguo Zong, Xianyong Bai, Bo Chen, Lingping He, Kefei Song

https://iopscience.iop.org/article/10.3847/1538-4357/acf836/pdf

The occurrence of X-class solar flares and their potential impact on the space weather often receive great attention than other flares. But predicting when and where an X-class flare will occur is still a challenge. With the multi-wavelength observation from the Solar Dynamics Observatory and FengYun- 3E satellite, we investigate the triggering of a GOES X1.0 flare occurring in the NOAA active region (AR) 12887. Our results show that this unique X-class flare is bred in a relatively small but complex quadrupolar AR. Before the X-class flare, two filaments (F1 and F2) exist below a null-point topology of the quadrupolar AR. Magnetic field extrapolation and observation reveal that F1 and F2 correspond to two magnetic flux ropes with the same chirality and their adjacent feet rooted at nonconjugated opposite polarities, respectively. Interestingly, these two polarities collide rapidly, accompanied by photospheric magnetic flux emergence, cancellation and shear motion in the AR center. Above this site, F1 and F2 subsequently intersect and merge to a longer filament (F3) via a tether-cutting-like reconnection process. As a result, the F3 rises and erupts, involving the large-scale arcades overlying filament and the quadrupolar magnetic field above the AR, and eventually leads to the eruption of the X-class flare with a quasi-X-shaped flare ribbon and a coronal mass ejection. It suggests that the rapid collision of nonconjugated opposite polarities provides a key condition for the triggering of this X-class flare, and also provides a featured case for flare trigger mechanism and space weather forecasting. **28 Oct 2021**

Spectral Observations and Modeling of a Solar White-light Flare Observed by CHASE

De-Chao **Song**, Jun Tian, Y. Li, M. D. Ding, Yang Su, Sijie Yu, Jie Hong, Ye Qiu, Shihao Rao, Xiaofeng Liu, Qiao Li, Xingyao Chen, Chuan Li, Cheng Fang
ApJ **952** L6 **2023**
https://arxiv.org/pdf/2307.12641.pdf
https://iopscience.iop.org/article/10.3847/2041-8213/ace18c/pdf
The heating mechanisms of solar white-light flares remain unclear. We present an X1.0 white-light flare on **2022 October 2** (SOL2022-10-02T20:25) observed by the Chinese \ha\ Solar Explorer (CHASE) that provides two-dimensional spectra in the visible light for the full solar disk with a seeing-free condition. The flare shows a prominent enhancement of ∼40\% in the photospheric \fe\ line at 6569.2 Å, and the nearby continuum also exhibits a maximum enhancement of ∼40\%. For the continuum near the \fe\ line at 6173 Å from the Helioseismic and Magnetic Imager (HMI) on board the Solar Dynamics Observatory (SDO), it is enhanced up to ∼20\%. At the white-light kernels, the \fe\ line at 6569.2 Å has a symmetric Gaussian profile that is still in absorption and the Hα line at 6562.8 Å displays a very broad emission profile with a central reversal plus a red or blue asymmetry. The white-light kernels are co-spatial with the microwave footpoint sources observed by the Expanded Owens Valley Solar Array (EOVSA) and the time profile of the white-light emission matches that of the hard X-ray emission above 30 keV from the Gamma-ray Burst Monitor (GBM) on Fermi. These facts indicate that the white-light emission is qualitatively related to a nonthermal electron beam. We also perform a radiative hydrodynamic simulation with the electron beam parameters constrained by the hard X-ray observations from Fermi/GBM. The result reveals that the white-light enhancement cannot be well explained by a pure electron-beam heating together with its induced radiative backwarming but may need additional heating sources such as \alfven\ waves.

A White-light Flare Powered by Magnetic Reconnection in the Lower Solar Atmosphere

Yongliang **Song**, Hui Tian, Xiaoshuai Zhu, Yajie Chen, Mei Zhang, Jingwen Zhang
ApJL **893** L13 **2020**
https://arxiv.org/pdf/2003.11747.pdf
https://doi.org/10.3847/2041-8213/ab83fa
White-light flares (WLFs), first observed in 1859, refer to a type of solar flares showing an obvious enhancement of the visible continuum emission. This type of enhancement often occurs in most energetic flares, and is usually interpreted as a consequence of efficient heating in the lower solar atmosphere through non-thermal electrons propagating downward from the energy release site in the corona. However, this coronal-reconnection model has difficulty in explaining the recently discovered small WLFs. Here we report a C2.3 white-light flare, which are associated with several observational phenomena: fast decrease in opposite-polarity photospheric magnetic fluxes, disappearance of two adjacent pores, significant heating of the lower chromosphere, negligible increase of hard X-ray flux, and an associated U-shaped magnetic field configuration. All these suggest that this white-light flare is powered by magnetic reconnection in the lower part of the solar atmosphere rather than by reconnection higher up in the corona. **2016 November 30**

Investigation of white-light emission in circular-ribbon flares

Yongliang **Song**, Hui Tian
ApJ **867** 159 **2018**
https://arxiv.org/pdf/1810.02958.pdf
sci-hub.tw/10.3847/1538-4357/aae5d1
Using observations by the Solar Dynamics Observatory from June 2010 to December 2017, we have performed the first statistical investigation of circular-ribbon flares (CFs) and examined the white-light emission in these CFs. We find 90 CFs occurring in 36 active regions (ARs), including 8 X-class, 34 M-class, 48 C- and B-class flares. The occurrence rate of white-light flares (WLFs) is 100\% (8/8) for X-class CFs, ∼62\% (21/34) for M-class CFs, and ∼8\% (4/48) for C- and B-class CFs. Sometimes we observe several CFs in a single AR, and nearly all of them are WLFs. Compared to normal CFs, CFs with white-light enhancement tend to have a shorter duration, smaller size, stronger electric current and more complicated magnetic field. We find that for X-class WLFs, the white-light enhancement is positively correlated with the flare class, implying that the white-light enhancement is largely determined by the amount of released energy. However, there is no such correlation for M- and C-class WLFs, suggesting that other factors such as the time scale, spatial scale and magnetic field complexity may play important roles in the generation of white-light emission if the released energy is not high enough. **2011 September 6, 2011.09.07, 2012.05.10, 2013 November 5, 2015.10.16, 2016.11.30**

Observations of white-light flares in NOAA active region 11515: high occurrence rate and relationship with magnetic transients

Y. L. **Song**, H. Tian, M. Zhang, M. D. Ding
A&A 613, A69 **2018**

https://arxiv.org/pdf/1801.04371.pdf
https://www.aanda.org/articles/aa/pdf/2018/05/aa31817-17.pdf
There are two goals in this study. One is to investigate how frequently white-light flares (WLFs) occur in a flare-productive active region (NOAA active region 11515). The other is to investigate the relationship between WLFs and magnetic transients (MTs). We use the full-disk continuum filtergrams and line-of-sight magnetograms taken by SDO/HMI to identify WLFs and MTs, respectively. Images taken by SDO/AIA are also used to show the morphology of the flares in the upper atmosphere. We found at least 20 WLFs out of a total of 70 flares above C class (28.6%) in NOAA active region 11515 during its passage across the solar disk. Each of these WLFs occurred in a small region, with a short duration of about 5 minutes. The enhancement of white-light continuum intensity is usually small, with an average enhancement of 8.1%. The 20 WLFs observed were found along an unusual configuration of the magnetic field characterized by a narrow ribbon of negative field. Furthermore, the WLFs were found to be accompanied by MTs, with radical changes in magnetic field strength (or even a sign reversal) observed during the flare. In contrast, there is no obvious signature of MTs in those 50 flares without white-light enhancements. Our results suggest that WLFs occur much more frequently than what was previously thought, with most WLFs being fairly weak enhancements. This may explain why WLFs are not frequently reported. Our observations also suggest that MTs and WLFs are closely related and appear co-spatial and co-temporal, when considering HMI data. A larger enhancement of WL emission is often accompanied by a larger change of the line-of-sight component of the unsigned magnetic field. Considering the close relationship between MTs and WLFs, many previously reported flares with MTs may be WLFs. **2012.07.03-06**

Observations of a white-light flare associated with a filament eruption

Y. L. **Song**, Y. Guo, H. Tian, X. S. Zhu, M. Zhang, Y. J. Zhu
ApJ **854** 64 **2018**
https://arxiv.org/pdf/1801.04408.pdf
http://sci-hub.tw/http://iopscience.iop.org/0004-637X/854/1/64/
We present observations of an M5.7 white-light flare (WLF) associated with a small filament eruption in NOAA active region 11476 on **2012 May 10**. During this flare, a circular flare ribbon appeared in the east and a remote brightening occurred in the northwest of the active region. Multi-wavelength data are employed to analyze the WLF, including white light (WL), ultraviolet, extreme ultraviolet, hard X-ray (HXR) and microwave. A close spatial and temporal relationship between the WL, HXR and microwave emissions is found in this WLF. However, the peak time of the WL emission lagged that of the HXR and microwave emissions by about 1-2 minutes. Such a result tends to support the back-warming mechanism for the WL emission. Interestingly, the enhanced WL emission occurred at the two footpoints of the filament. Through forced and potential field extrapolations, we find that the three-dimensional magnetic field in the flare region has a fan-spine feature and that a flux rope lies under the dome-like field structure. We describe the entire process of flare evolution into several steps, each producing the sequent brightening below the filament, the circular flare ribbons and the WL enhancement respectively. We suggest that reconnection between the magnetic field of the filament and the overlying magnetic field or reconnection within the flux rope leads to the WL enhancement.

On the relationship between sunspot structure and magnetic field changes associated with solar flares

Yongliang **Song**, Mei Zhang
2016 *ApJ* **826** 173
http://arxiv.org/pdf/1605.01163v1.pdf
Many previous studies have shown that magnetic fields as well as sunspot structures present rapid and irreversible changes associated with solar flares. In this paper we first use five X-class flares observed by SDO/HMI to show that not only the magnetic fields and sunspot structures do show rapid, irreversible changes but also these changes are closely related, both spatially and temporally. The magnitudes of the correlation coefficients between the temporal variations of horizontal magnetic field and sunspot intensity are all larger than 0.90, with a maximum value of 0.99 and an average value of 0.96. Then using four active regions in quiescent times, three observed and one simulated, we show that in sunspot penumbra regions there also exists a close correlation between sunspot intensity and horizontal magnetic field strength, in addition to the well-known one between sunspot intensity and normal magnetic field strength. Connecting these two observational phenomena, we show that the sunspot structure change and the magnetic field change are the two facets of the same phenomena of solar flares, one change might be induced by the change of the other due to a linear correlation between sunspot intensity and magnetic field strength out of a local force balance.

Dark Post-Flare Loops Observed by Solar Dynamics Observatory

Qiao **Song**, Jing-Song Wang, Xueshang Feng, Xiaoxin Zhang
ApJ **821** 83 **2016**
http://arxiv.org/pdf/1604.01510v1.pdf

Solar post-flare loops (PFLs) are arcade-like loop systems that appear during the gradual phases of eruptive flares. The extreme ultraviolet (EUV) observations from the Atmospheric Imaging Assembly (AIA) on board the Solar Dynamics Observatory (SDO) allow us to investigate the fine structures in PFLs. In this work, we focus on studying the dark post-flare loops (DPFLs) during X-class flares, which are more evident in SDO/AIA data than in previous EUV data. We identify and analyze the DPFLs observed by SDO and find that: (1) the DPFLs of an X5.4 flare have an average lifetime of 10.0 ± 5.5 minutes, an average width of 1022 ± 339 km, and an average maximum length of 33 ± 10 Mm, (2) blob-like falling features with a size close to the resolution of SDO/AIA are identified in the DPFLs and they have an average velocity of 76 ±19 km s−1, and (3) the average widths of the DPFLs slightly increase with the characteristic temperatures in AIA 304, 171, 193, and 211 {\AA} channels. Our investigation shows that DPFLs are found in all of the 20 cases within this study, which suggests that they are a common phenomenon in X-class flares and are probably produced by the same mechanism that creates coronal rain. **2011-09-22, 2011-09-24, 2012=01=27, 2012 March 7. 2012-07-12, 2014 February 25**

Flares and magnetic non-potentiality of NOAA AR 11158

Qiao **Song**, Jun Zhang, Shu-Hong Yang, Yang Liu
E-print, Jan **2013**
Magnetic non-potentiality is important for understanding flares and other solar activities in active regions (ARs). Five non-potential parameters, i.e. Electric current, current helicity, source field, photospheric free energy, and angular shear, are calculated to quantify the non-potentiality of NOAA AR 11158. Benefitting from the high spatial resolution, high cadence and continuous temporal coverage of vector magnetograms from the Helioseismic and Magnetic Imager onboard the Solar Dynamics Observatory, both the long-term evolution of the AR and the rapid change during flares are studied. We confirm that, compared with the magnetic flux, the magnetic non-potentiality has a closer connection with the flare, and the emerging flux regions are important for understanding the magnetic non-potentiality and flares. The main results are as follows. (1) The vortex in the source field directly displays the deflection of the horizontal magnetic field. The deflection corresponds to the fast rotating sunspot with a time delay, which suggests that the sunspot rotation leads to an increase in the non-potentiality. (2) Two areas that have evident changes in the azimuth of the vector magnetic field are found near the magnetic polarity inversion line. The change rates of the azimuth are about 1.3? h−1 and 3.6? h−1, respectively. (3) Rapid and prominent increases are found in the variation of helicity during four flares in the regions where their initial brightening occurs. The recovery of the increases takes 3?4 h for the two biggest flares (X2.2 and M6.6), but only takes about 2 h for the two other smaller flares (M2.2 and M1.6). **2011 February 12 to 16**

CO-ANALYSIS OF SOLAR MICROWAVE AND HARD X-RAY SPECTRAL EVOLUTIONS. I. IN TWO FREQUENCY OR ENERGY RANGES

Qiwu **Song**1, Guangli Huang1 and Hiroshi Nakajima
2011 ApJ 734 113
Solar microwave and hard X-ray spectral evolutions are co-analyzed in the **2000 June 10 and 2002 April 10** flares, and are simultaneously observed by the Owens-Valley Solar Array in the microwave band and by Yohkoh/Hard X-ray Telescope or RHESSI in the hard X-ray band, with multiple subpeaks in their light curves. The microwave and hard X-ray spectra are fitted by a power law in two frequency ranges of the optical thin part and two photon energy ranges, respectively. Similar to an earlier event in Shao & Huang, the well-known soft-hard-soft pattern of the lower energy range changed to the hard-soft-hard (HSH) pattern of the higher energy range during the spectral evolution of each subpeak in both hard X-ray flares. This energy dependence is actually supported by a positive correlation between the overall light curves and spectral evolution in the lower energy range, while it becomes an anti-correlation in the higher energy range. Regarding microwave data, the HSH pattern appears in the spectral evolution of each subpeak in the lower frequency range, which is somewhat similar to Huang & Nakajima. However, it returns back to the well-known pattern of soft-hard-harder for the overall spectral evolution in the higher frequency range of both events. This frequency dependence is confirmed by an anti-correlation between the overall light curves and spectral evolution in the lower frequency range, but it becomes a positive correlation in the higher frequency range. The possible mechanisms are discussed, respectively, for reasons why hard X-ray and microwave spectral evolutions have different patterns in different energy and frequency intervals.

Statistical Assessment of Photospheric Magnetic Features in Imminent Solar Flares Predictions

Hui **Song**, Vasyl Yurchyshyn, Ju Jing, Changyi Tan, V.I. Abramenko and Haimin Wang
BBSO, Number: 1338, 2007; Solar Phys (**2009**) 254: 101–125
Abstract: In this study we used the ordinal logistic regression method to establish a prediction model, which estimates the probability for each solar active region to produce X-, M- or C-class flares during the next 1-day time period. Three predictive

parameters are: (1) total unsigned magnetic flux T_{flux}, which is a measure of an active region's size, (2) the length of strong-gradient neutral line L_{gnl}, which describes the global non-potentiality of an active region, and (3) total magnetic dissipation E_{diss}, which is another proxy measure of an active region's non-potentiality. They are all derived from SOHO MDI magnetograms. The ordinal response variable is the different level of solar flares magnitude. By analyzing 230 active regions, L_{gnl} is proved to be the most powerful predictor, if only one predictor is chosen. Compared with the current predictions methods used by Solar Monitor at Solar Data Analysis Center (SDAC) and NOAA Space Environment Center (SEC), the ordinal logistic model using L_{gnl} and T_{flux} as predictors demonstrated its automaticity, simpleness and fairly high prediction accuracy. To our knowledge, this is the first time the ordinal logistic regression model was used in solar physics to predict solar flares.

Exhaustive study of three-time periods of solar activity due to single active regions: sunspot, flare, CME, and, geo-effective characteristics

Shirsh Lata **Soni**, Manohar Lal Yadav, Radhe Syam Gupta, Pyare lal Verma
Astrophysics and space science journal **2020**
https://arxiv.org/ftp/arxiv/papers/2012/2012.04853.pdf
In this paper, we present the multi-wavelength study of a high level of solar activity during which a single active region produced multiple flares/CMEs. According to the sunspot observations, the current solar cycle 24 manifest to be less intense in comparison with the previous recent sunspot cycles. In the course of the current sunspot cycle 24, several small and large sunspot groups have produced various moderate and intense flare/CME events. There are a few active regions with a large number of flaring activities passed across the visible disk of the Sun during 2012-2015. In this study, we consider the three periods **22-29 Oct 2013, 01-08 Nov 2013, and 25 Oct- 08-Nov 2014**, during which 228 flares have been observed. Considering only active regions near the central part of the disk, 59 CMEs (halo or partial) have been reported among which only 39 events are associated with flares. We conclude that an active region with a larger area, more complex morphology and stronger magnetic field has a comparatively higher possibility of producing extremely fast CMEs (speed > 1500 km/sec). So that among the 5 X class flares of the reported periods, 3 of them (60%) are associated with a CME. The lift-off time for CME-flare associated events has a +15 to+30 minute time interval range after the occurrence time of associated flares suggesting that the flares produce the CMEs. Additionally, we compiled the geomagnetic storms occurring within1-5 days after the CME onset. 10% of the 59 CMEs are related to a magnetic storm but all are moderate storms.

Multi-wavelength Study of Energetic Processes during Solar Flares occurrence

Shirsh Lata **Soni**, Radhe Shyam Gupta, Adya Prasad Mishra
Research in astronomy and Astrophysics **2020**
https://arxiv.org/ftp/arxiv/papers/2005/2005.11829.pdf
This paper is an attempt to understand the physical processes occurring in different layers of solar atmosphere during a solar flare. For a complete understanding of the flare we must analyze multi-wavelength datasets, as emission at different wavelength originates from different layers of the solar atmosphere. Also, flares are transient and localized events observed to occur at all longitudes. With these considerations, we have carried out multi-wavelength analysis of two representative flare events. One event occurred close to the centre of the solar disk and other occurred close to the limb. In the former case, we examine the emission from the lower layers of the solar atmosphere. Therefore the chromospheres, transition region and also the photospheric magneto-gram can be analyzed. On the other hand, in near-limb event, coronal features can be clearly studied. In this paper, the first event studied is the M 1.1 class flare from the active region NOAA 10649 located at S10E14 and the second event is the M 1.4 class flare from the active region NOAA 10713 located at S12W90. In both cases, we have observed the excellent multi-wavelength data sets. The observations from multi-instrumental data clearly shows that flares occur in the vicinity of sunspots. These are regions of strong magnetic field with mixed polarity. **17 July 2004, 29 December2004**

On the differences in the periodic behaviour of magnetic helicity flux in flaring active regions with and without X-class events

Sz. **Soós**, M. B. Korsós, H. Morgan, R. Erdélyi
ApJ **925** 129 **2022**
https://arxiv.org/pdf/2112.05933.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ac4094/pdf
Observational pre-cursors of large solar flares provide a basis for future operational systems for forecasting. Here, we study the evolution of the normalized emergence (EM), shearing (SH) and total (T) magnetic helicity flux components for 14 flaring with at least one X-class flare) and 14 non-flaring (< M5-class flares) active regions (ARs) using the Spaceweather Helioseismic Magnetic Imager Active Region Patches vector magnetic field data. Each of the selected ARs contain a δ-type spot. The three helicity components of these ARs were analyzed using wavelet analysis. Localised

peaks of the wavelet power spectrum (WPS) were identified and statistically investigated. We find that: i) the probability density function of the identified WPS peaks for all the EM, SH and T profiles can be fitted with a set of Gaussian functions centered at distinct periods between ~ 3 to 20 hours. ii) There is a noticeable difference in the distribution of periods found in the EM profiles between the flaring and non-flaring ARs, while no significant difference is found in the SH and T profiles. iii) In flaring ARs, the distributions of the shorter EM/SH/T periods (< 10 hrs) split up into two groups after flares, while the longer periods (> 10 hrs) do not change. iv) When the EM periodicity does not contain harmonics, the ARs do not host a large energetic flare. Finally, v) significant power at long periods (~ 20 hour) in the T and EM components may serve as pre-cursor for large energetic flares.
Table 1. Summary table of the studied 28 active regions (AR 11158-12740)

Analysis of Lower Hybrid Drift Waves in Kappa Distributions over Solar Atmosphere

Antony **Soosaleon**, Blesson Jose
2021
https://arxiv.org/pdf/2102.01323.pdf
Kappa distributions and with loss cone features have been frequently observed with flares emissions with the signatures of Lower hybrid waves. We have analysed the plasma with Kappa distributions and with loss cone features for the drift wave instabilities in perpendicular propagation for Large flare and Normal flare and Coronal condition . While analysing the growth/damping rate, we understand that the growth of propagation of EM waves increases with kappa distribution index for all the three cases. In comparing the propagation large flare shows lesser growth in compared with the normal and the coronal plasmas. When added the loss cone features to Kappa distributions, we find that the damping of EM wave propagation takes place. The damping rate EM waves is increases with perpendicular temperature and loss cone index l, in all the three cases but damping is very high for large flare and then normal in comparision with coronal condition. This shows that the lower hybrid damping may be the source of coronal heating.

Sign singularity and flares in solar active region NOAA 11158

Luca **Sorriso-Valvo**, Gaetano De Vita, Maria D. Kazachenko, Sam Krucker, Leonardo Primavera,Sergio Servidio, Antonio Vecchio, Brian T. Welsch, George H. Fisher, Fabio Lepreti, Vincenzo Carbone
2015 *ApJ* **801** 36
http://arxiv.org/pdf/1501.04279v1.pdf
Solar Active Region NOAA 11158 has hosted a number of strong flares, including one X2.2 event. The complexity of current density and current helicity are studied through cancellation analysis of their sign-singular measure, which features power-law scaling. Spectral analysis is also performed, revealing the presence of two separate scaling ranges with different spectral index. The time evolution of parameters is discussed. Sudden changes of the cancellation exponents at the time of large flares, and the presence of correlation with EUV and X-ray flux, suggest that eruption of large flares can be linked to the small scale properties of the current structures. **10-17 Feb 2011**, **2011/02/15**

A CRITICAL EXAMINATION OF THE FUNDAMENTAL ASSUMPTIONS OF SOLAR FLARE AND CORONAL MASS EJECTION MODELS

D. S. **Spicer**1, R. Bingham2,3, and R. Harrison
2013 ApJ 768 8
The fundamental assumptions of conventional solar flare and coronal mass ejection (CME) theory are re-examined. In particular, the common theoretical assumption that magnetic energy that drives flares and CMEs can be stored in situ in the corona with sufficient energy density is found wanting. In addition, the observational constraint that flares and CMEs produce non-thermal electrons with fluxes of order 1034-1036 electrons s–1, with energies of order 10-20 keV, must also be explained. This constraint when imposed on the "standard model" for flares and CMEs is found to miss the mark by many orders of magnitude. We suggest, in conclusion, there are really only two possible ways to explain the requirements of observations and theory: flares and CMEs are caused by mass-loaded prominences or driven directly by emerging magnetized flux.

Velocity Response of the Observed Explosive Events in the Lower Solar Atmosphere. I. Formation of the Flowing Cool-loop System

A. K. **Srivastava**1, Yamini K. Rao1, P. Konkol2, K. Murawski2, M. Mathioudakis3, Sanjiv K. Tiwari4,5, E. Scullion6, J. G. Doyle7, and B. N. Dwivedi1
2020 ApJ 894 155
https://doi.org/10.3847/1538-4357/ab86bb
We observe plasma flows in cool loops using the Slit-Jaw Imager on board the Interface Region Imaging Spectrometer (IRIS). Huang et al. observed unusually broadened Si iv 1403 Å line profiles at the footpoints of such loops that were attributed to signatures of explosive events (EEs). We have chosen one such unidirectional flowing cool-loop system observed by IRIS where one of the footpoints is associated with significantly broadened Si iv line profiles. The line-profile broadening indirectly indicates the occurrence of numerous EEs below the transition region (TR), while it

directly infers a large velocity enhancement/perturbation, further causing the plasma flows in the observed loop system. The observed features are implemented in a model atmosphere in which a low-lying bipolar magnetic field system is perturbed in the chromosphere by a velocity pulse with a maximum amplitude of 200 km s−1. The data-driven 2D numerical simulation shows that the plasma motions evolve in a similar manner as observed by IRIS in the form of flowing plasma filling the skeleton of a cool-loop system. We compare the spatio-temporal evolution of the cool-loop system in the framework of our model with the observations, and conclude that their formation is mostly associated with the velocity response of the transient energy release above their footpoints in the chromosphere/TR. Our observations and modeling results suggest that the velocity responses most likely associated to the EEs could be one of the main candidates for the dynamics and energetics of the flowing cool-loop systems in the lower solar atmosphere.

MHD Seismology as a Tool to Diagnose the Coronae of X-ray Active Sun-like Flaring Stars

A.K. **Srivastava**, S. Lalitha

E-print, Sept **2013**, The Proceedings of ISSTP-2012

It is now well accepted that the detection of impulsively generated multiple MHD modes are potentially used in diagnosing the local plasma conditions of the solar corona. Analogously, such analyses can also be significantly used in diagnosing the coronae of X-ray active Sun-like stars. In the present paper, we briefly review the detection of MHD modes in coronae of some X-ray active Sun-like stars, e.g. Proxima Centauri, XI-Boo etc using XMM-Newton observations, and discuss the implications in deriving physical information about their localized magnetic atmosphere. We conclude that the refinement in the MHD seismology of solar corona is also providing the best analogy to develop the stellar seismology of magnetically active and flaring Sun-like stars to deduce the local physical conditions of their coronae.

X6.9-class Flare Induced Vertical Kink Oscillations in a Large-Scale Plasma Curtain as Observed by SDO/AIA

A.K. **Srivastava**, M. Goossens

E-print, Sept **2013**; **2013** ApJ 777 17

We present rare observational evidence of vertical kink oscillations in a laminar and diffused large-scale plasma curtain as observed by the Atmospheric Imaging Assembly (AIA) on board the Solar Dynamics Observatory (SDO). The X6.9 class flare in the Active Region 11263 on **09 August 2011**, induces a global large-scale disturbance that propagates in a narrow lane above the plasma curtain and creates a low density region that appears as a dimming in the observational image data. This large-scale propagating disturbance acts as a non-periodic driver that interacts asymmetrically and obliquely with the top of the plasma curtain, and triggers the observed oscillations. In the deeper layers of the curtain, we find evidence of vertical kink oscillations with two periods (795 s and 530 s). On the magnetic surface of the curtain where the density is inhomogeneous due to the coronal dimming, non-decaying vertical oscillations are also observed (period approx 763-896 s). We infer that the global large-scale disturbance triggers vertical kink oscillations in the deeper layers as well as on the surface of the large-scale plasma curtain. The properties of the excited waves strongly depend on the local plasma and magnetic field conditions.

Discovery of the Sausage-Pinch Instability in Solar Corona

Abhi K. **Srivastava**1, R. Erdélyi2, V. Fedun2, P. Kayshap1, N.C. Joshi1, D. Tripathi

UKSP nugget 34, **2013.** http://www.uksolphys.org/?p=6158

A wide range of MHD instabilities have been observed in recent years in association with various solar dynamical processes. An instability known as the sausage instability (m = 0) mode, which is theoretically investigated in astrophysical plasma [7,9,10], has – to the best of our knowledge - not yet been observed in the solar atmosphere (although it is worth mentioning that sausage oscillations of the stable flux-tubes are well-observed [11,12,13]). In this nugget, we outline in brief the discovery of the sausage-pinch instability in the solar corona, in an activated partial filament eruption observed by SDO/AIA.

These types of magnetic instabilities can act as canonical plasma processes to trigger large-scale solar eruptions**.**

12 September 2011

OBSERVATIONAL EVIDENCE OF SAUSAGE-PINCH INSTABILITY IN SOLAR CORONA BY SDO/AIA

A. K. **Srivastava**1, R. Erdélyi2, Durgesh Tripathi3, V. Fedun2,4, N. C. Joshi1, and P. Kayshap

2013 ApJ 765 L42

We present the first observational evidence of the evolution of sausage-pinch instability in active region 11295 during a prominence eruption using data recorded on **2011 September 12** by the Atmospheric Imaging Assembly (AIA) onboard the Solar Dynamics Observatory (SDO). We have identified a magnetic flux tube visible in AIA 304 Å that shows curvatures on its surface with variable cross-sections as well as enhanced brightness. These curvatures evolved and thereafter smoothed out within a timescale of a minute. The curved locations on the flux tube exhibit a radial outward enhancement of the surface of about 1-2 Mm (a factor of two larger than the original thickness of the flux tube) from

the equilibrium position. AIA 193 Å snapshots also show the formation of bright knots and narrow regions in-between at the four locations as that of 304 Å along the flux tube where plasma emission is larger compared to the background. The formation of bright knots over an entire flux tube as well as the narrow regions in <60 s may be the morphological signature of the sausage instability. We also find the flows of confined plasma (propagation of brightness) in these bright knots along the field lines, which indicates the dynamicity of the flux tube that probably causes the dominance of the longitudinal field component over short temporal scales. The observed longitudinal motion of the plasma frozen in the magnetic field lines further vanishes the formed curvatures and plasma confinements as well as growth of instability to stabilize the flux tube.

Multiwavelength Observations of Supersonic Plasma Blob Triggered by Reconnection-Generated Velocity Pulse in AR10808

A.K. **Srivastava**, R. Erdélyi, K. Murawski, Pankaj Kumar
Solar Phys., 281(2), 729-747, **2012**
Using multi-wavelength observations of Solar and Heliospheric Observatory (SoHO)/Michelson Doppler Imager (MDI), Transition Region and Coronal Explorer (TRACE, 171 Å), and Hα from Culgoora Solar Observatory at Narrabri, Australia, we present a unique observational signature of a propagating supersonic plasma blob before an M6.2-class solar flare in active region 10808 on **9 September 2005**. The blob was observed between 05:27 UT and 05:32 UT with almost a constant shape for the first 2 – 3 min, and thereafter it quickly vanished in the corona. The observed lower-bound speed of the blob is estimated as ≈ 215 km s−1 in its dynamical phase. The evidence of the blob with almost similar shape and velocity concurrent in Hα and TRACE 171 Å images supports its formation by a multi-temperature plasma. The energy release by a recurrent three-dimensional reconnection process via the separator dome below the magnetic null point, between the emerging flux and pre-existing field lines in the lower solar atmosphere, is found to be the driver of a radial velocity pulse outwards that accelerates this plasma blob in the solar atmosphere. In support of identification of the possible driver of the observed eruption, we solve the two-dimensional ideal magnetohydrodynamic equations numerically to simulate the observed supersonic plasma blob. The numerical modelling closely match the observed velocity, evolution of multi-temperature plasma, and quick vanishing of the blob found in the observations. Under typical coronal conditions, such blobs may also carry an energy flux of 7.0×106 erg cm−2 s−1 to balance the coronal losses above active regions.

OBSERVATIONS OF POST-FLARE PLASMA DYNAMICS DURING AN M1.0 FLARE IN AR11093 BY THE SOLAR DYNAMICS OBSERVATORY/ATMOSPHERIC IMAGING ASSEMBLY*

Abhishek K. **Srivastava**1,2 and K. Murawski
2012 ApJ 744 173
We observe the motion of cool and hot plasma in a multi-stranded post-flare loop (PFL) system that evolved in the decay phase of a two-ribbon M1.0 class flare in AR 11093 on **2010 August 7** using the Solar Dynamics Observatory/Atmospheric Imaging Assembly 304 Å and 171 Å filters. The moving intensity feature and its reflected counterpart are observed in the loop system at multiple temperatures. The observed hot counterpart of the plasma probably envelopes the cool confined plasma and moves comparatively faster (~34 km s–1) than the latter (29 km s–1) in the form of a spreading intensity feature. The propagating plasma and intensity reflect from the region of another footpoint of the loop. The subsonic speed of the moving plasma and associated intensity feature may be most likely evolved in the PFL system through impulsive flare heating processes. Complementing our observations of moving multi-temperature intensity features in the PFL system and its reflection, we also attempt to solve two-dimensional ideal magnetohydrodynamic equations numerically using the VAL-IIIC atmosphere as an initial condition to simulate the observed plasma dynamics. We consider a localized thermal pulse impulsively generated near one footpoint of the loop system during the flare processes, which is launched along the magnetic field lines at the solar chromosphere. The pulse steepens into a slow shock at higher altitudes while moving along this loop system, which triggers plasma perturbations that closely exhibit the observed plasma dynamics.

Transient induced MHD oscillations : A tool to probe the solar active regions

Srivastava, Abhishek K.; Nakariakov, V. M.; Dwivedi, B. N.; Kumar, Pankaj
E-print, Oct **2011**. Proc. of the 1st Asian-Pacific Solar Phys. Meeting
Solar transients and eruptive phenomena which are ubiquitous in the solar atmosphere, can shed new light to the understanding of the outstanding problems like coronal heating and the solar wind acceleration. Observations in the entire electromagnetic spectrum of such dynamical processes of large and small-scale transient/eruptive events, with highly dynamic magnetic field configuration, and energetic particles, provide crucial information about the plasma processes at mega-Kelvin temperature embedded in a complex magnetic field, and also energy build-up/energy-release processes, taking place in such events. One of the most important phenomenological aspects of solar eruptive phenomena is the induced magnetohydrodynamic (MHD) waves generated during these energetic processes, which carry a potential signature to probing the solar active regions. In this paper, we briefly review the recent trends of the

transient (e.g., flares) induced quasi-periodic oscillations in the solar atmosphere and discuss their implications in diagnosing the solar active regions, providing the clue to understanding local plasma dynamics and heating.

Observation of Kink Instability as Driver of Recurrent Flares in AR 10960

Srivastava, A. K.; Kumar, Pankaj; Zaqarashvili, T. V.; Filippov, B. P.; Khodachenko, M. L.; Uddin, Wahab
E-print Jan **2011**; Publication in Advances in Geosciences

We study the active region NOAA 10960, which produces two flare events (B5.0, M8.9) on **04 June 2007**. We find the observational signature of right handed helical twists in the loop system associated with this active region. The first B5.0 flare starts with the activation of helical twist showing ~3 turns. However, after ~20 minutes another helical twist (with ~2 turns) appears, which triggers M8.9 flare. Both helical structures were closely associated with a small positive polarity sunspot in the AR. We interpret these observations as evidence of kink instability, which triggers the recurrent solar flares.

OBSERVATION OF KINK INSTABILITY DURING SMALL B5.0 SOLAR FLARE ON 2007 JUNE 4

A. K. **Srivastava**1, T. V. Zaqarashvili2,3, Pankaj Kumar1, and M. L. Khodachenko2
Astrophysical Journal, 715:292–299, **2010** May

Using multi-wavelength observations of *SOHO*/MDI, SOT–*Hinode*/blue-continuum (4504 Å), *G* band (4305 Å), Ca ii H (3968 Å), and TRACE 171 Å, we present the observational signature of a highly twisted magnetic loop in AR 10960 during the period 04:43 UT–04:52 UT on 2007 June 4. SOT–*Hinode*/blue-continuum (4504 Å) observations show that penumbral filaments of positive polarity sunspot have counterclockwise twist, which may be caused by the clockwise rotation of the spot umbrae. The coronal loop, whose one footpoint is anchored in this sunspot, shows strong right-handed twist in chromospheric SOT–*Hinode*/Ca ii H (3968 Å) and coronal TRACE 171Å images. The length and the radius of the loop are $L \sim 80$ Mm and $a \sim 4.0$ Mm, respectively. The distance between neighboring turns of magnetic field lines (i.e., pitch) is estimated as ≈10 Mm. The total twist angle, $\sqrt{} \sim 12\pi$ (estimated for the homogeneous distribution of the twist along the loop), is much larger than the Kruskal–Shafranov instability criterion. We detected clear double structure of the loop top during 04:47 UT–04:51 UT on TRACE 171Å images, which is consistent with simulated kink instability in curved coronal loops.We suggest that the kink instability of this twisted magnetic loop triggered a B5.0 class solar flare, which occurred between 04:40 UT and 04:51 UT in this active region.

Spatially inhomogeneous acceleration of electrons in solar flares

Duncan J. **Stackhouse**, Eduard P. Kontar
A&A 612, A64 **2018**
https://arxiv.org/pdf/1801.04743.pdf
sci-hub.se/10.1051/0004-6361/201730708

The imaging spectroscopy capabilities of the Reuven Ramaty high energy solar spectroscopic imager (RHESSI) enable the examination of the accelerated electron distribution throughout a solar flare region. In particular, it has been revealed that the energisation of these particles takes place over a region of finite size, sometimes resolved by RHESSI observations. In this paper, we present, for the first time, a spatially distributed acceleration model and investigate the role of inhomogeneous acceleration on the observed X-ray emission properties. We have modelled transport explicitly examining scatter-free and diffusive transport within the acceleration region and compare with the analytic leaky-box solution. The results show the importance of including this spatial variation when modelling electron acceleration in solar flares. The presence of an inhomogeneous, extended acceleration region produces a spectral index that is, in most cases, different from the simple leaky-box prediction. In particular, it results in a generally softer spectral index than predicted by the leaky-box solution, for both scatter-free and diffusive transport, and thus should be taken into account when modelling stochastic acceleration in solar flares. **2011 Feb 24**

Analysis and Modeling of High-frequency Emission and Deep Seismic Sources of Sunquakes

John T. **Stefan**1 and Alexander G. Kosovichev1,2
2022 ApJL 937 L26
https://arxiv.org/pdf/2209.11286.pdf
https://iopscience.iop.org/article/10.3847/2041-8213/ac8f92/pdf

Recent work published by Lindsey et al. find evidence for a deep and compact seismic source for the sunquake associated with the **2011 July 30** M9.3 flare, as well as seismic emission extending up to 10 mHz. We examine the sunquake independently, and a possible wave front is found in the 8 mHz band, though no wave front is easily discernible in the 10 mHz band. Additionally, we perform numerical simulations of seismic excitation modeled with the reported parameters and changes in the power spectra with increasing depth of the excitation source are examined. It is

found that the peak frequency decreases for increasing depths, but a shallow minimum is indicated between z = 0 and z = −840 km. Analysis of the suspected wave front of the M9.3 sunquake finds that the power spectrum of the reported seismic emission is close to that of background oscillations, though with a peak frequency noticeably lower than the background peak. Additionally, it is found that the amplitude of the source estimated by Lindsey et al. is too low to produce the observed wave front.

Estimation of Key Sunquake Parameters through Hydrodynamic Modeling and Cross-Correlation Analysis

John T. **Stefan**, Alexander G. Kosovichev
ApJ **2019**
https://arxiv.org/pdf/1911.06839.pdf
Sunquakes are one of the more distinct secondary phenomena related to solar flares, where energy deposition in the lower layers of the Sun's atmosphere excites acoustic waves easily visible in HMI dopplergrams. We explore two possible sources of sunquakes in the context of the electron beam hypothesis, as an instantaneous transfer of momentum and as a gradual applied force. We model the sunquake excitation and compare with five observed sunquake events using a cross-correlation analysis. We find that at least half the events studied are consistent with the electron beam hypothesis and estimate the energy required to excite the sunquakes to be within the range determined by previous studies. **2012 Oct 23, 2013 Nov 5, 2014 Mar 29, 2015 Sep 30, 2017 Sep 6**

A novel technique to measure intensity fluctuations in EUV images and to detect coronal sound waves nearby active regions*

G. **Stenborg**1, E. Marsch2, A. Vourlidas3, R. Howard3 and K. Baldwin4
A&A 526, A58 (**2011**)
Context. In the past years, evidence for the existence of outward-moving (Doppler blue-shifted) plasma and slow-mode magneto-acoustic propagating waves in various magnetic field structures (loops in particular) in the solar corona has been found in ultraviolet images and spectra. Yet their origin and possible connection to and importance for the mass and energy supply to the corona and solar wind is still unclear. There has been increasing interest in this problem thanks to the high-resolution observations available from the extreme ultraviolet (EUV) imagers on the Solar TErrestrial RElationships Observatory (STEREO) and the EUV spectrometer on the Hinode mission.
Aims. Flows and waves exist in the corona, and their signatures appear in EUV imaging observations but are extremely difficult to analyse quantitatively because of their weak intensity. Hence, such information is currently available mostly from spectroscopic observations that are restricted in their spatial and temporal coverage. To understand the nature and origin of these fluctuations, imaging observations are essential. Here, we present measurements of the speed of intensity fluctuations observed along apparently open field lines with the Extreme UltraViolet Imagers (EUVI) onboard the STEREO mission. One aim of our paper is to demonstrate that we can make reliable kinematic measurements from these EUV images, thereby complementing and extending the spectroscopic measurements and opening up the full corona for such an analysis. Another aim is to examine the assumptions that lead to flow versus wave interpretation for these fluctuations.
Methods. We have developed a novel image-processing method by fusing well established techniques for the kinematic analysis of coronal mass ejections (CME) with standard wavelet analysis. The power of our method lies with its ability to recover weak intensity fluctuations along individual magnetic structures at any orientation , anywhere within the full solar disk , and using standard synoptic observing sequences (cadence <3 min) without the need for special observation plans.
Results. Using information from both EUVI imagers, we obtained wave phase speeds with values on the order of 60–90 km s-1, compatible with those obtained by other previous measurements. Moreover, we studied the periodicity of the observed fluctuations and established a predominance of a 16-min period, and other periods that seem to be multiples of an underlying 8-min period.
Conclusions. The validation of our analysis technique opens up new possibilities for the study of coronal flows and waves, by extending it to the full disk and to a larger number of coronal structures than has been possible previously. It opens up a new scientific capability for the EUV observations from the recently launched Solar Dynamics Observatory. Here we clearly establish the ubiquitous existence of sound waves which continuously propagate along apparently open magnetic field lines.

Scattering Polarization in Solar Flares

Jiri **Stepan** and Petr Heinzel
RHESSI Science Nuggets, October **2013**, No. 210
http://sprg.ssl.berkeley.edu/~tohban/wiki/index.php/Scattering_Polarization_in_Solar_Flares
We call the direct excitation of polarization "impact polarization." Like any process creating spectral line polarization, impact polarization results from an anisotropy of the medium in which the lines are formed. In particular, the impact-polarization models assume that the distribution of velocities of particles is not isotropic. If the atoms of the plasmas

collide with these anisotropically moving particles, the subsequent photons emitted from the atoms are linearly polarized. (see **2013** ApJ 778 L6)

The nature of separator current layers in MHS equilibria I. Current parallel to the separator

J. E. H. **Stevenson**, C. E. Parnell, E. R. Priest and A. L. Haynes
A&A 573, A44 (**2015**)
Context. Separators, which are in many ways the three-dimensional equivalent to two-dimensional nulls, are important sites for magnetic reconnection. Magnetic reconnection occurs in strong current layers which have very short length scales.
Aims. The aim of this work is to explore the nature of current layers around separators. A separator is a special field line which lies along the intersection of two separatrix surfaces and forms the boundary between four topologically distinct flux domains. In particular, here the current layer about a separator that joins two 3D nulls and lies along the intersection of their separatrix surfaces is investigated.
Methods. A magnetic configuration containing a single separator embedded in a uniform plasma with a uniform electric current parallel to the separator is considered. This initial magnetic setup, which is not in equilibrium, relaxes in a non-resistive manner to form an equilibrium. The relaxation is achieved using the 3D MHD code, Lare3d, with resistivity set to zero. A series of experiments with varying initial current are run to investigate the characteristics of the resulting current layers present in the final (quasi-)equilibrium states.
Results. In each experiment, the separator collapses and a current layer forms along it. The dimensions and strength of the current layer increase with initial current. It is found that separator current layers formed from current parallel to the separator are twisted. Also the collapse of the separator is a process that evolves like an infinite-time singularity where the length, width and peak current in the layer grow slowly whilst the depth of the current layer decreases.

Automatic recognition of complex magnetic regions on the Sun in GONG magnetogram images and prediction of flares: Techniques for the flare warning program Flarecast

Steward, Graham A.; Lobzin, Vasili V.; Wilkinson, Phil J.; Cairns, Iver H.; Robinson, Peter A.
Space Weather, Vol. 9, No. 11, S11004, **2011**
http://dx.doi.org/10.1029/2011SW000703
In the present paper, Global Oscillation Network Group (GONG) solar magnetograms are used to automatically identify active regions by thresholding the line-of-sight component of the solar magnetic field. The flare potential of the regions is predicted by locating strong-gradient polarity inversion lines (SPILs) and estimating their parameters. The parameters of interest are the length of the SPIL, a proxy for its curvature; the maximum west-east and south-north gradients of the magnetic field in its vicinity; and a sum of the magnetic field gradients, the summation being performed along the SPIL. Analysis for thresholding of one, two, and three parameters and the corresponding probabilities for correct prediction of flares are presented and compared. The probability for correct prediction of X-ray flares of class C or greater in a 24 h window exceeds 88%, while the probability of false alarms is less than 10% if the decision rule involves thresholding of three specific parameters. These parameters are the steepest south-north gradient of the magnetic field, the maximum curvature of the SPILs, and the length of the longest SPIL, all being calculated for the entire region rather than for a particular SPIL. The steepest south-north gradient of the magnetic field is also used to estimate the probabilities for a flare to belong to classes C, M, or X. These techniques are now implemented in the flare warning program **Flarecast**. The first automatically predicted M- and X-class flares are presented, and Flarecast is found to predict well the observed X-ray flares.

Oscillatory reconnection and waves driven by merging magnetic flux ropes in solar flares

J. **Stewart**, P.K. Browning, M. Gordovskyy
MNRAS **2022**
https://arxiv.org/pdf/2205.03106.pdf
Oscillatory reconnection is a process that has been suggested to underlie several solar and stellar phenomena, and is likely to play an important role in transient events such as flares. Quasi-periodic pulsations (QPPs) in flare emissions may be a manifestation of oscillatory reconnection, but the underlying mechanisms remain uncertain. In this paper, we present 2D magnetohydrodynamic (MHD) simulations of two current-carrying magnetic flux ropes with an out-of-plane magnetic field undergoing oscillatory reconnection in which the two flux ropes merge into a single flux rope. We find that oscillatory reconnection can occur intrinsically without an external oscillatory driver during flux rope coalescence, which may occur both during large-scale coronal loop interactions and the merging of plasmoids in fragmented current

sheets. Furthermore, we demonstrate that radially propagating non-linear waves are produced in the aftermath of flux rope coalescence, due to the post-reconnection oscillations of the merged flux rope. The behaviour of these waves is found to be almost independent of the initial out-of-plane magnetic field. It is estimated that the waves emitted through merging coronal loops and merging plasmoids in loop-top current sheets would have a typical phase speed of 90 km/s and 900 km/s respectively. It is possible that the properties of the waves emitted during flux rope coalescence could be used as a diagnostic tool to determine physical parameters within a coalescing region.

Solar flare hard X-rays from the anchor points of an eruptive filament

Muriel Zoë **Stiefel**, Andrea Francesco Battaglia, Krzysztof Barczynski, Hannah Collier, Anna Volpara, Paolo Massa, Conrad Schwanitz, Sofia Tynelius, Louise Harra, Säm Krucker

A&A **2022**

https://arxiv.org/pdf/2212.11327.pdf

Context. We present an analysis of a GOES M1.8 flare with excellent observational coverage in UV, EUV, and X-ray, including observations from the instruments IRIS, SDO with AIA, Hinode/EIS, Hinode/XRT, and Solar Orbiter with the Spectrometer/Telescope for Imaging X-rays (STIX). Hard X-ray emission is often observed at the footpoints of flare loops and is occasionally observed in the corona. In this flare, four nonthermal hard X-ray sources are seen.
Aim. Our aim is to understand why we can observe four individual nonthermal sources in this flare and how we can characterize the physical properties of these four sources.
Methods. We used the multiwavelength approach to analyze the flare and characterize the four sources. To do this, we combined imaging at different wavelengths and spectroscopic fitting in the EUV and X-ray range.
Results. The flare is eruptive with an associated coronal mass ejection, and it shows the classical flare picture of a heated flare loop seen in EUV and X-rays, and two nonthermal hard X-ray footpoints at the loop ends. In addition to the main flare sources, we observed two outer sources in the UV, EUV, and nonthermal X-ray range located away from the main flare loop to the east and west. The two outer sources are clearly correlated in time, and they are only seen during the first two minutes of the impulsive phase, which lasts a total of about four minutes.
Conclusions. Based on the analysis, we determine that the outer sources are the anchor points of an erupting filament. The hard X-ray emission is interpreted as flare-accelerated electrons that are injected upward into the filament and then precipitate along the filament toward the chromosphere, producing Bremsstrahlung. While sources like this have been speculated to exist, this is the first report of their detection. **23 September 2021**

Spectral and Imaging Diagnostics of Spatially-Extended Turbulent Electron Acceleration and Transport in Solar Flares

Morgan **Stores**, Natasha L. S. Jeffrey, James A. McLaughlin

ApJ **2023**

https://arxiv.org/pdf/2301.13682.pdf

Solar flares are efficient particle accelerators with a large fraction of released magnetic energy (10-50%) converted into energetic particles such as hard X-ray producing electrons. This energy transfer process is not well constrained, with competing theories regarding the acceleration mechanism(s), including MHD turbulence. We perform a detailed parameter study examining how various properties of the acceleration region, including its spatial extent and the spatial distribution of turbulence, affect the observed electron properties, such as those routinely determined from X-ray imaging and spectroscopy. Here, a time-independent Fokker-Planck equation is used to describe the acceleration and transport of flare electrons through a coronal plasma of finite temperature. Motivated by recent non-thermal line broadening observations that suggested extended regions of turbulence in coronal loops, an extended turbulent acceleration region is incorporated into the model. We produce outputs for the density weighted electron flux, a quantity directly related to observed X-rays, modelled in energy and space from the corona to chromosphere. We find that by combining several spectral and imaging diagnostics (such as spectral index differences or ratios, energy or spatial-dependent flux ratios, and electron depths into the chromosphere) the acceleration properties, including the timescale and velocity dependence, can be constrained alongside the spatial properties. Our diagnostics provide a foundation for constraining the properties of acceleration in an individual flare from X-ray imaging spectroscopy alone, and can be applied to past, current and future observations including those from RHESSI and Solar Orbiter.

RHESSI nugget #448 2023 https://sprg.ssl.berkeley.edu/~tohban/wiki/index.php/Diagnostics_of_Spatially-Extended_Turbulent_Acceleration_and_Transport

The Spatial and Temporal Variations of Turbulence in a Solar Flare

Morgan **Stores**, Natasha L. S. Jeffrey, Eduard P. Kontar
ApJ **923** 40 **2021**
https://arxiv.org/pdf/2110.01542.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ac2c65/pdf
https://doi.org/10.3847/1538-4357/ac2c65
Magnetohydrodynamic (MHD) plasma turbulence is believed to play a vital role in the production of energetic electrons during solar flares and the non-thermal broadening of spectral lines is a key sign of this turbulence. Here, we determine how flare turbulence evolves in time and space using spectral profiles of Fe xxiv, Fe xxiii and Fe xvi, observed by Hinode/EIS. Maps of non-thermal velocity are created for times covering the X-ray rise, peak, and decay. For the first time, the creation of kinetic energy density maps reveal where energy is available for energization, suggesting that similar levels of energy may be available to heat and/or accelerate electrons in large regions of the flare. We find that turbulence is distributed throughout the entire flare; often greatest in the coronal loop tops, and decaying at different rates at different locations. For hotter ions (Fe xxiv and Fe xxiii), the non-thermal velocity decreases as the flare evolves and during/after the X-ray peak shows a clear spatial variation decreasing linearly from the loop apex towards the ribbon. For the cooler ion (Fe xvi), the non-thermal velocity remains relativity constant throughout the flare, but steeply increases in one region corresponding to the southern ribbon, peaking just prior to the peak in hard X-rays before declining. The results suggest turbulence has a more complex temporal and spatial structure than previously assumed, while newly introduced turbulent kinetic energy maps show the availability of the energy and identify important spatial inhomogeneities in the macroscopic plasma motions leading to turbulence. **2013-05-15**

Predictive Capabilities of Avalanche Models for Solar Flares

A. **Strugarek**, P. Charbonneau
Solar Physics, Volume 289, Issue 11, pp 4137-4150 **2014**
We assess the predictive capabilities of various classes of avalanche models for solar flares. We demonstrate that avalanche models cannot generally be used to predict specific events because of their high sensitivity to the embedded stochastic process. We show that deterministically driven models can nevertheless alleviate this caveat and be efficiently used for predictions of large events. Our results suggest a new approach for predictions of large (typically X-class) solar flares based on simple and computationally inexpensive avalanche models.

Deterministically Driven Avalanche Models of Solar Flares

Antoine **Strugarek**, Paul Charbonneau, Richard Joseph, Dorian Pirot
E-print, March **2014**; Solar Phys. August **2014**, Volume 289, Issue 8, pp 2993-3015
We develop and discuss the properties of a new class of lattice-based avalanche models of solar flares. These models are readily amenable to a relatively unambiguous physical interpretation in terms of slow twisting of a coronal loop. They share similarities with other avalanche models, such as the classical stick–slip self-organized critical model of earthquakes, in that they are driven globally by a fully deterministic energy-loading process. The model design leads to a systematic deficit of small-scale avalanches. In some portions of model space, mid-size and large avalanching behavior is scale-free, being characterized by event size distributions that have the form of power-laws with index values, which, in some parameter regimes, compare favorably to those inferred from solar EUV and X-ray flare data. For models using conservative or near-conservative redistribution rules, a population of large, quasiperiodic avalanches can also appear. Although without direct counterparts in the observational global statistics of flare energy release, this latter behavior may be relevant to recurrent flaring in individual coronal loops. This class of models could provide a basis for the prediction of large solar flares.

Burst-on-Tail (BOT)

Alexei **Struminsky** and Ivan Zimovets
RHESSI Science Nugget, No. 195, March **2013**
http://sprg.ssl.berkeley.edu/~tohban/wiki/index.php/Burst-on-Tail_(BOT)
A highly non-thermal development in the late phase of the flare process.
In this Nugget we present an outstanding example of strong electron acceleration in a solar flare without a visible response in soft X-ray emission and propose its possible interpretations. **SOL2003-10-26**

Oscillatory reconnection and waves driven by merging magnetic flux ropes in solar flares

J **Stewart**, P K Browning, M Gordovskyy
Monthly Notices of the Royal Astronomical Society, Volume 513, Issue 4, July **2022**, Pages 5224–5237,
https://doi.org/10.1093/mnras/stac1286
Oscillatory reconnection is a process that has been suggested to underlie several solar and stellar phenomena, and is likely to play an important role in transient events such as flares. Quasi-periodic pulsations in flare emissions may be a manifestation of oscillatory reconnection, but the underlying mechanisms remain uncertain. In this paper, we present

2D magnetohydrodynamic simulations of two current-carrying magnetic flux ropes with an out-of-plane magnetic field undergoing oscillatory reconnection in which the two flux ropes merge into a single flux rope. We find that oscillatory reconnection can occur intrinsically without an external oscillatory driver during flux rope coalescence, which may occur both during large-scale coronal loop interactions and the merging of plasmoids in fragmented current sheets. Furthermore, we demonstrate that radially propagating non-linear waves are produced in the aftermath of flux rope coalescence, due to the post-reconnection oscillations of the merged flux rope. The behaviour of these waves is found to be almost independent of the initial out-of-plane magnetic field. It is estimated that the waves emitted through merging coronal loops and merging plasmoids in loop-top current sheets would have a typical phase speed of 90 and 900 km s−1, respectively. It is possible that the properties of the waves emitted during flux rope coalescence could be used as a diagnostic tool to determine physical parameters within a coalescing region.

Automatic recognition of complex magnetic regions on the Sun in SDO magnetogram images and prediction of flares: Techniques and results for the revised flare prediction program Flarecast

Graham **Steward**, Vasili Lobzin, Iver H. Cairns, Bo Li, David Neudegg
Space Weather Volume 15, Issue 9 September **2017** Pages 1151–1164 DOI 10.1002/2017SW001595
In the present paper, solar magnetograms provided by the Helioseismic and Magnetic Imager onboard Solar Dynamics Observatory spacecraft are used to identify active regions automatically by thresholding the line-of-sight component of the solar magnetic field. The flare potential of the regions is predicted by locating potential active regions with strong-gradient polarity inversion lines (SPILs) and estimating 18 physically relevant parameters of these regions. In particular, parameters of interest include the sum of north-south gradients, sum of east-west gradients, length of SPIL, and total integrated magnetic flux. For deterministic prediction of flares, analyses for thresholding of single parameters and different combinations, which include up to four parameters, are presented and compared. If the false alarm rate does not exceed 10% (20%), the probabilities for correct prediction of X-ray flares of class M and greater, M5 and greater, and X in the 24 h window are 71% (86%), 84% (96%), and 94% (100%), respectively. These probabilities are for the best four-parameter technique found. A technique for probabilistic forecasting was also developed. These deterministic and probabilistic techniques will be implemented in a revised version of the flare warning program, Flarecast, which will be operational in the Australian Space Forecast Centre.

Solar flare hard X-rays from the anchor points of an eruptive filament

Muriel Zoë **Stiefel**1, Andrea Francesco Battaglia1,2, Krzysztof Barczynski1,3, Hannah Collier1,2, Anna Volpara4, Paolo Massa5, Conrad Schwanitz1,3, Sofia Tynelius1, Louise Harra3,1 and Säm Krucker2,6

ww.aanda.org/articles/aa/pdf/2023/02/aa45044-22.pdf
Context. We present an analysis of a GOES M1.8 flare with excellent observational coverage in UV, extreme-UV (EUV), and X-ray, including observations from the Interface Region Imaging Spectrograph (IRIS), from the Solar Dynamics Observatory (SDO) with the Atmospheric Imaging Assembly (AIA), from the Hinode/EUV Imaging Spectrometer (EIS), from the Hinode/X-ray Telescope (XRT), and from Solar Orbiter with the Spectrometer/Telescope for Imaging X-rays (STIX). Hard X-ray emission is often observed at the footpoints of flare loops and is occasionally observed in the corona. In this flare, four nonthermal hard X-ray sources are seen.
Aims. Our aim is to understand why we can observe four individual nonthermal sources in this flare and how we can characterize the physical properties of these four sources.
Methods. We used the multiwavelength approach to analyze the flare and characterize the four sources. To do this, we combined imaging at different wavelengths and spectroscopic fitting in the EUV and X-ray range.
Results. The flare is eruptive with an associated coronal mass ejection, and it shows the classical flare picture of a heated flare loop seen in EUV and X-rays, and two nonthermal hard X-ray footpoints at the loop ends. In addition to the main flare sources, we observed two outer sources in the UV, EUV, and nonthermal X-ray range located away from the main flare loop to the east and west. The two outer sources are clearly correlated in time, and they are only seen during the first two minutes of the impulsive phase, which lasts a total of about four minutes.
Conclusions. Based on the analysis, we determine that the outer sources are the anchor points of an erupting filament. The hard X-ray emission is interpreted as flare-accelerated electrons that are injected upward into the filament and then precipitate along the filament toward the chromosphere, producing Bremsstrahlung. While sources like this have been speculated to exist, this is the first report of their detection. **23 September 2021**

The Tests and Calibrations of the Hard X-ray Imager Aboard ASO-S.

Su, Y., Zhang, Z., Chen, W. et al.
Sol Phys 299, 153 (**2024**).
https://doi.org/10.1007/s11207-024-02392-x
https://link.springer.com/content/pdf/10.1007/s11207-024-02392-x.pdf

The Hard X-ray Imager (HXI) aboard the Advanced Space-based Solar Observatory (ASO-S) is an instrument designed to observe hard X-ray (HXR) spectra and images of solar flares. Having 91 subcollimators to modulate incident X-rays, HXI can obtain 91 modulation data and 45 visibilities to reconstruct images with a spatial resolution as high as ∼3.1 arcsec. HXI was launched on 9 October 2022 and powered up on 17 October 2022. After the on-orbit testing phase lasting for three months, HXI was ready for regular observations on 18 January 2023. With fine-tuning of the detectors and electronics, we were able to expand the energy range from ∼30 – 200 keV to ∼10 keV – 300 keV, which significantly raised the scientific values of the data and the number of detected flare events. This paper presents the changes and improvements of HXI instrument since 2019, the important ground tests, on-orbit tests, and calibration works. We also present the light curves, spectra, and reconstructed images of one flare observed by HXI on **6 January 2023.**

Determination of Differential Emission Measure from Solar Extreme Ultraviolet Images

Yang **Su**1,2, Astrid M. Veronig3, Iain G. Hannah4, Mark C. M. Cheung5, Brian R. Dennis6, Gordon D. Holman6, Weiqun Gan1,2, and Youping Li1
2018 ApJL 856 L17
http://iopscience.iop.org/article/10.3847/2041-8213/aab436/pdf
The Atmospheric Imaging Assembly (AIA) on board the Solar Dynamic Observatory (SDO) has been providing high-cadence, high-resolution, full-disk UV-visible/extreme ultraviolet (EUV) images since 2010, with the best time coverage among all the solar missions. A number of codes have been developed to extract plasma differential emission measures (DEMs) from AIA images. Although widely used, they cannot effectively constrain the DEM at flaring temperatures with AIA data alone. This often results in much higher X-ray fluxes than observed. One way to solve the problem is by adding more constraint from other data sets (such as soft X-ray images and fluxes). However, the spatial information of plasma DEMs are lost in many cases. In this Letter, we present a different approach to constrain the DEMs. We tested the sparse inversion code and show that the default settings reproduce X-ray fluxes that could be too high. Based on the tests with both simulated and observed AIA data, we provided recommended settings of basis functions and tolerances. The new DEM solutions derived from AIA images alone are much more consistent with (thermal) X-ray observations, and provide valuable information by mapping the thermal plasma from ~0.3 to ~30 MK. Such improvement is a key step in understanding the nature of individual X-ray sources, and particularly important for studies of flare initiation. **2013 November 10-13**

High-resolution Observations of Flares in an Arch Filament System

Yingna **Su**1,2, Rui Liu3,4, Shangwei Li1,5, Wenda Cao6,7, Kwangsu Ahn6, and Haisheng Ji
2018 ApJ 855 77
http://sci-hub.tw/http://iopscience.iop.org/0004-637X/855/2/77/
https://arxiv.org/pdf/1803.06085.pdf
We study five sequential solar flares (SOL**2015-08-07**) occurring in Active Region 12396 observed with the Goode Solar Telescope (GST) at the Big Bear Solar Observatory, complemented by Interface Region Imaging Spectrograph and SDO observations. The main flaring region is an arch filament system (AFS) consisting of multiple bundles of dark filament threads enclosed by semicircular flare ribbons. We study the magnetic configuration and evolution of the active region by constructing coronal magnetic field models based on SDO/HMI magnetograms using two independent methods, i.e., the nonlinear force-free field (NLFFF) extrapolation and the flux rope insertion method. The models consist of multiple flux ropes with mixed signs of helicity, i.e., positive (negative) in the northern (southern) region, which is consistent with the GST observations of multiple filament bundles. The footprints of quasi-separatrix layers (QSLs) derived from the extrapolated NLFFF compare favorably with the observed flare ribbons. An interesting double-ribbon fine structure located at the east border of the AFS is consistent with the fine structure of the QSL's footprint. Moreover, magnetic field lines traced along the semicircular footprint of a dome-like QSL surrounding the AFS are connected to the regions of significant helicity and Poynting flux injection. The maps of magnetic twist show that positive twist became dominant as time progressed, which is consistent with the injection of positive helicity before the flares. We hence conclude that these circular shaped flares are caused by 3D magnetic reconnection at the QSLs associated with the AFS possessing mixed signs of helicity.

Statistical Study of Free Magnetic Energy and Flare Productivity of Solar Active Regions

J. T. **Su**1,2,3, J. Jing1, S. Wang1,2, T. Wiegelmann4, and H. M. Wang
ApJ 788 150, **2014**
http://arxiv.org/pdf/1405.2131v1.pdf
Photospheric vector magnetograms from the Helioseismic and Magnetic Imager on board the Solar Dynamic Observatory are utilized as the boundary conditions to extrapolate both nonlinear force-free and potential magnetic fields in solar corona. Based on the extrapolations, we are able to determine the free magnetic energy (FME) stored in active regions (ARs). Over 3000 vector magnetograms in 61 ARs were analyzed. We compare FME with the ARs' flare

index (FI) and find that there is a weak correlation (<60%) between FME and FI. FME shows slightly improved flare predictability relative to the total unsigned magnetic flux of ARs in the following two aspects: (1) the flare productivity predicted by FME is higher than that predicted by magnetic flux and (2) the correlation between FI and FME is higher than that between FI and magnetic flux. However, this improvement is not significant enough to make a substantial difference in time-accumulated FI, rather than individual flare, predictions.

Table 2. Information of 61 chosen ARs

Imaging coronal magnetic-field reconnection in a solar flare

Su, Y., Veronig, A. M., Holman, G. D., Dennis, B. R., Wang, T. J., Temmer, M., Gan, W. Q.
E-print, July **2013, File**; Nature Physics Volume: 9 Issue: 8 Pages: 489-493, **2013**

Magnetic-field reconnection is believed to play a fundamental role in magnetized plasma systems throughout the Universe1, including planetary magnetospheres, magnetars and accretion disks around black holes. This letter present extreme ultraviolet and X-ray observations of a solar flare showing magnetic reconnection with a level of clarity not previously achieved. The multi-wavelength extreme ultraviolet observations from SDO/AIA show inflowing cool loops and newly formed, outflowing hot loops, as predicted. RHESSI X-ray spectra and images simultaneously show the appearance of plasma heated to >10 MK at the expected locations. These two data sets provide solid visual evidence of magnetic reconnection producing a solar flare, validating the basic physical mechanism of popular flare models. However, new features are also observed that need to be included in reconnection and flare studies, such as three-dimensional non-uniform, non-steady and asymmetric evolution. **2011 August 17**

OBSERVATIONS OF A TWO-STAGE SOLAR ERUPTIVE EVENT (SEE): EVIDENCE FOR SECONDARY HEATING

Yang **Su**1,2,3, Brian R. Dennis1, Gordon D. Holman1, Tongjiang Wang1,2, Phillip C. Chamberlin1, Sabrina Savage1 and Astrid Veronig
2012 ApJ 746 L5

We present RHESSI, SDO/AIA, SOHO/LASCO, STEREO, and GOES observations of a partially occulted solar eruptive event that occurred at the southwest limb on **2011 March 8**. The GOES X-ray light curve shows two peaks separated by almost 2 hr that we interpret as two stages of a single event associated with the delayed eruption of a coronal mass ejection (CME). A hot flux rope formed during the first stage and continued expanding and rising throughout the event. The speed of the flux rope decreased from ~120 to 14 km s–1 during the decay phase of the first stage and increased again during the second stage to become the CME with a speed of ~516 km s–1. RHESSI and GOES data analyses show that the plasma temperature reached over 20 MK in the first stage, then decreased to ~10 MK and increased to 15 MK in the second stage. This event provides clear evidence for a secondary heating phase. The enhanced EUV and X-ray emission came from the high corona (~60 arcsec above the limb) in the second stage, ~40 arcsec higher than the site of the initial flare emission. STEREO-A on-disk observations indicate that the post-flare loops during this stage were of larger scale sizes and spatially distinct from those in the first stage.

IMAGING OBSERVATIONS OF QUASI-PERIODIC PULSATIONS IN SOLAR FLARE LOOPS WITH SDO/AIA

J. T. **Su**1, Y. D. Shen2, Y. Liu2, Y. Liu3, and X. J. Mao
2012 ApJ 755 113

Quasi-periodic pulsations (QPPs) of flaring emission with periods from a few seconds to tens of minutes have been widely detected from radio bands to γ-ray emissions. However, in the past the spatial information of pulsations could not be utilized well due to the instrument limits. We report here imaging observations of the QPPs in three loop sections during a C1.7 flare with periods of P = 24 s-3 minutes by means of the extreme-ultraviolet 171 Å channel of the Atmospheric Imaging Assembly (AIA) instrument on board the Solar Dynamics Observatory. We confirm that the QPPs with the shortest period of 24 s were not of an artifact produced by the Nyquist frequency of the AIA 12 s cadence. The QPPs in the three loop sections were interconnected and closely associated with the flare. The detected perturbations propagated along the loops at speeds of 65-200 km s–1, close to those of acoustic waves in them. The loops were made up of many bright blobs arranged in alternating bright and dark changes in intensity (spatial periodical distribution) with the wavelengths 2.4-5 Mm (as if they were magnetohydrodynamic waves). Furthermore, in the time-distance diagrams, the detected perturbation wavelengths of the QPPs are estimated to be ~10 Mm, which evidently do not fit the above ones of the spatial periodic distributions and produce a difference of a factor of 2-4 with them. It is suggested that the short QPPs with periods P < 60 s were possibly sausage-mode oscillations and the long QPPs with periods P > 60 s were the higher (e.g., >2nd) harmonics of slow magnetoacoustic waves.

EXTREME-ULTRAVIOLET MULTI-WAVELENGTH OBSERVATIONS OF QUASI-PERIODIC PULSATIONS IN A SOLAR POST-FLARE CUSP-SHAPE LOOP WITH SDO/AIA

J. T. **Su**1, Y. D. Shen2, and Y. Liu

2012 ApJ 754 43

We present extreme-ultraviolet multi-wavelength observations with the SDO/AIA instruments of quasi-periodic pulsations (QPPs) propagating along a cusp-shaped loop formed after an M2.2 flare on the Sun. Our motivation is to detect whether there were slow-mode magnetoacoustic waves propagating along its protruding flux tube. To this end, with fast Fourier transform we extract the short (<3 minutes) and long (>3 minutes) period components of the QPPs from time-space diagrams of the tube slices. We find that velocity differences did exist among the short/long-period components of different wavelengths, but only one event in the long-period ones showed they were greater than the measurement errors (e.g., 65 km s–1), which were 330 km s–1 detected in 171 Å, 590 km s–1 in 211 Å, and 180 km s–1 in 304 Å. The intensity modulation in all wavelengths is found to be very large, e.g., ~60% of the emission trend for an event in the 171 Å passband, which would be an order of magnitude higher than the perturbation of the plasma density in the slow-mode magnetoacoustic waves. Moreover, only the QPPs with upward velocities of 50-300 km s–1 are found in the tube, and the downward ones of several tens of kilometers are never unambiguously detected. Therefore, most of the QPP events under study were likely the episodic outflows along the tube, and the one with a supersonic speed of 590 km s–1 may be a kink wave.

Two-Stage SEE shows reconnection

Yang **Su** and Brian Dennis:

RHESSI science nugget No. 158, 8 Sept **2011**

http://sprg.ssl.berkeley.edu/~tohban/wiki/index.php/Two-stage_SEE_Shows_Reconnection

A beautiful eruptive event (a SEE) appears to show reconnection in an example of the new EVE "super-late" phase of a flare. We report here on an event on **8 March 2011** with similar strong evidence for a second stage of energy release high in the corona.

OBSERVATIONS AND MAGNETIC FIELD MODELING OF THE FLARE/CORONAL MASS EJECTION EVENT ON 2010 APRIL 8

Yingna **Su**1, Vincent Surges1,2, Adriaan van Ballegooijen1, Edward DeLuca1 and Leon Golub

2011 ApJ 734 53, **File**

We present a study of the flare/coronal mass ejection event that occurred in Active Region 11060 on **2010 April 8**. This event also involves a filament eruption, EIT wave, and coronal dimming. Prior to the flare onset and filament eruption, both SDO/AIA and STEREO/EUVI observe a nearly horizontal filament ejection along the internal polarity inversion line, where flux cancellations frequently occur as observed by SDO/HMI. Using the flux-rope insertion method developed by van Ballegooijen, we construct a grid of magnetic field models using two magneto-frictional relaxation methods. We find that the poloidal flux is significantly reduced during the relaxation process, though one relaxation method preserves the poloidal flux better than the other. The best-fit pre-flare NLFFF model is constrained by matching the coronal loops observed by SDO/AIA and Hinode/XRT. We find that the axial flux in this model is very close to the threshold of instability. For the model that becomes unstable due to an increase of the axial flux, the reconnected field lines below the X-point closely match the observed highly sheared flare loops at the event onset. The footpoints of the erupting flux rope are located around the coronal dimming regions. Both observational and modeling results support the premise that this event may be initiated by catastrophic loss of equilibrium caused by an increase of the axial flux in the flux rope, which is driven by flux cancellations.

OBSERVATIONAL EVIDENCE OF CHANGING PHOTOSPHERIC VECTOR MAGNETIC FIELDS ASSOCIATED WITH SOLAR FLARES

J. T. **Su**1,2, J. Jing1, H. M. Wang1, X. J. Mao2,3, X. F. Wang2, H. Q. Zhang2, Y. Y. Deng2, J. Guo2 and G. P. Wang

2011 ApJ 733 94

Recent observations have provided evidence that the solar photospheric magnetic fields could have rapid and permanent changes in both longitudinal and transverse components associated with major flares. As a result, the Lorentz force (LF) acting on the solar photosphere and solar interior could be perturbed, and the change of LF is always nearly in the downward direction. However, these rapid and permanent changes have not been systematically investigated, yet, using vector magnetograms. In this paper, we analyze photospheric vector magnetograms covering five flares to study the evolution of photospheric magnetic fields. In particular, we investigate two-dimensional spatial distributions of the

changing LF. Around the major flaring polarity inversion line, the net change of the LF is directed downward in an area of ~1019 cm2 for X-class flares. For all events, the white-light observations show that sunspots darken in this location after flares, and magnetic fields become more inclined, which is consistent with the ideas put forward by Hudson et al. and Fisher et al., and observations.

EVIDENCE FOR THE FULL HARD X-RAY SPECTRAL SIGNATURE OF NONUNIFORM IONIZATION IN A SOLAR FLARE

Yang **Su**1,2,3, Gordon D. Holman2 and Brian R. Dennis
2011 ApJ 731 106
The hard X-ray (HXR) emission from solar flares is observed primarily from the footpoints of flare magnetic loops, where nonthermal electrons are understood to emit thick-target bremsstrahlung as they stream from the fully ionized hot corona to the denser, cooler, and partially ionized chromosphere. The change in the plasma ionization along the path of the electrons should result in a characteristic upward break and corresponding flattening of the X-ray spectrum with increasing energy at lower energies, and a downward break at higher energies. Due to the presence of thermal emission, the upward break usually cannot be observed. We report the first evidence for both breaks in spectra measured with the Reuven Ramaty High Energy Solar Spectroscopic Imager (RHESSI) during the GOES X1.2 class flare that happened on 2002 October 31. The RHESSI X-ray spectral analysis shows both the breakup at ~49 keV and the breakdown at ~134 keV at the HXR peak time. The time evolution of both breaks also agrees with the nonuniform ionization (NUI) model. Other possible explanations for the breaks are considered, but the NUI model provides the simplest explanation for the spectral shape and its time evolution. We find that the average column density of the fully ionized plasma changed from 2 ×1019 cm–2 in the rise phase to 7 ×1021 cm–2 after the peak. This indicates that plasma in the target was heated and became ionized during the flare, in agreement with heating by the nonthermal electrons and chromospheric evaporation expected in the collisional thick-target model.

OBSERVATIONAL EVIDENCE OF UNWINDING AND CHIRALITY CHANGING IN PENUMBRAL FILAMENTS BY HINODE

Jiangtao **Su**1,2, Yu Liu3, Hongqi Zhang1,2, Xinjie Mao4, Yin Zhang1,2 and Han He1,2
ApJ 710 170-179, **2010**
In this paper, we present a very important and quite controversial observational property of penumbral filaments that may exhibit twisting motions and change their chirality. Using high-resolution observations from the Solar Optical Telescope on board *Hinode*, we study the unwinding and twisting motions in the penumbral filaments of active region NOAA 10930. Penumbral filaments, including those to the northwest of the magnetic polarity inversion line (PIL) and those inside the PIL region, are found to make unwinding motions associated with the decrease of their right-handed twists. After unwinding, the filaments inside the PIL region are found to twist continuously to develop left-handed twists in them. Moreover, we find the filament elongating, expanding, splitting, and the screw pitch decreasing in the unwinding process and, getting shorter, shrinking, merging, and the screw pitch increasing in the twisting process. These observational results indicate that penumbral filaments are more inclined to be twisted magnetic flux tubes in nature.

On classification of RHESSI flares

Yang **Su**, W.Q. Gan and Y.P. Li
Advances in Space Research, Volume 41, Issue 6, **2008**, Pages 988-991
https://sci-hub.tw/10.1016/j.asr.2007.07.010
Based on the light curves and images of RHESSI flares, we tried to make a preliminary classification of solar flares. Three basic types of flares seem to be existed: accordantly gradual flares, accordantly impulsive flares, and early impulsive flares. The proportion for each type is given. The possible physical meaning related to different types is discussed. **27 Feb 2002, 14 July 2002, 3 Aug 2002**

Flare Energy Build-Up in a Decaying Active Region Near a Coronal Hole

Yingna **Su**1,2, Adriaan van Ballegooijen1, Brigitte Schmieder3, Arkadiusz Berlicki4,5,3, Yang Guo3, Leon Golub1,Guangli Huang2
E-print, Aug **2009**; ApJ, 704:341–353, **2009** October, **File**
A B1.7 two-ribbon flare occurred in a highly non-potential decaying active region near a coronal hole at 10:00 UT on **May 17, 2008**. This flare is ?large? in the sense that it involves the entire region, and it is associated with both a filament eruption and a CME. We present multi-wavelength observations from EUV (TRACE, STEREO/EUVI), X-rays (Hinode/XRT), and Hα (THEMIS, BBSO) prior to, during and after the flare. Prior to the flare, the region contained two filaments. The long J-shaped sheared loops corresponding to the southern filament were evolved from two short loop systems, which happened around 22:00 UT after a filament eruption on May 16. Formation of highly sheared loops in the south eastern part of the region was observed by STEREO 8 hours before the flare. We also perform non-linear force free field (NLFFF) modeling for the region at two times prior to the flare, using the flux rope insertion method.

The models include the non-force-free effect of magnetic buoyancy in the photosphere. The best-fit NLFFF models show good fit to observations both in the corona (X-ray and EUV loops) and chromosphere (Hα filament). We find that the horizontal fields in the photosphere are relatively insensitive to the present of flux ropes in the corona. The axial flux of the flux rope in the NLFFF model on May 17 is twice that on May 16, and the model on May 17 is only marginally stable. We also find that the quasi-circular flare ribbons are associated with the separatrix between open and closed fields. This observation and NLFFF modeling suggest that this flare may be triggered by the reconnection at the null point on the separatrix surface.

LOCAL TWIST AND CURRENT HELICITY DISTRIBUTIONS OF ACTIVE REGION NOAA 10930

J. T. **Su**1,2, T. Sakurai1, Y. Suematsu1, M. Hagino1, and Yu Liu3
Astrophysical Journal, 697:L103–L107, **2009** June 1 doi:10.1088/0004-637X/697/2/L103
Hinode high-quality vector magnetograms and *G*-band data are utilized to study the distributions of local twist α_z and current helicity h_c on the active region of NOAA 10930. The new findings are as follows. (1) The patches of positive and negative helicities were intermixed showing a mesh pattern in the umbra and a thread pattern in the penumbra. (2) For its main stable sunspot (MSS), there was a positive-helicity patch accounting for ~43% of the umbra area surrounding the inner umbra, which had a predominantly negative helicity. For its minor rotating sunspot (MRS), there was a negative-helicity patch appearing in the umbra. (3) The fine distributions of α_z and h_c on a penumbral filament indicated that it may be possible for the two opposite helicities to coexist in a filament and their magnitudes were nearly equivalent.

Evolution of the Sheared Magnetic Fields of two X-class Flares Observed by Hinode/XRT

E-print, August 2007
We present multi-wavelength observations of the evolution of the sheared magnetic fields in NOAA Active Region 10930, where two X-class flares occurred on **2006 December 13 and December 14**, respectively. Observations made with the X-ray Telescope (XRT) and the Solar Optical Telescope (SOT) aboard Hinode suggest that the gradual formation of the sheared magnetic fields in this active region is caused by the rotation and west-to-east motion of an emerging sunspot. In the pre-flare phase of the two flares, XRT shows several highly sheared X-ray loops in the core field region, corresponding to a filament seen in the TRACE EUV observations. XRT observations also show that part of the sheared core field erupted, and another part of the sheared core field stayed behind during the flares, which may explain why a large part of the filament is still seen by TRACE after the flare. About 2-3 hours after the peak of each flare, the core field becomes visible in XRT again, and shows a highly sheared inner and less sheared outer structure. We also find that the post-flare core field is clearly less sheared than the pre-flare core field, which is consistent with the idea that the energy released during the flares is stored in the highly sheared fields prior to the flare.

Estimations of Elemental Abundances During Solar Flares Observed in Soft X-rays by the MinXSS-1 CubeSat Mission

Crisel **Suarez**, Christopher S. Moore
ApJ 957 14 **2023**
https://arxiv.org/pdf/2308.16235.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/acf0c2/pdf
Solar flares are complex phenomena emitting all types of electromagnetic radiation, and accelerating particles on timescales of minutes, converting magnetic energy to thermal, radiative, and kinetic energy through magnetic

reconnections. As a result, local plasma can be heated to temperatures in excess of 20 MK. During the soft X-ray (SXR) solar flare peak, the elemental abundance of low first-ionization potential (FIP) elements are typically observed to be depleted from coronal values. We explored the abundance variations using disk-integrated solar spectra from the Miniature X-ray Solar Spectrometer CubeSat-1 (MinXSS-1). MinXSS-1 is sensitive to the 1-12 keV energy range with an effective 0.25 keV full-width at half-maximum (FWHM) resolution at 5.9 keV. During the year-long mission of MinXSS-1, between May 2016 - May 2017, 21 flares with intermittent data downlinks were observed ranging from C to M class. We examine the time evolution of temperature, volume emission measure, and elemental abundances of Fe, Ca, Si, S, and Ar with CHIANTI spectral models near the peak SXR emission times observed in the MinXSS-1 data. We determined the average absolute abundance of A(Fe) = 7.81, A(Ca) = 6.84, A(S) = 7.28, A(Si) = 7.90, and A(Ar) = 6.56. These abundances are depleted from coronal values during the SXR peak compared to non-flaring times. The elemental abundance values that are depleted from their coronal values are consistent with the process of chromospheric evaporation, in which the lower atmospheric plasma fills the coronal loops. **2016-07-21-23**

Emission Measure Distribution for Diffuse Regions in Solar Active Regions

Srividya **Subramanian**, Durgesh Tripathi, James A. Klimchuk, Helen E. Mason
ApJ, ApJ 795 76 **2014**
http://arxiv.org/pdf/1409.1447v1.pdf
Our knowledge of the diffuse emission that encompasses active regions is very limited. In the present paper we investigate two off-limb active regions, namely AR10939 and AR10961, to probe the underlying heating mechanisms. For this purpose we have used spectral observations from Hinode/EIS and employed the emission measure (EM) technique to obtain the thermal structure of these diffuse regions. Our results show that the characteristic EM distributions of the diffuse emission regions peak at log T = 6.25 and the cool-ward slopes are in the range 1.4 - 3.3. This suggests that both low as well as high frequency nanoflare heating events are at work. Our results provide additional constraints on the properties of these diffuse emission regions and their contribution to the background/foreground when active region cores are observed on-disk. **2007 Jan 26, (2007 Aug 01-08, AR 10961)**

What is the true nature of blinkers?

S. **Subramanian**1, M. S. Madjarska1, J. G. Doyle1 and D. Bewsher
A&A 538, A50 (**2012**)
Aims. The aim of this work is to identify the true nature of the transient EUV brightenings, called blinkers.
Methods. Co-spatial and co-temporal multi-instrument data, including imaging (EUVI/STEREO, XRT and SOT/Hinode), spectroscopic (CDS/SoHO and EIS/Hinode) and magnetogram (SOT/Hinode) data, of an isolated equatorial coronal hole were used. An automatic program for identifying transient brightenings in CDS O v 629 Å, EUVI 171 Å and XRT was applied.
Results. We identified 28 blinker groups in the CDS O v 629 Å raster images. All CDS O v 629 Å blinkers showed counterparts in EUVI 171 Å and 304 Å images. We classified these blinkers into two categories, one associated with coronal counterparts and other with no coronal counterparts as seen in XRT images and EIS Fe xii 195.12 Å raster images. Around two-thirds of the blinkers show coronal counterparts and correspond to various events like EUV/X-ray jets, brightenings in coronal bright points or foot-point brightenings of larger loops. These brightenings occur repetitively and have a lifetime of around 40 min at transition region temperatures. The remaining blinker groups with no coronal counterpart in XRT and EIS Fe xii 195.12 Å appear as point-like brightenings and have chromospheric/transition region origin. They take place only once and have a lifetime of around 20 min. In general, lifetimes of blinkers are different at different wavelengths, i.e. different temperatures, decreasing from the chromosphere to the corona.
Conclusions. This work shows that the term blinker covers a range of phenomena. Blinkers are the EUV response of various transient events originating at coronal, transition region and chromospheric heights. Hence, events associated with blinkers contribute to the formation and maintenance of the temperature gradient in the transition region and the corona.

A question raised from the observation of dynamic cusp formation: When and where does particle acceleration occur?

Linhui **Sui**, Gordon D. Holman, & Brian R. Dennis

E-print, Oct 2007, Adv. Space Res. Volume 41, Issue 6, **2008**, Pages 976-983
We present observations of a C9.4 flare on **2002 June 2** in EUV (TRACE) and X-rays (RHESSI). The multiwavelength data reveal: (1) the involvement of a quadrupole magnetic configuration; (2) loop expansion and ribbon motion in the pre-impulsive phase; (3) gradual formation of a new compact loop with a long cusp at the top during the impulsive phase of the flare; (4) appearance of a large, twisted loop above the cusp expanding outward immediately after the hard X-ray peak; and (5) X-ray emission observed only from the new compact loop and the cusp. In particular, the gradual formation of an EUV cusp feature is very clear. The observations also reveal the timing of the cusp formation and particle acceleration: most of the impulsive hard X-rays (>25 keV) were emitted before the cusp was seen. This suggests that fast reconnection occurred during the restructuring of the magnetic configuration, resulting in more efficient particle acceleration, while the reconnection slowed after the cusp was completely formed and the magnetic geometry was stabilized. This observation is consistent with the observations obtained with Yohkoh/Soft X-ray Telescope (SXT) that soft X-ray cusp structures only appear after the major impulsive energy release in solar flares. These observations have important implications for the modeling of magnetic reconnection and particle acceleration.

Nonthermal X-Ray Spectral Flattening toward Low Energies in Early Impulsive Flares

Sui, Linhui; Holman, Gordon D.; Dennis, Brian R.
Astrophysical Journal, Volume 670, Issue 1, pp. 862-871. **2007**
https://iopscience.iop.org/article/10.1086/522198/pdf
The determination of the low-energy cutoff to nonthermal electron distributions is critical to the calculation of the nonthermal energy in solar flares. The most direct evidence for low-energy cutoffs is flattening of the power-law, nonthermal X-ray spectra at low energies. However, because of the plasma preheating often seen in flares, the thermal emissions at low energies may hide such spectral flattening of the nonthermal component. We select a category of flares, which we call ``early impulsive flares," in which the >25 keV hard X-ray (HXR) flux increase is delayed by less than 30 s after the flux increase at lower energies. Thus, the plasma preheating in these flares is minimal, so the nonthermal spectrum can be determined to lower energies than in flares with significant preheating. Out of a sample of 33 early impulsive flares observed by the Ramaty High Energy Solar Spectroscopy Imager (RHESSI), nine showed spectral flattening toward low energies. In these events, the break energy of the double power-law fit to the HXR spectra lies in the range 10-50 keV, significantly lower than the value we have seen for other flares that do not show such early impulsive emissions. In particular, it correlates with the HXR flux. After correcting the spatially integrated spectra for albedo from isotropically emitted X-rays and using RHESSI imaging spectroscopy to exclude the extended albedo halo, we find that albedo associated with isotropic or nearly isotropic electrons can only account for the spectral flattening in three flares near Sun center. The spectral flattening in the remaining six flares is found to be consistent with the existence of a low-energy cutoff in the electron spectrum, falling in the range 15-50 keV, which also correlates with the HXR flux. **. 26 Feb 2002, 22 Apr 2002, 2002 June 2, 29 June 2002, 14 Nov 2002**
2. EARLY IMPULSIVE FLARES

Motion of 3-6 keV Nonthermal Sources along the Legs of a Flare Loop

Sui, Linhui; Holman, Gordon D.; Dennis, Brian R.
Astrophysical Journal, Volume 645, Issue 2, pp. L157-L160. **2006**
https://iopscience.iop.org/article/10.1086/506325/pdf
Observations of nonthermal X-ray sources are critical to the study of electron acceleration and transport in solar flares. Strong thermal emission radiated from the preheated plasma before the flare impulsive phase often makes it difficult to detect low-energy X-ray sources that are produced by relatively low-energy nonthermal electrons. Knowledge of the distribution of these low-energy nonthermal electrons is particularly important in determining the total nonthermal electron energy in solar flares. We report on an ``early impulsive flare" in which impulsive hard X-ray emission was seen early in the flare before the soft X-ray emission had risen significantly, indicating limited plasma preheating. Early in the flare, RHESSI <25 keV images show coronal sources that moved first downward and then upward along the legs of a flare loop. In particular, the 3-6 keV source appeared as a single coronal source at the start of the flare, and then it evolved into two coronal sources moving down along the two legs of the loop. After nearly reaching the two footpoints at the hard X-ray peak, the two sources moved back up to the looptop again. RHESSI images and light curves all indicate that nonthermal emission dominated at energies as low as 3-6 keV. We suggest that the evolution of both the spectral index and the low-energy cutoff of the injected electron distribution could result in the accelerated electrons reaching a lower altitude along the legs of the dense flare loop and hence result in the observed downward and upward motions of the nonthermal sources. **2002 November 28**

Magnetic helicity evolution during active region emergence and subsequent flare productivity

Zheng **Sun**, Ting Li, Quan Wang, Shangbin Yang, Mei Zhang, Yajie Chen
A&A 686, A148 **2024**
https://arxiv.org/pdf/2403.18354.pdf
https://www.aanda.org/articles/aa/pdf/2024/06/aa48734-23.pdf
Aims. Solar active regions (ARs), which are formed by flux emergence, serve as the primary sources of solar eruptions. However, the specific physical mechanism that governs the emergence process and its relationship with flare productivity remains to be thoroughly understood. Methods. We examined 136 emerging ARs, focusing on the evolution of their magnetic helicity and magnetic energy during the emergence phase. Based on the relation between helicity accumulation and magnetic flux evolution, we categorized the samples and investigated their flare productivity. Results. The emerging ARs we studied can be categorized into three types, Type-I, Type-II, and Type-III, and they account for 52.2%, 25%, and 22.8% of the total number in our sample, respectively. Type-I ARs exhibit a synchronous increase in both the magnetic flux and magnetic helicity, while the magnetic helicity in Type-II ARs displays a lag in increasing behind the magnetic flux. Type-III ARs show obvious helicity injections of opposite signs. Significantly, 90% of the flare-productive ARs (flare index > 6) were identified as Type-I ARs, suggesting that this type of AR has a higher potential to become flare productive. In contrast, Type-II and Type-III ARs exhibited a low and moderate likelihood of becoming active, respectively. Our statistical analysis also revealed that Type-I ARs accumulate more magnetic helicity and energy, far beyond what is found in Type-II and Type-III ARs. Moreover, we observed that flare-productive ARs consistently accumulate a significant amount of helicity and energy during their emergence phase. Conclusions. These findings provide valuable insight into the flux emergence phenomena, offering promising possibilities for early-stage predictions of solar eruptions. **2012-11-25-27, 2013-06-11-14, 2016-03-12-14**

Deep Learning–based Solar Flare Forecasting Model. III. Extracting Precursors from EUV Images

Dezhi **Sun**1,2, Xin Huang3,1, Zhongrui Zhao1,2, and Long Xu1
2023 ApJS 266 8
https://iopscience.iop.org/article/10.3847/1538-4365/acc248/pdf
A solar flare is one of the most intense solar activities, and flare forecasting is necessary to avoid its destructive impact on the near-Earth space environment and technological infrastructure. Previous studies have demonstrated the importance of the photospheric magnetic field in the occurrence of flares. Therefore, most of the input data in traditional solar flare forecasting models are magnetograms of active regions. The magnetic field of the photosphere is routinely measured and observed, but the magnetic field of the corona is not. Hence, the goal of our work is to test whether precursors can be extracted from coronal multiwavelength images of active regions and to build a flare-forecasting model. Therefore, we investigated the effect of using extreme ultraviolet (EUV) images (at 94, 131, 171, 193, 211, and 335 Å) of the active region on solar flare forecasting. We generated a data set consisting of EUV images of the active regions observed by the Solar Dynamics Observatory/Atmospheric Imaging Assembly from 2010 to 2016. Based on this data set, a deep-learning method was used to extract precursors from EUV multiwavelength images. The test results of the forecasting model were discussed and analyzed, and the following conclusions were drawn. (1) Each wavelength achieved good results using the EUV multiwavelength images for flare forecasting. The 94 Å wavelength demonstrated the best result among the single-wavelength results. (2) Among the combined multiwavelength results, the best fusion results were obtained for all six wavelengths. **2012 March 7, 2015 Sep 27**

Solar Flare Forecast Using 3D Convolutional Neural Networks

Pengchao **Sun**3,1, Wei Dai3,1, Weiqi Ding1, Song Feng4,1, Yanmei Cui2, Bo Liang1, Zeyin Dong1, and Yunfei Yang1
2022 ApJ 941 1
https://iopscience.iop.org/article/10.3847/1538-4357/ac9e53/pdf
Solar flares are immense energy explosions in the solar atmosphere and severely influence space weather. So, forecasting solar flare eruptions is extremely important. Spatial distribution and evolution of active region (AR) magnetic fields are closely related to flare eruptions. In this paper, we simultaneously utilized the two characteristics to build two flare-forecast models using three-dimensional convolutional neural networks (3D CNNs). The two models forecast whether an AR would erupt a ≥C- or ≥M-class flare within the next 24 hr, respectively. The magnetogram

sequences provided by the Space-weather Helioseismic and Magnetic Imager Active Region Patches are selected to train our models. We used several performance metrics, such as true skill statistics (TSS), to evaluate our models. The TSS scores of the ≥C and ≥M models reach 0.756 and 0.826, respectively, indicating that our models have superior forecast performance. We used the the gradient-weighted class activation mapping (Grad-CAM) method to visually explain our flare-forecast models. The Grad-CAM illustrates that the 3D CNNs may extract the spatial distribution and evolution of AR magnetic fields simultaneously for flare forecasts. So, the 3D CNN method is valid for flare forecasts, and it utilizes the characteristics related to flare eruptions.

Predicting Solar Flares Using CNN and LSTM on Two Solar Cycles of Active Region Data

Zeyu **Sun**, Monica G. Bobra, Xiantong Wang, Yu Wang, Hu Sun, Tamas Gombosi, Yang Chen, Alfred Hero

ApJ **931** 163 **2022**

https://arxiv.org/pdf/2204.03710.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/ac64a6/pdf

We consider the flare prediction problem that distinguishes flare-imminent active regions that produce an M- or X-class flare in the future 24 hours, from quiet active regions that do not produce any flare within ±24 hours. Using line-of-sight magnetograms and parameters of active regions in two data products covering Solar Cycle 23 and 24, we train and evaluate two deep learning algorithms -- CNN and LSTM -- and their stacking ensembles. The decisions of CNN are explained using visual attribution methods. We have the following three main findings. (1) LSTM trained on data from two solar cycles achieves significantly higher True Skill Scores (TSS) than that trained on data from a single solar cycle with a confidence level of at least 0.95. (2) On data from Solar Cycle 23, a stacking ensemble that combines predictions from LSTM and CNN using the TSS criterion achieves significantly higher TSS than the "select-best" strategy with a confidence level of at least 0.95. (3) A visual attribution method called Integrated Gradients is able to attribute the CNN's predictions of flares to the emerging magnetic flux in the active region. It also reveals a limitation of CNN as a flare prediction method using line-of-sight magnetograms: it treats the polarity artifact of line-of-sight magnetograms as positive evidence of flares.

Improved and Interpretable Solar Flare Predictions with Spatial & Topological Features of the Polarity-Inversion-Line Masked Magnetograms

Hu **Sun**,Ward Manchester IV,Yang Chen

Space Weather **Volume19, Issue12** e2021SW002837 **2021**

https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2021SW002837

https://doi.org/10.1029/2021SW002837

Many current research efforts undertake the solar flare classification task using the Space-weather HMI Active Region Patch (SHARP) parameters as the predictors. The SHARP parameters are scalar quantities based on spatial average or integration of physical quantities derived from the vector magnetic field, which loses information of the two-dimensional spatial distribution of the field and related quantities. In this paper, we construct two new sets of spatial features to expand the feature set used for the flare classification task. The first set uses the idea of topological data analysis to summarize the geometric information of the distributions of various SHARP quantities across active regions. The second set utilizes tools coming from spatial statistics to analyze the vertical magnetic field component Br and summarize its spatial variations and clustering patterns. All features are constructed within regions near the polarity inversion lines (PILs) and classification performances using the new features are compared against those using SHARP parameters (also along the PIL). We found that using the new features can improve the skill scores of the flare classification model and new features tend to have higher feature importance, especially the spatial statistics features. This potentially suggests that even using a single magnetic field component, Br, instead of all SHARP parameters, one can still derive strongly predictive features for flare classification. **2011.02.13**

Non-Neutralized Electric Current of Active Regions Explained as a Projection Effect

Xudong **Sun**, Mark C. M. Cheung

Solar Phys. **296**, Article number: 7 **2021**

https://arxiv.org/pdf/2011.11873.pdf

https://link.springer.com/content/pdf/10.1007/s11207-020-01742-9.pdf

Active regions (ARs) often possess an observed net electric current in a single magnetic polarity. We show that such "non-neutralized" currents can arise from a geometric projection effect when a twisted flux tube obliquely intersects the photosphere. To this end, we emulate surface maps of an emerging AR by sampling horizontal slices of a semi-torus flux tube at various heights. Although the tube has no net toroidal current, its poloidal current, when projected along the vertical direction, amounts to a significant non-neutralized component on the surface. If the tube emerges only partially as in realistic settings, the non-neutralized current will 1) develop as double ribbons near the sheared polarity inversion line, (2) positively correlate with the twist, and 3) reach its maximum before the magnetic flux. The projection effect may be important to the photospheric current distribution, in particular during the early stages of flux emergence.

Interpreting LSTM Prediction on Solar Flare Eruption with Time-series Clustering

Hu **Sun** (1), Ward Manchester (2), Zhenbang Jiao (1), Xiantong Wang (2), Yang Chen

ApJ **2020**

https://arxiv.org/pdf/1912.12360.pdf

We conduct a post hoc analysis of solar flare predictions made by a Long Short Term Memory (LSTM) model employing data in the form of Space-weather HMI Active Region Patches (SHARP) parameters. These data are distinguished in that the parameters are calculated from data in proximity to the magnetic polarity inversion line where the flares originate. We train the the LSTM model for binary classification to provide a prediction score for the probability of M/X class flares to occur in next hour. We then develop a dimension-reduction technique to reduce the dimensions of SHARP parameter (LSTM inputs) and demonstrate the different patterns of SHARP parameters corresponding to the transition from low to high prediction score. Our work shows that a subset of SHARP parameters contain the key signals that strong solar flare eruptions are imminent. The dynamics of these parameters have a highly uniform trajectory for many events whose LSTM prediction scores for M/X class flares transition from very low to very high. The results suggest that there exist a few threshold values of a subset of SHARP parameters when surpassed could indicate a high probability of strong flare eruption. Our method has distilled the knowledge of solar flare eruption learnt by deep learning model and provides a more interpretable approximation where more physics related insights could be derived.

Appendix A Summary of Sudden Transition Cases (2011-2017)

Expansion of Solar Coronal Hot Electrons in an Inhomogeneous Magnetic Field: 1-D PIC Simulation

Jicheng **Sun**, Xinliang Gao, Yangguang Ke, Quanming Lu, Xueyi Wang, Shui Wang

ApJ **887** 96 **2019**

https://arxiv.org/ftp/arxiv/papers/1911/1911.07207.pdf

https://doi.org/10.3847/1538-4357/ab5060

The expansion of hot electrons in flaring magnetic loops is crucial to understanding the dynamics of solar flares. In this paper we investigate, for the first time, the transport of hot electrons in a magnetic mirror field based on a 1-D particle-in-cell (PIC) simulation. The hot electrons with small pitch angle transport into the cold plasma, which leads to the generation of Langmuir waves in the cold plasma and ion acoustic waves in the hot plasma. The large pitch angle electrons can be confined by the magnetic mirror, resulting in the different evolution time scale between electron parallel and perpendicular temperature. This will cause the formation of electron temperature anisotropy, which can generate the whistler waves near the interface between hot electrons and cold electrons. The whistler waves can scatter the large pitch angle electrons to smaller value through the cyclotron resonance, leading to electrons escaping from the hot region. These results indicate that the whistler waves may play an important role in the transport of electrons in flaring magnetic loops. The findings from this study provide some new insights to understand the electron dynamics of solar flares.

Super-Flaring Active Region 12673 Has One of the Fastest Magnetic Flux Emergence Ever Observed

Xudong **Sun**, Aimee A. Norton

Research Notes of the AAS **1** 24 **2017**

Investigating the Magnetic Imprints of Major Solar Eruptions with SDO/HMI High-Cadence Vector Magnetograms

Xudong **Sun**, J. Todd Hoeksema, Yang Liu, Maria Kazachenko, Ruizhu Chen

ApJ **2017**

https://arxiv.org/pdf/1702.07338.pdf

The solar active region photospheric magnetic field evolves rapidly during major eruptive events, suggesting appreciable feedback from the corona. The new high-cadence (90 s or 135 s) vector magnetogram dataset from the Helioseismic and Magnetic Imager (HMI) is suited for investigating these "magnetic imprints". Observations of an archetypical event, SOL**2011-02-15T01**:56, show the following trends. Firstly, the horizontal magnetic field component (Bh) exhibits permanent, step-like changes with a time scale of several minutes, whereas the radial component (Br) varies less. Secondly, Bh near the main polarity inversion line increases significantly during the earlier phase of the associated flare, whereas Bh in the periphery decreases at later times with smaller magnitudes. Thirdly, transient artifacts coincide with enhanced flare emission, where the Stokes profiles are no longer adequately modeled under

standard settings, and the inferred magnetic field becomes unreliable. Our results corroborate previous findings, remove certain ambiguities that arise from line-of-sight only or lower-cadence vector observations, and provide insights on the momentum processes during solar eruption. The dataset may also be useful to the study of sunquakes and data-driven modeling of the solar corona.

Why Is the Great Solar Active Region 12192 CME-Poor?

Xudong **Sun**, Monica G. Bobra, J. Todd Hoeksema, Yang Liu, Yan Li, Chenglong Shen, Sebastien Couvidat, Aimee A. Norton, George H. Fisher

ApJL **2015**

http://arxiv.org/pdf/1502.06950v1.pdf

Solar active region (AR) **12192 of October 2014** hosts the largest sunspot group in 24 years. It is the most prolific flaring site of Cycle 24, but surprisingly produced no coronal mass ejection (CME) from the core region during its disk passage. Here, we study the magnetic conditions that prevented eruption and the consequences that ensued. We find AR 12192 to be "big but mild"; its core region exhibits weaker non-potentiality, stronger overlying field, and smaller flare-related field changes compared to two other major flare-CME-productive ARs (11429 and 11158). These differences are present in the intensive-type indices (e.g., means) but generally not the extensive ones (e.g., totals). AR 12192's large amount of magnetic free energy does not translate into CME productivity. The unexpected behavior suggests that AR eruptiveness is limited by some relative measure of magnetic non-potentiality over the restriction of background field, and that confined flares may leave weaker photospheric and coronal imprints compared to their eruptive counterparts. **18-28 Oct 2014, 2012-03-07, 2011-02-15**

Dynamic Evolution of an X-shaped Structure above a Trans-equatorial Quadrupole Solar Active Region Group

J. Q. **Sun**, X. Cheng, Y. Guo, M. D. Ding, Y. Li

ApJL, **2014**

http://arxiv.org/pdf/1405.1563v1.pdf

In the solar corona, magnetic reconnection usually takes place at the singular configuration of magnetic field, in particular near a magnetic null owing to its high susceptibility to perturbations. In this Letter, we report a rare X-shaped structure, encompassing a magnetic null, above a trans-equatorial quadrupole active region group that is well observed by the Atmospheric Imaging Assembly (AIA). The observations show that this X-shaped structure is visible in all AIA EUV passbands and stably exists for days. However, possibly induced by flare activities at the northern part of the quadrupole active region group, the X-shaped structure starts to destabilize and meanwhile a jet erupted near its center at 15:05 UT on **2013 October 7**. Through the non-linear force-free field modeling, we identify a magnetic null, which is above the quadrupole polarities and well corresponds to the X-shaped structure. After the jet eruption, the temperature and emission measure of the plasma near the X-shaped structure rise from 2.3 MK and 1.2x10^27 cm-5 at 15:01 UT to 5.4 MK and 3.7x10^27 cm-5 at 15:36 UT, respectively, revealed by the differential emission measure analysis, indicating that magnetic reconnection most likely takes place there to heat the plasma. Moreover, the height of the null has an increase of 10 Mm, which is most likely due to the partial opening of the field lines near the fan surface that makes the null underneath rise to seek for a new equilibrium.

Differential Emission Measure Analysis of A Limb Solar Flare on 2012 July 19

J. Q. **Sun**, X. Cheng, M. D. Ding

2014 ApJ 786 73

http://arxiv.org/pdf/1403.6202v2.pdf

We perform Differential Emission Measure (DEM) analysis of an M7.7 flare that occurred on 2012 July 19 and was well observed by the Atmospheric Imaging Assembly (AIA) aboard the Solar Dynamic Observatory. Using the observational data with unprecedented high temporal and spatial resolution from six AIA coronal passbands, we calculate the DEM of the flare and derive the time series of maps of DEM-weighted temperature and emission measure (EM). It is found that, during the flare, the highest EM region is located in the flare loop top with a value varying between 8.4 10^28 cm^-5 and 2.5 10^30 cm^-5. The temperature there rises from 8 MK at about 04:40 UT (the initial rise phase) to a maximum value of 13 MK at about 05:20 UT (the hard X-ray peak). Moreover, we find a hot region that is above the flare loop top with a temperature even up to 16 MK. We also analyze the DEM properties of the reconnection site. The temperature and density there are not as high as that in the loop top and the flux rope, indicating that the main heating may not take place inside the reconnection site. In the end, we examine the dynamic behavior of the flare loops. Along the flare loop, both the temperature and the EM are the highest in the loop top and gradually

decrease towards the footpoints. In the northern footpoint, an upward force appears with a biggest value in the impulsive phase, which we conjecture originates from chromospheric evaporation.

Hot Spine Loops and the Nature of a Late-Phase Solar Flare

Xudong **Sun**, J. Todd Hoeksema, Yang Liu, Guillaume Aulanier, Yingna Su, Iain G. Hannah, Rachel A. Hock

E-print, Oct **2013**; **2013** ApJ 77, 139.

http://arxiv.org/pdf/1310.1438v1.pdf

The fan-spine magnetic topology is believed to be responsible for many curious features in solar explosive events. A spine field line links distinct flux domains, but direct observation of such feature has been rare. Here we report a unique event observed by the Solar Dynamic Observatory where a set of hot coronal loops (over 10 MK) connected to a quasi-circular chromospheric ribbon at one end and a remote brightening at the other. Magnetic field extrapolation suggests these loops are partly tracer of the evolving spine field line. Continuous slipping- and null-point-type reconnections were likely at work, energizing the loop plasma and transferring magnetic flux within and across the fan quasi-separatrix layer. We argue that the initial reconnection is of the "breakout" type, which then transitioned to a more violent flare reconnection with an eruption from the fan dome. Significant magnetic field changes are expected and indeed ensued. This event also features an extreme-ultraviolet (EUV) late phase, i.e. a delayed secondary emission peak in warm EUV lines (about 2-7 MK). We show that this peak comes from the cooling of large post-reconnection loops beside and above the compact fan, a direct product of eruption in such topological settings. The long cooling time of the large arcades contributes to the long delay; additional heating may also be required. Our result demonstrates the critical nature of cross-scale magnetic coupling - topological change in a sub-system may lead to explosions on a much larger scale. **2011 November 15**

A NON-RADIAL ERUPTION IN A QUADRUPOLAR MAGNETIC CONFIGURATION WITH A CORONAL NULL

Xudong **Sun**, J. Todd Hoeksema1, Yang Liu, Qingrong Chen, and Keiji Hayashi

2012 ApJ 757 149

We report one of the several homologous non-radial eruptions from NOAA active region (AR) 11158 that are strongly modulated by the local magnetic field as observed with the Solar Dynamic Observatory. A small bipole emerged in the sunspot complex and subsequently created a quadrupolar flux system. Nonlinear force-free field extrapolation from vector magnetograms reveals its energetic nature: the fast-shearing bipole accumulated ~2 × 1031 erg free energy (10% of AR total) over just one day despite its relatively small magnetic flux (5% of AR total). During the eruption, the ejected plasma followed a highly inclined trajectory, over 60° with respect to the radial direction, forming a jet-like, inverted-Y-shaped structure in its wake. Field extrapolation suggests complicated magnetic connectivity with a coronal null point, which is favorable of reconnection between different flux components in the quadrupolar system. Indeed, multiple pairs of flare ribbons brightened simultaneously, and coronal reconnection signatures appeared near the inferred null. Part of the magnetic setting resembles that of a blowout-type jet; the observed inverted-Y structure likely outlines the open field lines along the separatrix surface. Owing to the asymmetrical photospheric flux distribution, the confining magnetic pressure decreases much faster horizontally than upward. This special field geometry likely guided the non-radial eruption during its initial stage.

EVOLUTION OF MAGNETIC FIELD AND ENERGY IN A MAJOR ERUPTIVE ACTIVE REGION BASED ON SDO/HMI OBSERVATION

Xudong **Sun**1,2, J. Todd Hoeksema1, Yang Liu1, Thomas Wiegelmann3, Keiji Hayashi1, Qingrong Chen2 and Julia Thalmann

2012 ApJ 748 77

We report the evolution of the magnetic field and its energy in NOAA active region 11158 over five days based on a vector magnetogram series from the Helioseismic and Magnetic Imager (HMI) on board the Solar Dynamic Observatory (SDO). Fast flux emergence and strong shearing motion led to a quadrupolar sunspot complex that produced several major eruptions, including the first X-class flare of Solar Cycle 24. Extrapolated nonlinear force-free coronal fields show substantial electric current and free energy increase during early flux emergence near a low-lying sigmoidal filament with a sheared kilogauss field in the filament channel. The computed magnetic free energy reaches a maximum of ~2.6 × 1032 erg, about 50% of which is stored below 6 Mm. It decreases by ~0.3 × 1032 erg within 1 hr of the X-class flare, which is likely an underestimation of the actual energy loss. During the flare, the photospheric field changed rapidly: the horizontal field was enhanced by 28% in the core region, becoming more inclined and more parallel to the polarity inversion line. Such change is consistent with the conjectured coronal field "implosion" and is supported by the coronal loop retraction observed by the Atmospheric Imaging Assembly (AIA). The extrapolated field

becomes more "compact" after the flare, with shorter loops in the core region, probably because of reconnection. The coronal field becomes slightly more sheared in the lowest layer, relaxes faster with height, and is overall less energetic.

The EIS flare catalogue 1 year anniversary

Jian **Sun**, Lucie Green and Deb Baker
Hinode/EIS Nugget, Feb **2012**
http://msslxr.mssl.ucl.ac.uk:8080/SolarB/nuggets/nugget_2012feb.jsp
The catalogue is accessed via the Hinode/EIS website **http://msslxr.mssl.ucl.ac.uk:8080/SolarB/eisflarecat.jsp** hosted at UCL-MSSL. Flare events can be seen by year in the lists or the database can be searched. Once a flare event is identified, a link takes you to a summary page showing the location of the EIS observations overlaid on a full Sun context image and also a timeline showing the EIS observations against the context of the GOES X-ray data (see Figure 1). Both context images show whether the observations are slit or slot and the details of the slit/slot width. From this same page you can view thumbnails of the EIS data, download the data files and find more information on the EIS study that was used.

CME productivity associated with Solar Flare peak X-ray emission flux

G.S.**Suryanarayana** K.M.Balakrishna
Advances in Space Research Volume 61, Issue 9, 1 May **2018**, Pages 2482-2489
http://sci-hub.tw/http://linkinghub.elsevier.com/retrieve/pii/S0273117718301236
It is often noticed that the occurrence rate of Coronal Mass Ejections (CMEs) increases with increase in flare duration where peak flux too increase. However, there is no complete association between the duration and peak flux. Distinct characteristics have been reported for active regions (ARs) where flares and CMEs occur in contrast to ARs where flares alone occur. It is observed that peak flux of flares is higher when associated with CMEs compared to peak flux of flares with which CMEs are not associated. In other words, it is likely that flare duration and peak flux are independently affected by distinct active region dynamics. Hence, we examine the relative ability of flare duration and peak flux in enhancing the CME productivity. We report that CME productivity is distinctly higher in association with the enhancement of flare peak flux in comparison to corresponding enhancement of flare duration.

Abnormal rotation rates of sunspots and durations of associated flares

G. S. **Suryanarayana**, K. M. Hiremath, S. P. Bagare and M. Hegde
A&A 580, A25 (**2015**), **File**
http://www.aanda.org/articles/aa/pdf/2015/08/aa23389-14.pdf
Context. Short-duration and long-duration flares are important in terms of their association with coronal heating and coronal mass ejections, respectively. Sunspot motions in the photosphere have been known to be associated with flare occurrences.
Aims. We study the association between the abnormal rotation rates (longitudinal displacement in a given latitude in contrast with the rotation of spots around their umbral centre) of sunspots and flare duration.
Methods. We compute the rotation rates of sunspots for different days during their evolution. We consider rotation rates that are in excess of one standard deviation as abnormal rotation rates. Also, the duration of time between the initial and final stages of the flares are computed.
Results. Using Kodaikanal Observatory white light picture and GOES soft X-ray flare data, we find that a good we find that duration of flare is independent of sunspot area.
Conclusions. The present study suggests that sub-surface dynamics plays a dominant role in determining the duration and rate of dissipation of energy during flares. **2000.01.13-16, 2000.02.05-09, 2000.02.14, 2000.02.29-03.03, 2000.03.10-22, 2000.04.02-09**

Plasma Heating in a Post Eruption Current Sheet: A Case Study Based on Ultraviolet, Soft, and Hard X-Ray Data

R. **Susino**1,3, A. Bemporad1, and Säm Krucker
2013 ApJ 777 93
Off-limb observations of the solar corona after coronal mass ejections (CMEs) often show strong, compact, and persistent UV sources behind the eruption. They are primarily observed by the SOHO/UVCS instrument in the "hot" [Fe XVIII] λ974 line and are usually interpreted as a signature of plasma heating due to magnetic reconnection in the post-CME current sheet (CS). Nevertheless, the physical process itself and the altitude of the main energy release are currently not fully understood. In this work, we study the evolution of plasma heating after the CME of **2004 July 28** by comparing UV spectra acquired by UVCS with soft and hard X-ray (SXR, HXR) images of the post-flare loops taken by GOES/SXI and RHESSI. The X-ray data show a long-lasting extended source that is rising upward, toward the high-temperature source detected by UVCS. UVCS data show the presence of significant non-thermal broadening in the CS (a signature of turbulent motions) and a strong density gradient across the CS region. The thermal energy released in the

HXR source is on the order of ~1032 erg, a factor ~2-5 larger than the energy required to explain the high-temperature plasma sampled by UVCS. Nevertheless, the very different time evolutions of SXR and HXR sources compared with the UV emission suggest that reconnection occurring above the post-eruption arcades is not directly responsible for the high-temperature plasma sampled higher up by UVCS. We conclude that an additional plasma heating mechanism (such as turbulent reconnection) in the CS is likely required.

The Evolution of the Net Twist Current and the Net Shear Current in Active Region NOAA 10930

Yogita **Suthar**, P. Venkatakrishnan, B. Ravindra, S. N. A. Jaaffrey
Solar Phys., July **2014**, Volume 289, Issue 7, pp 2459-2471
The electric current exists because of the non-potential magnetic field in solar active regions. We present the evolution of net current in the solar active region NOAA 10930 as the sum of shear current and twist current by using 27 high-resolution vector magnetograms obtained with Hinode/SOT-SP during 9 – 15 December 2006. This active region was highly eruptive and produced a large number of flares ranging from B to X class. We derived local distribution of shear and twist current densities in this active region and studied the evolution of net shear current (NSC) and net twist current (NTC) in the N-polarity and S-polarity regions separately. We found the following: i) The twist current density was dominant in the umbrae. ii) The footpoint of the emerging flux rope showed a dominant twist current. iii) The shear current density and twist current density appeared in alternate bands around the umbrae. iv) On the scale of the active region, NTC was always larger than NSC. v) Both NTC and NSC decreased after the onset of an X3.4 class flare that occurred on **13 December 2006**.

FLARING SOLAR HALE SECTOR BOUNDARIES

L. **Svalgaard**1, I. G. Hannah2 and H. S. Hudson
2011 ApJ 733 49
http://arxiv.org/pdf/1010.2710v2.pdf
The sector structure that organizes the magnetic field of the solar wind into large-scale domains has a clear pattern in the photospheric magnetic field as well. The rotation rate, 27-28.5 days, implies an effectively rigid rotation originating deeper in the solar interior than the sunspots. The photospheric magnetic field is known to be concentrated near that portion (the Hale boundary) in each solar hemisphere, where the change in magnetic sector polarity matches that between the leading and following sunspot polarities in active regions in the respective hemispheres. We report here that flares and microflares also concentrate at the Hale boundaries, implying that flux emergence and the creation of free magnetic energy in the corona also have a direct cause in the deep interior.

Evolution and motions of magnetic fragments during the active region formation and decay: A statistical study

Michal **Švanda** (1 and 2), M. Sobotka (1), L. Mravcová (2 and 1), T. Výbošťoková (3)
A&A **2021**
https://arxiv.org/pdf/2102.02807.pdf
Context: The evolution of solar active regions is still not fully understood. The growth and decay of active regions have mostly been studied in case-by-case studies.
Aims: Instead of studying the evolution of active regions case by case, we performed a large-scale statistical study to find indications for the statistically most frequent scenario.
Methods: We studied a large sample of active regions recorded by the Helioseismic and Magnetic Imager instrument. The sample was split into two groups: forming (367 members) and decaying (679 members) active regions. We tracked individual dark features (i.e. those that are assumed to be intensity counterparts of magnetised fragments from small objects to proper sunspots) and followed their evolution. We investigated the statistically most often locations of fragment merging and splitting as well as their properties.
Results: Our results confirm that statistically, sunspots form by merging events of smaller fragments. The coalescence process is driven by turbulent diffusion in a process similar to random-walk, where supergranular flows seem to play an important role. The number of appearing fragments does not seem to significantly correlate with the number of sunspots formed. The formation seems to be consistent with the magnetic field accumulation. Statistically, the merging occurs most often between a large and a much smaller object. The decay of the active region seems to take place preferably by a process similar to the erosion. **AR11076**

Understanding the HMI pseudocontinuum in white-light solar flares

M. **Svanda** (1 and 2), Jan Jurcak (1), Jana Kasparova (1), Lucia Kleint
ApJ **860** 144 **2018**
https://arxiv.org/pdf/1805.03369.pdf
We analyse observations of the X9.3 solar flare (SOL**2017-09-06**T11:53) observed by SDO/HMI and Hinode/SOT. Our aim is to learn about the nature of the HMI pseudocontinuum Ic used as a proxy for the white-light continuum. From

model atmospheres retrieved by an inversion code applied to the Stokes profiles observed by the Hinode satellite we synthesise profiles of the FeI 617.3 nm line and compare them to HMI observations. Based on a pixel-by-pixel comparison we show that the value of Ic represents the continuum level well in quiet-Sun regions only. In magnetised regions it suffers from a simplistic algorithm that is applied to a complex line shape. During this flare both instruments also registered emission profiles in the flare ribbons. Such emission profiles are poorly represented by the six spectral points of HMI, the used algorithm does not account for emission profiles in general, and thus the derived pseudocontinuum intensity does not approximate the continuum value properly.

Large-scale horizontal flows in the solar photosphere
V. Possible evidence for the disconnection of bipolar sunspot groups from their magnetic roots

M. **Švanda**1, 2, 3, M. Klvaňa2, and M. Sobotka2
A&A 506, 875-884 **(2009**)
In a recent paper (Švanda et al. 2008, A&A, 477, 285) we pointed out that, based on the tracking of Doppler features in the full-disc MDI Dopplergrams, the active regions display two dynamically different regimes. We speculated that this could be a manifestation of the sudden change in the active regions dynamics, caused by the dynamic disconnection of sunspots from their magnetic roots as proposed by Schüssler & Rempel (2005, A&A, 441, 337). Here we investigate the dynamic behaviour of the active regions recorded in the high-cadence MDI data over the last solar cycle in order to confirm the predictions in the Schüssler's & Rempel's paper. We find that, after drastic reduction of the sample, which is done to avoid disturbing effects, a large fraction of active regions displays a sudden decrease in the rotation speed, which is compatible with the mechanism of the dynamic disconnection of sunspots from their parental magnetic structures.

The Misnomer of “Post-Flare Loops”

Zdenˇek **Švestka**
Solar Phys (**2007**) 246: 393–397, **File**
https://link.springer.com/content/pdf/10.1007%2Fs11207-007-9088-1.pdf
Attention is drawn to the fact that the term “post-flare loops” is incorrect and should be avoided, because the loops are parts of the flare itself. Two other names for these loop systems are suggested.

Ссылаться на этот обзор
VARIETIES OF CORONALMASS EJECTIONS AND THEIR RELATION TO FLARES
ZDENˇEK **ŠVESTKA** **Review**
Space Science Reviews **95:** 135–146, **2001**
https://sci-hub.ru/10.1023/A:1005225208925
Most coronal mass ejections (CMEs) start as coronal storms which are caused by an opening of channels of closed field lines along the zero line of the longitudinal magnetic field. This can happen along any zero line on the Sun where the configuration is destabilized. If the opening includes a zero line inside an active region, one observes a chromospheric flare. If this does not happen, no flare is associated with the CME in the chromosphere, but the process, as well as the response in the corona (a Long Decay Event in X-rays) remains the same. The only difference between flare-associated and non-flare-associated CMEs is the strength of the magnetic field in the region of the field line opening. This can explain essentially all differences which have been observed between these two kinds of CMEs. However, there are obviously also other sources of CMEs, different from coronal storms: sprays (giving rise to narrow, pointed ejections), erupting interconnecting loops (often destabilized by flares), and growing coronal holes. This paper tries to summarize and interpret observations which support this general picture, and demonstrates that both CMEs and flares must be properly discussed in any study of solar-terrestrial relations.

Eruptive Solar Flares, ed. Z. **Svestka**
Svestka, Z., &Cliver, E.W. , et al. **1992**, in Eruptive Solar Flares, ed. Z. Svestka (Berlin: Springer), 1

HISTORY AND BASIC CHARACTERISTICS OF ERUPTIVE FLARES
Svestka, Z., &Cliver, E.W. , **1992, File**
https://sci-hub.ru/10.1007/3-540-55246-4_70
We review the evolution of our knowledge and understanding of the eruptive

(dynamic, two-ribbon) flare phenomenon.
In the conclusion, we summarize the basic characteristics of eruptive flares.

Solar flares - The gradual phase **Review**

Zdenˇek **Švestka**
Solar Phys (**1989**) V. 121, No 1-2 p. 399-417; Discussion, p. 500 **File**
https://link.springer.com/content/pdf/10.1007/BF00161709.pdf
There are two kinds of the gradual phase of flares: (1) flares in which all the energy is released within the impulsive phase, and the gradual phase is simply the cooling of the heated flare plasma (confined flares) and (2) flares in which the energy release continues during the gradual phase (dynamic flares). The simplest case of the former, the single-loop flare, and the associated phenomena of coronal 'tongues', flaring arches, and bright surges are briefly addressed. Dynamic flares are discussed in more detail, including the Kopp and Pneuman (1976) model of these flares, subsequent modifications of the model, loop shrinking, giant postflare X-ray arches, radio type IV events and noise storms, complex structures of dynamic flares, and small dynamic flares. Flare hybrids are briefly addressed.

On the varieties of solar flares.

Švestka, Z.:
In: Neidig, D.F. (ed.) The Lower Atmosphere of Solar Flares, Proceedings of the Solar Maximum Mission Symposium, Sunspot, NM, Aug. 20 – 24, 1985 (A87-26201 10-92), Sunspot, NM, National Solar Observatory, **1986**, 332. ADS.
http://articles.adsabs.harvard.edu/pdf/1986lasf.conf..332S
An attempt is made to classify flares starting with two axiomatic assumptions: (1) that a flare is a short-lived release of energy in consequence of a rearrangement of the magnetic structure, and (2) the mode of energy release is a reconnection of magnetic field lines. Somewhat surprisingly, in spite of the enormous diversity of the flare phenomena, two classes are derived: dynamic flares and confined flares, where the confined flares may be subdivided in two subclasses. All the other varieties may be due to differences in the boundary conditions of the flare process. The paper discusses the various factors which cause the varieties in flares, and the association of the two basic types of flares with different kinds of radiation and with othere active phenomena on the Sun.

The reported durations of GOES Soft X-Ray flares in different solar cycles

Bill **Swalwell**, Silvia Dalla, Stephen Kahler, Stephen White, Alan Ling, Rodney Viereck, and Astrid Veronig
Space Weather **Volume16, Issue6** Pages 660-666 **2018**
https://arxiv.org/pdf/1805.10246.pdf
http://sci-hub.tw/https://onlinelibrary.wiley.com/doi/abs/10.1029/2018SW001886
The Geostationary Orbital Environmental Satellites (GOES) Soft X-ray (SXR) sensors have provided data relating to, \textit{inter alia}, the time, intensity and duration of solar flares since the 1970s. The GOES SXR Flare List has become the standard reference catalogue for solar flares and is widely used in solar physics research and space weather. We report here that in the current version of the list there are significant **differences between the mean duration of flares which occurred before May 1997 and the mean duration of flares thereafter.** Our analysis shows that the reported flare timings for the pre-May 1997 data were not based on the same criteria as is currently the case. This finding has serious implications for all those who used flare duration (or fluence, which depends on the chosen start and end times) as part of their analysis of pre-May 1997 solar events, or statistical analyses of large samples of flares, \textit{e.g.} as part of the assessment of a Solar Energetic Particle forecasting algorithm.

Fine wave structure of umbral flashes

R. **Sych**, M. Wang
A&A **2017**
https://arxiv.org/pdf/1710.08100.pdf
Context. Umbral flashes (UFs) are most common phenomenon of wave processes in sunspots. Studying the relationship between wave time dynamics and UF origin requires further investigating their fine spatial and height structure. Aims. We investigated the association between a short-time increase in the variations of 3-minute EUV emission at footpoints of coronal magnetic loops and the UF emergence in sunspot umbrae. Methods. We applied the Pixelized Wavelet Filtering (PWF) technique to analyze a cube of the images obtained by SDO/AIA at 1600{\AA}, 304{\AA}, and 171{\AA} to study the spatio-temporal dynamic of oscillations in individual magnetic loops. The time-distance plots were used to obtain the wave front propagation velocity. We used the magnetic field extrapolation for SDO/HMI magnetograms to obtain localization of the magnetic loop footpoins. Results. For the first time, we obtained 2D images of fine wave processes in magnetic structures of different scales related to umbral flashes. UFs sources were mainly localized at the magnetic loop footpoints anchored in an umbra.We revealed two types UFs, point and extended. The

first type is related to the footpoints of open field lines, the second is associated with the closed. The time dynamics of UFs shows an increase the oscillations before the peak value within one low-frequency wave train. It is shown that the maxima of oscillation trains coincide with the peak intensity of umbral flashes. Conclusions. The sunspot wave dynamics showed a relation between the localization of oscillations power peak at the coronal magnetic loop footpoints and the UF origin. The spatial structure of the UF sources, their power and lifetime are determined by the cut-off frequency of the waves for the detected waveguides. We concluded that UFs are a process of short-time increase of the wave activity at the footpoints of magnetic loops. **December 8, 2010**

MHD waves in sunspots **Review**

Robert **Sych**
Chapter in AGU Monograph **2015**
http://arxiv.org/pdf/1509.06466v1.pdf
The review addresses the spatial frequency morphology of sources of sunspot oscillations and waves, including their localization, size, oscillation periods, height localization with the mechanism of cut-off frequency that forms the observed emission variability. Dynamic of sunspot wave processes, provides the information about the structure of wave fronts and their time variations, investigates the oscillation frequency transformation depending on the wave energy is shown. The initializing solar flares caused by trigger agents like magnetoacoustic waves, accelerated particle beams, and shocks are discussed. Special attention is paid to the relation between the flare reconnection periodic initialization and the dynamics of sunspot slow magnetoacoustic waves. A short review of theoretical models of sunspot oscillations is provided.

Sunspot waves and flare energy release

R. **Sych**, M. Karlický, A. Altyntsev, J. Dudík, L. Kashapova
A&A, 577, A43 **2014**
http://arxiv.org/pdf/1409.2947v1.pdf
We address a possibility of the flare process initiation and further maintenance of its energy release due to a transformation of sunspot longitudinal waves into transverse magnetic loop oscillations with initiation of reconnection. This leads to heating maintaining after the energy release peak and formation of a flat stage on the X-ray profile. We applied the time-distance plots and pixel wavelet filtration (PWF) methods to obtain spatio-temporal distribution of wave power variations in SDO/AIA data. To find magnetic waveguides, we used magnetic field extrapolation of SDO/HMI magnetograms. The propagation velocity of wave fronts was measured from their spatial locations at specific times. In correlation curves of the 17 GHz (NoRH) radio emission we found a monotonous energy amplification of 3-min waves in the sunspot umbra before the **2012 June 7** flare. This dynamics agrees with an increase in the wave-train length in coronal loops (SDO/AIA, 171 {\AA}) reaching the maximum 30 minutes prior to the flare onset. A peculiarity of this flare time profile in soft X-rays (RHESSI, 3-25 keV) is maintaining the constant level of the flare emission for 10 minutes after the short impulse phase, which indicates at the energy release continuation. Throughout this time, we found 30-sec period transverse oscillations of the flare loop in the radio-frequency range (NoRH, 17 GHz). This periodicity is apparently related to the transformation of propagating longitudinal 3-min waves from the sunspot into the loop transverse oscillations. The magnetic field extrapolation showed the existence of the magnetic waveguide (loop) connecting the sunspot with the energy release region. A flare loop heating can be caused by the interaction (reconnections) of this transversally oscillating waveguide with the underlying twisted loops.

Relationship between wave processes in sunspots and quasi-periodic pulsations in active region flares

R. **Sych**, V.M. Nakariakov, M. Karlicky, and S. Anfinogentov
E-print, Aug **2009**, A&A, 505 (**2009**) 791-799
http://www.aanda.org/10.1051/0004-6361/200912132
A phenomenological relationship between oscillations in a sunspot and quasi-periodic pulsations in flaring energy releases at an active region above the sunspot, is established. The analysis of the microwave emission recorded by the Nobeyama Radioheliograph at 17 GHz shows a gradual increase in the power of the 3-min oscillation train in the sunspot associated with AR 10756 before flares in this active region. The flaring light curves are found to be bursty with a period of 3 min. Our analysis of the spatial distribution of the 3-min oscillation power implies that the oscillations follow from sunspots along coronal loops towards the flaring site. It is proposed that quasi-periodic pulsations in the flaring energy releases can be triggered by 3-min slow magnetoacoustic waves leaking from sunspots.

The calcium abundance in flare plasmas is estimated using X-ray spectra from the Solar Maximum Mission Bent Crystal Spectrometer (BCS) during the decays of 194 flares (GOES classifications from B6.4 to X13) occurring between 1980 and 1989. Previous work by Sylwester et al. found that the abundance varied from flare to flare. That analysis is improved on here using updated instrument parameters and by including all calcium lines viewed by the BCS instead of only the resonance line, so greatly enhancing the photon count statistics. The abundance variations are confirmed with the average abundance, A(Ca) (expressed logarithmically with A(H)=12), equal to 6.77±0.20 for 194 flares (141 of which are new in this study). This range corresponds to factors of between 1.7 and 7.2 larger than the photospheric abundance and so our results are in line with a ``FIP" (first ionization potential) effect whereby low-FIP elements like Ca (FIP = 6.11~eV) have enhanced coronal abundances. The Ca flare abundance is uncorrelated with solar activity indices, but weak correlations are suggested with GOES flare class and duration (larger A(Ca) for smaller and shorter flares). The ponderomotive force theory of Laming explaining the FIP effect gives a range of parameters within which our estimates of A(Ca) agree with the theory. However, this then gives rise to disagreements with previous estimates of the flare silicon and sulfur abundances, although those of argon and iron are in good agreement. Small adjustments of the theory may thus be necessary.

https://doi.org/10.3847/1538-4357/ab86ba
The {\em Bent Crystal Spectrometer}\/ (BCS) on the NASA {\em Solar Maximum Mission}\/ spacecraft observed the X-ray spectra of numerous solar flares during the periods 1980 February to November and 1984~--~1989. The instrument, the first of its kind to use curved crystal technology, observed the resonance lines of He-like Ca (\caxix) and Fe (\fexxv) and neighboring satellite lines, allowing the study of the rapid evolution of flare plasma temperature, turbulence, mass motions etc. To date there has not been a solar X-ray spectrometer with comparable spectral and time resolution, while subsequent solar cycles have delivered far fewer and less intense flares. The BCS data archive thus offers an unparalleled resource for flare studies. A recent re-assessment of the BCS calibration and its operations is extended here by using data during a spacecraft scan in the course of a flare on 1980 November~6 that highlights small deformations in the crystal curvature of the important channel~1 (viewing lines of \caxix\ and satellites). The results explain long-standing anomalies in spectral line ratios which have been widely discussed in the past. We also provide an in-flight estimation of the BCS collimator field of view which improves the absolute intensity calibration of the BCS. The BCS channel~1 background is shown to be entirely due to solar continuum radiation, confirming earlier analyses implying a time-variable flare abundance of Ca. We suggest that BCS high-resolution \caxix\ and \fexxv\ line spectra be used as templates for the analysis of X-ray spectra of non-solar sources.

RESIK SOLAR X-RAY FLARE ELEMENT ABUNDANCES ON A NON-ISOTHERMAL ASSUMPTION

B. **Sylwester**, K. J. H. Phillips, J. Sylwester, A.. Kepa
ApJ **805** 49 **2015**
http://arxiv.org/pdf/1503.00979.pdf
Solar X-ray spectra from the RESIK crystal spectrometer on the CORONAS-F spacecraft (spectral range 3.3-6.1A are analyzed for thirty-three flares using a method to derive abundances of Si, S, Ar, and K, emission lines of which feature prominently in the spectra. For each spectrum, the method first optimizes element abundances then derives the differential emission measure as a function of temperature based on a procedure given by Sylwester et al. and Withbroe. This contrasts with our previous analyses of RESIK spectra in which an isothermal assumption was used. The revised abundances (on a logarithmic scale with A(H) = 12) averaged for all the flares in the analysis are A(Si) = 7.53 +/- 0.08 (previously 7.89 +/- 0.13), A(S) = 6.91 +/- 0.07 (7.16 +/- 0.17), A(Ar) = 6.47 +/- 0.08 (6.45 +/- 0.07), and A(K) = 5.73 +/- 0.19 (5.86 +/- 0.20), with little evidence for time variations of abundances within the evolution of each flare. Our previous estimates of the Ar and K flare abundances are thus confirmed by this analysis but those for Si and S are reduced. This suggests the flare abundances of Si and Ar are very close to the photospheric abundance or solar proxies, while S is significantly less than photospheric and the K abundance is much higher than photospheric. These estimates differ to some extent from those in which a single enhancement factor applies to elements with first ionization potential less than 10~eV. **Table 2. RESIK Flares in this Analysis**

X-ray Flare Spectra from the DIOGENESS Spectrometer and its concept applied to ChemiX on the Interhelioprobe spacecraft

J. **Sylwester**, Z. Kordylewski, S. Plocieniak, M. Siarkowski, M. Kowalinski, S. Nowak, W. Trzebinski, M. Steslicki, B. Sylwester, E. Stanczyk, R. Zawerbny, Z. Szaforz, K. J. H. Phillips, F. Farnik, A. Stepanov
Solar Phys., **2015**
http://arxiv.org/pdf/1411.0850v1.pdf
The DIOGENESS X-ray crystal spectrometer on the CORONAS-F spacecraft operated for a single month (25~August to 17~September) in 2001 but in its short lifetime obtained one hundred and forty high-resolution spectra from some eight solar flares with GOES importance ranging from C9 to X5. The instrument included four scanning flat crystals with wavelength ranges covering the regions of Si XIII (6.65 Angstroms), S XV (5.04 Angstroms), and Ca XIX (3.18 Angstroms) X-ray lines and associated dielectronic satellites. Two crystals covering the Ca XIX lines were oriented in a ``Dopplerometer'' manner, i.e. such that spatial and spectral displacements both of which commonly occur in flares can be separated. We describe the DIOGENESS spectrometer and the spectra obtained during flares which include lines not hitherto seen from spacecraft instruments. An instrument with very similar concept is presently being built for the two Russian Interhelioprobe spacecraft due for launch in 2020 and 2022 that will make a near-encounter (perihelion approx. 0.3 a.u.) to the Sun in its orbit. We outline the results that are likely to be obtained. Aug. 25, Aug. 30, Sept. 2, Sept. 3, Sept. 16 **2001**

Solar Flare Composition and Thermodynamics from RESIK X-ray Spectra

B. **Sylwester**, J. Sylwester, K. J. H. Phillips, A. Kepa, T. Mrosek
2014, ApJ 787 122
http://arxiv.org/pdf/1404.5775v2.pdf
Previous estimates of the solar flare abundances of Si, S, Cl, Ar, and K from the RESIK X-ray crystal spectrometer on board the CORONAS-F spacecraft were made on the assumption of isothermal X-ray emission. We investigate the effect on these estimates by relaxing this assumption and instead determining the differential emission measure (DEM) or thermal structure of the emitting plasma by re-analyzing RESIK data for a GOES class M1.0 flare on 2002 November~14 (SOL**2002-11-14**T22:26) for which there was good data coverage. The analysis method uses a maximum-likelihood (Withbroe--Sylwester) routine for evaluating the DEM. In a first step, called here AbuOpt, an optimized set of abundances of Si, S, Ar, and K is found that is consistent with the observed spectra. With these abundances, the differential emission measure evolution during the flare is found. The abundance optimization leads to revised abundances of silicon and sulfur in the flare plasma: A(S)=6.94±0.06 and A(Si)=7.56±0.08 (on a logarithmic scale with A(H)=12). Previously determined abundances of Ar, K, and Cl from an isothermal assumption are still the preferred values. During the flare's maximum phase, the X-ray-emitting plasma has a basically two-temperature structure, with the cooler plasma with approximately constant temperature (3--6~MK) and a hotter plasma with temperature 16−21~MK. Using imaging data from the RHESSI hard X-ray spacecraft, the emission volume of the hot plasma is deduced from which lower limits of the electron density Ne and the thermal content of the plasma are given.

X-ray Flare Spectra from the DIOGENESS Spectrometer and Its Concept Applied to ChemiX on the Interhelioprobe Spacecraft

Janusz **Sylwester**, Zbigniew Kordylewski, Stefan Płocieniak …
Solar Phys. Volume 290, Issue 12, pp 3683-3697 **2015 Open Access**
The DIOGENESS X-ray crystal spectrometer on the CORONAS-F spacecraft operated only for a single month (25 August to 17 September) in 2001, but in its short lifetime obtained one hundred and forty high-resolution spectra of eight solar flares with GOES importance ranging from C9 to X5. The instrument included four scanning flat crystals with wavelength ranges covering the regions of Si xiii (6.65 Å), S xv (5.04 Å), and Ca xix (3.18 Å) X-ray lines and associated dielectronic satellites. Two crystals covering the Ca xix lines were oriented in a “dopplerometer” manner, i.e. such that spatial and spectral displacements, both of which commonly occur in flares, can be separated. We describe the DIOGENESS spectrometer and the spectra obtained during flares that include lines not hitherto seen from spacecraft instruments. An instrument with a very similar concept is currently being built for the two Russian Interhelioprobe spacecraft that are scheduled for launch in 2020 and 2022 and will make a near-encounter (perihelion ~ 0.3 AU) with the Sun in its orbit. We outline the results that are likely to be obtained.

THE SOLAR FLARE CHLORINE ABUNDANCE FROM RESIK X-RAY SPECTRA

B. **Sylwester**1, K. J. H. Phillips2, J. Sylwester1 and V. D. Kuznetsov
2011 ApJ 738 49
The abundance of chlorine is determined from X-ray spectra obtained with the RESIK instrument on CORONAS-F during solar flares between 2002 and 2003. Using weak lines of He-like Cl, Cl XVI, between 4.44 and 4.50 Å, and with temperatures and emission measures from GOES on an isothermal assumption, we obtained A(Cl) = 5.75 ± 0.26 on a scale A(H) = 12. The uncertainty reflects an approximately a factor of two scatter in measured line fluxes. Nevertheless, our value represents what is probably the best solar determination yet obtained. It is higher by factors of 1.8 and 2.7 than Cl abundance estimates from an infrared sunspot spectrum and nearby H II regions. The constancy of the RESIK

abundance values over a large range of flares (GOES class from below C1 to X1) argues for any fractionation that may be present in the low solar atmosphere to be independent of the degree of solar activity.

Chromospheric and coronal heating and jet acceleration due to reconnection driven by flux cancellation. II. Cancellation of two magnetic polarities of unequal flux

Syntelis P., Priest E. R

A&A **2021**

https://arxiv.org/pdf/2103.16184.pdf

Context. Recent observations have shown that magnetic flux cancellation occurs at the photosphere more frequently than previously thought.
Aims. In order to understand the energy release by reconnection driven by flux cancellation, we previously studied a simple model of two cancelling polarities of equal flux. Here, we further develop our analysis to achieve a more general setup where the two cancelling polarities have unequal magnetic fluxes and where many new features are revealed.
Methods. We carried out an analytical study of the cancellation of two magnetic fragments of unequal and opposite flux that approach one another and are located in an overlying horizontal magnetic field.
Results. The energy release as microflares and nanoflares occurs in two main phases. During phase 1a, a separator is formed and reconnection is driven at it as it rises to a maximum height and then moves back down to the photosphere, heating the plasma and accelerating plasma jets in the process. During phase 1b, once the separator moves back to the photosphere, it bifurcates into two null points. Reconnection is no longer driven at the separator and an isolated magnetic domain connecting the two polarities is formed. During phase 2, the polarities cancel out at the photosphere as magnetic flux submerges below the photosphere and as reconnection occurs at and above the photosphere and plasma jets and a mini-filament eruption can be produced.

Eruptions and Flaring Activity in Emerging Quadrupolar Regions

P. **Syntelis**, E. J. Lee, C. W. Fairbairn, V. Archontis, A. W. Hood

A&A **2019**

https://arxiv.org/pdf/1909.01446.pdf

Context. Some of the most dynamic active regions are associated with complex photospheric magnetic configurations such as quadrupolar regions, and especially ones with a δ-spot configuration and a strong Polarity Inversion Line (PIL). Aims. We study the formation and eruption of magnetic flux ropes in quadrupolar regions. Methods. 3D MHD simulations of the partial emergence of a highly twisted flux tube from the solar interior into a non-magnetized stratified atmosphere. Results. We emerge two Ω-shaped loops forming a quadrupolar region. The emerging flux forms two initially separated bipoles, that later come in contact creating a δ-spot central region. Above the two bipoles, two magnetic lobes expand and interact through a series of current sheets at the interface between them. Two recurrent confined eruptions are produced. In both cases, reconnection between sheared low-lying field lines forms a flux rope. Reconnection between the two lobes high in the atmosphere forms retracting field lines that push against the flux rope, creating a current sheet between them. It also forms a third magnetic lobe between the two emerged ones, that later acts as a strapping field. The flux rope eruptions are triggered when the reconnection between the flux ropes and the field above them becomes efficient enough to remove the tension of the overlying field. These reconnection events occur internally in the system. The first erupting flux rope almost fully reconnects with the overlying field. The second eruption is confined by the overlying field. During the confined eruption, the flux rope is enhanced in size, flux and twist, similar to confined-flare-to-flux-rope observations. Proxies of the emission reveal the two erupting filaments channels. A flare arcade is formed only in the second eruption due to the longer-lasting and more efficient reconnection below the flux rope.

Quasi-periodic pulsations in hard X-rays of partially occulted solar flares

Ż. **Szaforz**, M. Tomczak

Advances in Space Research Volume 64, Issue 5, 1 September **2019**, Pages 1100-1111

https://sci-hub.se/10.1016/j.asr.2019.06.006

We investigated solar flares partially occulted by the solar disk observed by the Yohkoh satellite. We found that about 30–40% of them show quasi-periodic pulsations (QPPs) in hard X-rays (HXR). A lack of usually brighter footpoint sources allowed us to reconstruct coronal HXR sources with a higher quality. We analyzed 28 partially occulted flares showing the QPPs and for the first time present results for such events as a group. In our opinion, the majority of the observed HXR loop-top sources can be explained as successive compression and rarefaction of magnetic traps described in a model of oscillating magnetic traps (OMT). In this model a particular value of a ratio between the diameter of traps and the period of pulsations is postulated. In our modification of this model, different values of the ratio are possible, with the exception of a lower range, where low values of magnetic field strength and high values of electron density number can excess the plasma-β parameter above unity (ballooning instability). **2 December 1991**
Table 1 List of partially occulted flares with the QPPs found in the Yohkoh HXT Flare Catalogue (1991-2001)

Testing the Model of Oscillating Magnetic Traps

Ż. **Szaforz**, M. Tomczak

Solar Phys., **2015**, Volume 290, Issue 1, pp 115-127

The aim of this paper is to test the model of oscillating magnetic traps (the OMT model), proposed by Jakimiec and Tomczak (Solar Phys. 261, 233, 2010). This model describes the process of excitation of quasi-periodic pulsations (QPPs) observed during solar flares. In the OMT model energetic electrons are accelerated within a triangular, cusp-like structure situated between the reconnection point and the top of a flare loop as seen in soft X-rays. We analyzed QPPs in hard X-ray light curves for 23 flares as observed by Yohkoh. Three independent methods were used. We also used hard X-ray images to localize magnetic traps and soft X-ray images to diagnose thermal plasmas inside the traps. We found that the majority of the observed pulsation periods correlates with the diameters of oscillating magnetic traps, as was predicted by the OMT model. We also found that the electron number density of plasma inside the magnetic traps in the time of pulsation disappearance is strongly connected with the pulsation period. We conclude that the observations are consistent with the predictions of the OMT model for the analyzed set of flares.

Coronal Magnetic Field Structure and Evolution for Flaring AR 11117 and Its Surroundings

Tilaye **Tadesse**, T. Wiegelmann, B. Inhester, A. Pevtsov

Solar Physics, November **2012**, Volume 281, Issue 1, pp 53-65

In this study, photospheric vector magnetograms obtained with the Synoptic Optical Long-term Investigations of the Sun (SOLIS) survey are used as boundary conditions to model three-dimensional nonlinear force-free (NLFF) coronal magnetic fields as a sequence of NLFF equilibria in spherical geometry. We study the coronal magnetic field structure inside an active region and its temporal evolution. We compare the magnetic field configuration obtained from NLFF extrapolation before and after the flaring event in active region (AR) 11117 and its surroundings observed on **27 October 2010**, and we also compare the magnetic field topologies and the magnetic energy densities and study the connectivities between AR 11117 and its surroundings. During the investigated time period, we estimate the change in free magnetic energy from before to after the flare to be 1.74×1032 erg, which represents about 13.5 % of the NLFF magnetic energy before the flare. In this study, we find that electric currents from AR 11117 to its surroundings were disrupted after the flare.

Magnetic Connectivity Between Active Regions 10987, 10988, and 10989 by Means of Nonlinear Force-Free Field Extrapolation

Tilaye **Tadesse**, T. Wiegelmann, B. Inhester and A. Pevtsov

Solar Physics, Volume 277, Number 1, 119-130, **2012**

Extrapolation codes for modelling the magnetic field in the corona in Cartesian geometry do not take the curvature of the Sun's surface into account and can only be applied to relatively small areas, e.g., a single active region. We apply a method for nonlinear force-free coronal magnetic field modelling of photospheric vector magnetograms in spherical geometry which allows us to study the connectivity between multi-active regions. We use Vector Spectromagnetograph (VSM) data from the Synoptic Optical Long-term Investigations of the Sun (SOLIS) survey to model the coronal magnetic field, where we study three neighbouring magnetically connected active regions (ARs 10987, 10988, 10989) observed on 28, 29, and 30 March 2008, respectively. We compare the magnetic field topologies and the magnetic energy densities and study the connectivities between the active regions. We have studied the time evolution of the magnetic field over the period of three days and found no major changes in topologies, as there was no major eruption event. From this study we have concluded that active regions are much more connected magnetically than the electric current.

Time-resolved emission from bright hot pixels of an active region observed in the EUV band with SDO/AIA and multi-stranded loop modeling

E. **Tajfirouze**, F. Reale, A. Petralia, P. Testa

ApJ 816, Issue 1, article id. 12 **2016**

http://arxiv.org/pdf/1510.07524v1.pdf

Evidence for small amounts of very hot plasma has been found in active regions and might be the indication of an impulsive heating, released at spatial scales smaller than the cross section of a single loop. We investigate the heating and substructure of coronal loops in the core of one such active region by analyzing the light curves in the smallest resolution elements of solar observations in two EUV channels (94 A and 335 A) from the Atmospheric Imaging Assembly on-board the Solar Dynamics Observatory. We model the evolution of a bundle of strands heated by a storm of nanoflares by means of a hydrodynamic 0D loop model (EBTEL). The light curves obtained from the random combination of those of single strands are compared to the observed light curves either in a single pixel or in a row of pixels, simultaneously in the two channels and using two independent methods: an artificial intelligent system (Probabilistic Neural Network, PNN) and a simple cross-correlation technique. We explore the space of the parameters

to constrain the distribution of the heat pulses, their duration and their spatial size, and, as a feedback on the data, their signatures on the light curves. From both methods the best agreement is obtained for a relatively large population of events (1000) with a short duration (less than 1 min) and a relatively shallow distribution (power law with index 1.5) in a limited energy range (1.5 decades). The feedback on the data indicates that bumps in the light curves, especially in the 94 A channel, are signatures of a heating excess that occurred a few minutes before. **28 October 2010**,

EUV Flickering of Solar Coronal Loops: A New Diagnostic of Coronal Heating

Tajfirouze, E.; Reale, F.; Peres, G.; Testa, P.
ApJL 817, Issue 2, article id. L11, 6 pp. (**2016**)
http://arxiv.org/pdf/1601.03935v1.pdf
A previous work of ours found the best agreement between EUV light curves observed in an active region core (with evidence of super-hot plasma) and those predicted from a model with a random combination of many pulse-heated strands with a power-law energy distribution. We extend that work by including spatially resolved strand modeling and by studying the evolution of emission along the loops in the EUV 94 " and 335 " channels of the Atmospheric Imaging Assembly on board the Solar Dynamics Observatory. Using the best parameters of the previous work as the input of the present one, we find that the amplitude of the random fluctuations driven by the random heat pulses increases from the bottom to the top of the loop in the 94 " channel and from the top to the bottom in the 335 " channel. This prediction is confirmed by the observation of a set of aligned neighboring pixels along a bright arc of an active region core. Maps of pixel fluctuations may therefore provide easy diagnostics of nanoflaring regions.

Quasi-periodic oscillations in flares and coronal mass ejections associated with magnetic reconnection

Takuya **Takahashi**, Jiong Qiu, Kazunari Shibata
ApJ **848** 102 **2017**
https://arxiv.org/pdf/1709.05234.pdf
We propose a mechanism for quasi-periodic oscillations of both coronal mass ejections (CMEs) and flare loops as related to magnetic reconnection in eruptive solar flares. We perform two-dimensional numerical MHD simulations of magnetic flux rope eruption, with three different values of the global Lundquist number. In the low Lundquist number run, no oscillatory behavior is found. In the moderate Lunquist number run, on the other hand, quasi-periodic oscillations are excited both at the bottom of the flux rope and at the flare loop-top. In the high Lundquist number run, quasi-periodic oscillations are also excited; in the meanwhile, the dynamics become turbulent due to the formation of multiple plasmoids in the reconnection current sheet. In high and moderate Lundquist number runs, thin reconnection jet collide with the flux rope bottom or flare loop-top and dig them deeply. Steep oblique shocks are formed as termination shocks where reconnection jet is bent (rather than decelerated) in horizontal direction, resulting in supersonic back-flows. The structure becomes unstable, and quasi-periodic oscillation of supersonic back-flows appear at locally confined high-beta region at both the flux rope bottom and flare loop-top. We compare the observational characteristics of quasi-periodic oscillations in erupting flux ropes, post-CME current sheets, flare ribbons and light curves, with corresponding dynamical structures found in our simulation. **2014 April 18**

Analysis of the Solar Flare Index for Solar Cycles 18 – 24: Extremely Deep Gnevyshev Gap in the Chromosphere

Jouni **Takalo**
Solar Phys. **2023**
https://arxiv.org/pdf/2306.04239.pdf
We study the solar flare index (SFI) for the solar cycles 18\,--\,24. We find that SFI has deeper Gnevyshev gap (GG) in its first principal component than other atmospheric parameters. The GG is extremely clear especially in the even cycles.
The GG of the SFI appears about a half year later as a drop in the interplanetary magnetic field near the Earth and in the geomagnetic Ap-index. The instantaneous response of the magnetic field to solar flares, however, shows about two to three days after the eruption as a high, sharp peak in the cross-correlation of the SFI and Ap-index and as a lower peak in SFI vs. IMF B cross-correlation. We confirm these rapid responses using superposed-epoch analysis.
The most active flare cycles during 1944-2020 are the Cycles 19 and 21. The Cycle 18 has very strong SFI days as much as Cycle 22, but it has least nonzero SFI days in the whole interval. Interestingly Cycle 20 can be compared to the Cycles 23 and 24 in its low flare activity, although it locates between the most active SFI cycles.

OBSERVATIONAL EVIDENCE OF PARTICLE ACCELERATION ASSOCIATED WITH PLASMOID MOTIONS

Shinsuke **Takasao**1, Ayumi Asai2,3, Hiroaki Isobe3,4, and Kazunari Shibata
2016 ApJ 828 103
https://arxiv.org/pdf/1611.00108v1.pdf

We report a strong association between the particle acceleration and plasma motions found in the **2010 August 18** solar flare. The plasma motions are tracked in the extreme ultraviolet (EUV) images taken by the Atmospheric Imaging Assembly (AIA) on board the Solar Dynamics Observatory and the Extreme UltraViolet Imager (EUVI) on the Solar Terrestrial Relations Observatory spacecraft Ahead, and the signature of particle acceleration was investigated by using Nobeyama Radioheliograph data. In our previous paper, we reported that in EUV images many plasma blobs appeared in the current sheet above the flare arcade. They were ejected bidirectionally along the current sheet, and the blobs that were ejected sunward collided with the flare arcade. Some of them collided or merged with each other before they were ejected from the current sheet. We discovered impulsive radio bursts associated with such plasma motions (ejection, coalescence, and collision with the post flare loops). The radio bursts are considered to be the gyrosynchrotron radiation by nonthermal high energy electrons. In addition, the stereoscopic observation by AIA and EUVI suggests that plasma blobs had a three-dimensionally elongated structure. We consider that the plasma blobs were three-dimensional plasmoids (i.e., flux ropes) moving in a current sheet. We believe that our observation provides clear evidence of particle acceleration associated with the plasmoid motions. We discuss possible acceleration mechanisms on the basis of our results.

ABOVE-THE-LOOP-TOP OSCILLATION AND QUASI-PERIODIC CORONAL WAVE GENERATION IN SOLAR FLARES

Shinsuke **Takasao**1,3 and Kazunari Shibata

2016 ApJ 823 150

http://arxiv.org/pdf/1606.09354v1.pdf

Observations revealed that various kinds of oscillations are excited in solar flare regions. Quasi-periodic pulsations (QPPs) in flare emissions are commonly observed in a wide range of wavelengths. Recent observations have found that fast-mode magnetohydrodynamic (MHD) waves are quasi-periodically emitted from some flaring sites (quasi-periodic propagating fast-mode magnetoacoustic waves; QPFs). Both QPPs and QPFs imply a cyclic disturbance originating from the flaring sites. However, the physical mechanisms remain puzzling. By performing a set of two-dimensional MHD simulations of a solar flare, we discovered the local oscillation above the loops filled with evaporated plasma (above-the-loop-top region) and the generation of QPFs from such oscillating regions. Unlike all previous models for QPFs, our model includes essential physics for solar flares such as magnetic reconnection, heat conduction, and chromospheric evaporation. We revealed that QPFs can be spontaneously excited by the above-the-loop-top oscillation. We found that this oscillation is controlled by the backflow of the reconnection outflow. The new model revealed that flare loops and the above-the-loop-top region are full of shocks and waves, which is different from the previous expectations based on a standard flare model and previous simulations. In this paper, we show the QPF generation process based on our new picture of flare loops and will briefly discuss a possible relationship between QPFs and QPPs. Our findings will change the current view of solar flares to a new view in which they are a very dynamic phenomenon full of shocks and waves.

Magnetohydrodynamic shocks in and above post-flare loops: two-dimensional simulation and a simplified model

Shinsuke **Takasao**, Takuma Matsumoto, Naoki Nakamura, Kazunari Shibata

ApJ **805** 135 **2015**

http://arxiv.org/pdf/1504.05700v1.pdf

Solar flares are an explosive phenomenon, where super-sonic flows and shocks are expected in and above the post-flare loops. To understand the dynamics of post-flare loops, a two-dimensional magnetohydrodynamic (2D MHD) simulation of a solar flare has been carried out. We found new shock structures in and above the post-flare loops, which were not resolved in the previous work by Yokoyama and Shibata 2001. To study the dynamics of flows along the reconnected magnetic field, kinematics and energetics of the plasma are investigated along selected field lines. It is found that shocks are crucial to determine the thermal and flow structures in the post-flare loops. On the basis of the 2D MHD simulation, we have developed a new post-flare loop model which we call the pseudo-2D MHD model. The model is based on the 1D MHD equations, where all the variables depend on one space dimension and all the three components of the magnetic and velocity fields are considered. Our pseudo-2D model includes many features of the multi-dimensional MHD processes related to magnetic reconnection (particularly MHD shocks), which the previous 1D hydrodynamic models are not able to include. We compare the shock formation and energetics of a specific field line in the 2D calculation with those in our pseudo-2D MHD model, and we found that they give similar results. This model will allow us to study the evolution of the post-flare loops in a wide parameter space without expensive computational cost and without neglecting important physics associated with magnetic reconnection.

SIMULTANEOUS OBSERVATION OF RECONNECTION INFLOW AND OUTFLOW ASSOCIATED WITH THE 2010 AUGUST 18 SOLAR FLARE

Shinsuke **Takasao**1,2, Ayumi Asai3, Hiroaki Isobe3 and Kazunari Shibata

2012 ApJ 745 L6
We report the simultaneous extreme-ultraviolet observation of magnetic reconnection inflow and outflow in a flare on **2010 August 18** observed by the Atmospheric Imaging Assembly on board the Solar Dynamics Observatory. We found that during the rise phase of the flare, some plasma blobs appeared in the sheet structure above the hot loops. The plasma blobs were ejected bidirectionally along the sheet structure (outflow), at the same time as the threads visible in extreme-ultraviolet images moved toward the sheet structure (inflow). The upward and downward ejection velocities are 220-460 km s–1 and 250-280 km s–1, respectively. The inflow speed changed from 90 km s–1 to 12 km s–1 in 5 minutes. By using these velocities, we estimated the nondimensional reconnection rate, which we found to vary during this period from 0.20 to 0.055. We also found that the plasma blobs in the sheet structure collided or merged with each other before they were ejected from the sheet structure. We hypothesize that the sheet structure is the current sheet and that these plasma blobs are plasmoids or magnetic islands, which could be important for understanding the dynamics of the reconnection region.

Evolution and Flare Activity of Delta-Sunspots in Cycle 23

Kan **Takizawa**, Reizaburo Kitai
Solar Phys. Volume 290, Issue 7, pp 2093-2116 **2015**
http://arxiv.org/pdf/1507.06453v1.pdf
The emergence and magnetic evolution of solar active regions (ARs) of beta-gamma-delta type, which are known to be highly flare-productive, were studied with the SOHO/MDI data in Cycle 23. We selected 31 ARs that can be observed from their birth phase, as unbiased samples for our study. From the analysis of the magnetic topology (twist and writhe), we obtained the following results. i) Emerging beta-gamma-delta ARs can be classified into three topological types as "quasi-beta", "writhed" and "top-to-top". ii) Among them, the "writhed" and "top-to-top" types tend to show high flare activity. iii) As the signs of twist and writhe agree with each other in most cases of the "writhed" type (12 cases out of 13), we propose a magnetic model in which the emerging flux regions in a beta-gamma-delta AR are not separated but united as a single structure below the solar surface. iv) Almost all the "writhed"-type ARs have downward knotted structures in the mid portion of the magnetic flux tube. This, we believe, is the essential property of beta-gamma-delta ARs. v) The flare activity of beta-gamma-delta ARs is highly correlated not only with the sunspot area but also with the magnetic complexity. vi) We suggest that there is a possible scaling-law between the flare index and the maximum umbral area. **26-31 July 2002, 11-16 January 2005, 29 Nov-5 Dec 2005**
Table 1. Summary of parameters for 31 ARs studied.

The Effect of Resistivity on the Periodicity of Oscillatory Reconnection

Jordan **Talbot**1, James A. McLaughlin1, Gert J. J. Botha1, and Mark Hancock1
2024 ApJ 965 133
https://iopscience.iop.org/article/10.3847/1538-4357/ad2a5d/pdf
The oscillatory reconnection mechanism is investigated for a parameter study of eight orders of magnitude of resistivity, with a particular interest in the evolution of the oscillating current density at the null point and its associated periodicity. The resistive, nonlinear MHD simulations are solved in 2.5D for different levels of resistivity. Three methods (wavelet analysis, Fourier transform, and ANOVA) are used to investigate the effect of resistivity versus resultant period. It is found that there is an independence between the level of background resistivity and the period of the oscillatory reconnection mechanism. Conversely, it is found that resistivity has a significant effect on the maximum amplitude of the current density and the nature of its decay rate, as well as the magnitude of ohmic heating at the null.

The relationships among solar flare impulsiveness, energy release, and ribbon development

Cole A **Tamburri**, Maria D Kazachenko, Adam F Kowalski
ApJ **966** 94 **2024**
https://arxiv.org/pdf/2403.02457.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ad3047/pdf
We develop the impulsiveness index, a new classification system for solar flares using the SDO/EVE 304 Å Sun-as-a-star light curves. Impulsiveness classifies events based on the duration and intensity of the initial high-energy deposition of energy into the chromosphere. In stellar flare U-band light curves, Kowalski et al. (2013) found that impulsiveness is related to quantities such as a proxy for the Balmer jump ratio. However, the lack of direct spatial resolution in stellar flares limits our ability to explain this phenomenon. We calculate impulsiveness for 1368 solar flares between 04/2010 and 05/2014. We divide events into categories of low, mid, and high impulsiveness. We find, in a sample of 480 flares, that events with high maximum reconnection rate tend to also have high impulsiveness. For six case studies, we compare impulsiveness to magnetic shear, ribbon evolution, and energy release. We find that the end of the 304 Å light curve rise phase in these case studies corresponds to the cessation of PIL-parallel ribbon motion, while PIL-perpendicular motion persists afterward in most cases. The measured guide field ratio for low and mid-impulsiveness case study flares decreases about an order of magnitude during the impulsive flare phase. Finally, we find that, in four of the six case studies, flares with higher, more persistent shear tend to have low impulsiveness. Our study suggests that

impulsiveness may be related to other properties of the impulsive phase, though more work is needed to verify this relationship and apply our findings to stellar flare physics. **2012 Nov 20, 2013 May 16, 2013 Oct 13, 2013 Oct 15, 2014 Apr 4, 2014 Apr 15**

Statistical Investigation of the Kinematic and Thermal Properties of Supra-arcade Downflows Observed During a Solar Flare

Guangyu **Tan**, Yijun Hou, Hui Tian
MNRAS Volume 522, Issue 3, July **2023**, Pages 4468–4480,
https://doi.org/10.1093/mnras/stad1228
https://arxiv.org/pdf/2208.14737.pdf

Supra-arcade downflows (SADs) are dark structures descending towards post-reconnection flare loops observed in extreme ultraviolet or X-ray observations and are closely related to magnetic reconnection during solar flares. Due to the lack of statistical study on SADs in a single flare, evolutions of kinematic and thermal properties of SADs during the flare process still remain obscure. In this work, we identified 81 SADs in a flare that occurred on **2013 May 22** using observations of the Atmospheric Imaging Assembly (AIA) on the Solar Dynamics Observatory (SDO). The kinematic properties of each SAD, including the appearance time, height, projective velocity, and acceleration were recorded. We found that the appearance heights of SADs become larger during the flare, which is likely due to the lift of the bottom of the plasma sheet. In the flare decay phase, the region where SADs mainly appear moves from the north part to the south side possibly related to a secondary eruption in the south side. The trajectories of most SADs can be fitted by one or two deceleration processes, while some special ones have positive accelerations during the descent. For the thermal properties, we selected 54 SADs, whose front and body could be clearly distinguished from the surrounding during the entire descent, to perform Differential Emission Measure analysis. It is revealed that the temperatures of the SAD front and body tend to increase during their downward courses, and the relationship between the density and temperature indicates that the heating is mainly caused by adiabatic compression.

The early evolution of solar flaring plasma loops

Baolin **Tan**
Universe **2021** *7*(10), 378;
https://www.mdpi.com/2218-1997/7/10/378/pdf
https://doi.org/10.3390/universe7100378
https://arxiv.org/ftp/arxiv/papers/2110/2110.07846.pdf

Plasma loops are the elementary structures of solar flaring active regions which dominate the whole processes of flaring eruptions. The standard flare models are well explained the evolution and eruption after magnetic reconnection around the hot cusp-structure above the top of plasma loops, however, the early evolution of the plasma loops before the onset of magnetic reconnection has been poorly understood. Considering that magnetic-gradients are ubiquitous in solar plasma loops, this work applies the magnetic-gradient pumping (MGP) mechanism to study the early evolution of flaring plasma loops. The results indicate that the early evolution depend on the magnetic field distribution and the geometry of the plasma loops which dominates the balance between the accumulation and dissipation of energy around loop-tops. Driven by MGP process, both of the density and temperature as well as the plasma beta value around the looptop will increase in the early phase of the plasma loops evolution. In fact, the solar plasma loops will have two distinct evolutionary results: the low, initial dense plasma loops with relatively strong magnetic fields tend to be stable for their maximum beta value always smaller than the critical value, while the higher, initial dilute solar plasma loops with relatively weak magnetic fields tend to be unstable for their beta values exceeding the critical value at a time of about one hour after the formation of the solar magnetized plasma loop. The latter may produce ballooning instability and finally trigger the following magnetic reconnection and eruptions. These physical scenarios may provide us a new viewpoint to understand the nature and origin of solar flares.

Energy and spectral analysis of confined solar flares from radio and X-ray observations

Chengming **Tan**, Karl-Ludwig Klein, Yihua Yan, Satoshi Masuda, Baolin Tan, Jing Huang, Guowu Yuan
Research in Astronomy and Astrophysics **2021**
https://arxiv.org/pdf/2108.02601.pdf

The energy and spectral shape of radio bursts may help us understand the generation mechanism of solar eruptions, including solar flares, CMEs, eruptive filaments, and various scales of jets. The different kinds of flares may have different characteristics of energy and spectral distribution. In this work, we selected 10 mostly confined flare events during **October 2014** to investigate their overall spectral behavior and the energy emitted in microwaves by using radio observations from microwaves to interplanetary radio waves, and X-ray observations of GOES, RHESSI, and Fermi/GBM. We found that: All the confined flare events were associated with a microwave continuum burst extending to frequencies of 9.4 - 15.4 GHz, and the peak frequencies of all confined flare events are higher than 4.995 GHz and lower than or equal to 17 GHz. The median value is around 9 GHz. The microwave burst energy (or fluence) as well as the peak frequency are found to provide useful criteria to estimate the power of solar flares. The observations imply that the magnetic field in confined flares tends to be stronger than that in 412 flares studied by Nita et al. 2004. All 10 events

studied did not produce detectable hard X-rays with energies above 300 keV indicating the lack of efficient acceleration of electrons to high energies in the confined flares. **18, 22, 24, 27, 28, 29 Oct 2014**

Very Long-period Pulsations before the Onset of Solar Flares

Baolin **Tan**, Zhiqiang Yu, Jing Huang, Chengming Tan, Yin Zhang
ApJ 833 206 **2016**
https://arxiv.org/pdf/1610.09291v1.pdf
Solar flares are the most powerful explosions occurring in the solar system, which may lead to disastrous space weather events and impact various aspects of our Earth. So far, it is still a big challenge in modern astrophysics to understand the origin of solar flares and predict their onset. Based on the analysis of soft X-ray emission observed by the Geostationary Operational Environmental Satellite (GOES), this work reported a new discovery of very long-periodic pulsations occurred in the preflare phase before the onset of solar flares (preflare-VLPs). These pulsations are typically with period of 8 - 30 min and last for about 1 - 2 hours. They are possibly generated from LRC oscillations of plasma loops where electric current dominates the physical process during magnetic energy accumulation in the source region. The preflare-VLP provides an essential information for understanding the triggering mechanism and origin of solar flares, and may help us to response to solar explosions and the corresponding disastrous space weather events as a convenient precursory indicator. **13 July 2012, 25 Oct 2013, 19 Oct 2014, 26 October 2014, 5 May 2015**

Diagnose Physical Conditions Near the Flare Energy-release Sites from Observations of Solar Microwave Type III Bursts

Baolin **Tan**, Marian Karlicky, Hana Meszarosova, Guangli Huang
Research in Astron. & Astrophys. (RAA), **201**5
http://arxiv.org/pdf/1511.08863v1.pdf
In the physics of solar flares, it is crucial to diagnose the physical conditions near the flare energy-release sites. However, so far it is unclear how do diagnose these physical conditions. Solar microwave type III burst is believed to be a sensitive signature of the primary energy release and electron accelerations in solar flares. This work takes into account the effect of magnetic field on the plasma density and developed s set of formulas which can be used to estimate the plasma density, temperature, magnetic field near the magnetic reconnection site and particle acceleration region, and the velocity and energy of electron beams. We applied these formulas to three groups of microwave type III pairs in a X-class flare, and obtained some reasonable and interesting results. This method can be applied to other microwave type III bursts to diagnose the physical conditions of source regions, and provide some basic information to understand the intrinsic nature and fundamental processes occurring near the flare energy-release sites. **13 Dec 2006**

SMALL-SCALE MICROWAVE BURSTS IN LONG-DURATION SOLAR FLARES

Baolin **Tan**
2013 ApJ 773 165
Solar small-scale microwave bursts (SMBs), including microwave dot, spike, and narrow-band type III bursts, are characterized by very short timescales, narrow frequency bandwidth, and very high brightness temperatures. Based on observations of the Chinese Solar Broadband Radio Spectrometer at Huairou with superhigh cadence and frequency resolution, this work presents an intensive investigation of SMBs in several flares that occurred in active region NOAA 10720 during **2005 January 14-21**. Especially for long-duration flares, the SMBs occurred not only in the early rising and impulsive phase, but also in the flare decay phase and even after the end of the flare. These SMBs are strong bursts with inferred brightness temperatures of at least 8.18 × 1011-1.92 × 1013 K, very short lifetimes of 5-18 ms, relative frequency bandwidths of 0.7%-3.5%, and superhigh frequency drifting rates. Together with their obviously different polarizations from background emission (the quiet Sun, and the underlying flaring broadband continuum), such SMBs should be individual, independent strong coherent bursts related to some non-thermal energy release and the production of energetic particles in a small-scale source region. These facts show the existence of small-scale strong non-thermal energy releasing activities after the flare maxima, which is meaningful for predicting space weather. Physical analysis indicates that a plasma mechanism may be the most favorable candidate for the formation of SMBs. From the plasma mechanism, the velocities and kinetic energy of fast electrons can be deduced and the region of electron acceleration can also be tracked.

Evolution of Evershed and Shear Flows Associated with the X3.4 Flare of 2006 December 13

Changyi **Tan**, P.F. Chen, Valentyna Abramenko and Haimin Wang
BBSO Preprint #1363, 2008; *ApJ* **690** 1820-1828, **2009**
http://www.iop.org/EJ/abstract/0004-637X/690/2/1820
http://solar.njit.edu/preprints/tan1363.pdf
Rapid and irreversible penumbral decays related to X-class flares have been found in a number of studies. Since the Evershed flows are closely associated with morphology of sunspot penumbra, we use the state-of-art Hinode data to track Evershed flow in flaring active regions as well as shear flows close to the flaring neutral line. This paper concentrates on the study of AR 10930 around the time of an X3.4 flare on December 13, 2006. We utilize the seeing-free solar optical telescope G-band and *Stokes-V* data as tracers to obtain the horizontal component of the Evershed and shear flows by local correlation tracking. We find that: (1) An obvious

penumbral decay appears in this active region intimately associated with the X3.4 flare. (2) The mean magnitude of the horizontal speeds of the Evershed flows within the penumbra decay areas varies from 0.4 to 1 km s^{-1} temporally and spatially. (3) The Evershed flows decrease before the flare eruption in two of the four penumbral decay areas. (4) The mean shear flows along the magnetic neutral of this δ-sunspot started to decrease before the flare and continue to decrease for another hour after the flare. The magnitude of this flow apparently dropped from 0.2 to 0.06 km s^{-1}. (5) Quasi-periodic oscillating behavior of the plasma flows is observed in both Evershed flows and shear flows. We propose that the decays of the penumbra and the Evershed flow are related to the magnetic rearrangement involved in the CME/flare events.

Solar Flare Prediction Based on the Fusion of Multiple Deep-learning Models

Rongxin **Tang**1,2,3, Wenti Liao1,2, Zhou Chen1,2,4,5, Xunwen Zeng2, Jing-song Wang5, Bingxian Luo6,7, Yanhong Chen6, Yanmei Cui6, Meng Zhou2, Xiaohua Deng2Show full author list

https://iopscience.iop.org/article/10.3847/1538-4365/ac249e/pdf

Solar flare formation mechanisms and their corresponding predictions have commonly been difficult topics in solar physics for decades. The traditional forecasting method manually constructs a statistical relationship between the measured values of solar active regions and solar flares that cannot fully utilize the information related to solar flares contained in observational data. In this article, we first used neural-network methods driven by the measured magnetogram and magnetic characteristic parameters of the sunspot group to learn the prediction model and predict solar flares. The prediction fusion model is based on a deep neural network, convolutional neural network, and bidirectional long short-term memory neural network and can predict whether a sunspot group will have a flare event above class M or class C in the next 24 or 48 hr. The real skill statistics (TSS) and F1 scores were used to evaluate the performances of our fusion model. The test results clearly show that this fusion model can make full use of the information related to solar flares and combine the advantages of each independent model to capture the evolution characteristics of solar flares, which is a much better performance than traditional statistical prediction models or any single machine-learning method. We also proposed two frameworks, namely F1_FFM and TSS_FFM, which optimize the F1 score and TSS score, respectively. The cross validation results show that they have their respective advantages in the F1 score and TSS score.

Parametric Evolution of Power-law Energy Spectra of Flare Accelerated Electrons in the Solar Atmosphere

J. F. **Tang**1,2,3, D. J. Wu2, L. Chen2, L. Xu4, and B. L. Tan3

2020 ApJ 904 1

https://doi.org/10.3847/1538-4357/abc2ca

It is well known that solar hard X-ray bursts (HXRs) and solar radio bursts (SRBs) from solar flares both are produced directly by fast electron beams (FEBs) traveling through the solar atmosphere. The observed characteristics of HXRs and SRBs sensitively depend on the energy distribution of FEBs, which are believed commonly to have a power-law energy spectrum. When FEBs propagating in the solar atmosphere, however, their energy spectra can considerably vary due to the interaction with the atmospheric plasmas and this may significantly influence the observational characteristics of the producing HXRs and SRBs. In the present paper, based on flare atmospheric models, we investigate the parametric evolution of power-law spectra of FEBs due to their energy losses when propagating along flaring loops. The results show that an initially single power-law spectrum with a lower-energy cutoff can evolve into a more complex double power-law spectrum or a broken power-law spectrum with multi-breaking knees because of the dependence of the energy loss on the initial energies. The possible effects of the energy-spectral evolution of FEBs on observational characteristics of their HXR flares and SRBs are discussed. The present results are helpful to understand the physics of dynamical spectra of HXRs and SRBs from solar flares.

Observational Signatures of Impulsively Heated Coronal Loops: Power-Law Distribution of Energies

Y. **Taroyan**, R. Erdélyi & S. J. Bradshaw

Solar Physics, Volume 269, Number 2, 295-307, **2011**

It has been established that small scale heating events, known as nanoflares, are important for solar coronal heating if the power-law distribution of their energies has a slope α steeper than −2 (α<−2). Forward modeling of impulsively heated coronal loops with a set of prescribed power-law indices α is performed. The power-law distribution is incorporated into the governing equations of motion through an impulsive heating term. The results are converted into synthetic Hinode/EIS observations in the 40″ imaging mode, using a selection of spectral lines formed at various temperatures. It is shown that the intensities of the emission lines and their standard deviations are sensitive to changes in α. A method based on a combination of observations and forward modeling is proposed for determining whether the heating in a particular case is due to small or large scale events. The method is extended and applied to a loop structure that consists of multiple strands.

On Excited Frequencies for Alfvén Waves in a Coronal Arcade

Lucas A. **Tarr**

2017 ApJ 847 1

The normal modes of oscillation for a magnetic arcade are used to analytically solve an initial value problem and estimate the power spectra of wave frequencies generated by a reconnection event in the solar corona. Over a realistic range of parameters, I find that such a disturbance generates a peak power at ~10 s $^{\mathrm{mHz}}$ frequency and substantial power up to $^{\sim 4\ \mathrm{Hz}}$. The cadence and sensitivity of current instrumentation does not allow observations of oscillations at these frequencies, but in the near future, new instrumentation will be able to probe this regime and observationally determine its energetic importance.

Quiescent Reconnection Rate Between Emerging Active Regions and Preexisting Field, with Associated Heating: NOAA AR 11112

Lucas A. **Tarr**, Dana W. Longcope, David E. McKenzie, Keiji Yoshimura

Solar Physics, September **2014**, Volume 289, Issue 9, pp 3331-3349

When magnetic flux emerges from beneath the photosphere, it displaces the preexisting field in the corona, and a current sheet generally forms at the boundary between the old and new magnetic domains. Reconnection in the current sheet relaxes this highly stressed configuration to a lower energy state. This scenario is most familiar and most often studied in flares, where the flux transfer is rapid. We present here a study of steady, quiescent flux transfer occurring at a rate three orders of magnitude lower than that in a large flare. In particular, we quantify the reconnection rate and the related energy release that occurred as the new polarity emerged to form NOAA Active Region 11112 (**SOL16 October 2010**T00:00:00L205C117) within a region of preexisting flux. A bright, low-lying kernel of coronal loops above the emerging polarity, observed with the Atmospheric Imaging Assembly onboard the Solar Dynamics Observatory and the X-ray Telescope onboard Hinode, originally showed magnetic connectivity only between regions of newly emerged flux when overlaid on magnetograms from the Helioseismic and Magnetic Imager. Over the course of several days, this bright kernel advanced into the preexisting flux. The advancement of an easily visible boundary into the old flux regions allows measuring the rate of reconnection between old and new magnetic domains. We compare the reconnection rate with the inferred heating of the coronal plasma. To our knowledge, this is the first measurement of steady, quiescent heating related to reconnection. We determined that the newly emerged flux reconnects at a fairly steady rate of 0.38×10^{16} Mx s^{-1} over two days, while the radiated power varies between $(2-8)\times10^{25}$ erg s^{-1} over the same time. We found that as much as 40 % of the total emerged flux at any given time may have reconnected. The total amounts of transferred flux ($\sim 1\times10^{21}$ Mx) and radiated energy ($\sim 7.2\times10^{30}$ ergs) are comparable to that of a large M- or small X-class flare, but are stretched out over 45 hours.

CALCULATING SEPARATE MAGNETIC FREE ENERGY ESTIMATES FOR ACTIVE REGIONS PRODUCING MULTIPLE FLARES: NOAA AR11158

Lucas **Tarr**, Dana Longcope, and Margaret Millhouse

2013 ApJ 770 4

It is well known that photospheric flux emergence is an important process for stressing coronal fields and storing magnetic free energy, which may then be released during a flare. The Helioseismic and Magnetic Imager (HMI) on board the Solar Dynamics Observatory (SDO) captured the entire emergence of NOAA AR 11158. This region emerged as two distinct bipoles, possibly connected underneath the photosphere, yet characterized by different photospheric field evolutions and fluxes. The combined active region complex produced 15 GOES C-class, two M-class, and the X2.2 Valentine's Day Flare during **the four days after initial emergence on 2011 February 12.** The M and X class flares are of particular interest because they are nonhomologous, involving different subregions of the active region. We use a Magnetic Charge Topology together with the Minimum Current Corona model of the coronal field to model field evolution of the complex. Combining this with observations of flare ribbons in the 1600 Å channel of the Atmospheric Imaging Assembly on board SDO, we propose a minimization algorithm for estimating the amount of reconnected flux and resulting drop in magnetic free energy during a flare. For the **M6.6, M2.2, and X2.2 flares**, we find a flux exchange of 4.2×10^{20} Mx, 2.0×10^{20} Mx, and 21.0×10^{20} Mx, respectively, resulting in free energy drops of 3.89×10^{30} erg, 2.62×10^{30} erg, and 1.68×10^{32} erg.

CALCULATING ENERGY STORAGE DUE TO TOPOLOGICAL CHANGES IN EMERGING ACTIVE REGION NOAA AR 11112

Lucas **Tarr** and Dana Longcope

2012 ApJ 749 64

The minimum current corona model provides a way to estimate stored coronal energy using the number of field lines connecting regions of positive and negative photospheric flux. This information is quantified by the net flux connecting pairs of opposing regions in a connectivity matrix. Changes in the coronal magnetic field, due to processes such as magnetic reconnection, manifest themselves as changes in the connectivity matrix. However, the connectivity matrix

will also change when flux sources emerge or submerge through the photosphere, as often happens in active regions. We have developed an algorithm to estimate the changes in flux due to emergence and submergence of magnetic flux sources. These estimated changes must be accounted for in order to quantify storage and release of magnetic energy in the corona. To perform this calculation over extended periods of time, we must additionally have a consistently labeled connectivity matrix over the entire observational time span. We have therefore developed an automated tracking algorithm to generate a consistent connectivity matrix as the photospheric source regions evolve over time. We have applied this method to NOAA Active Region 11112, which underwent a GOES M2.9 class flare around 19:00 on **2010 October 16**th, and calculated a lower bound on the free magnetic energy buildup of ~8.25 × 1030 erg over 3 days.

Limb Event Brightenings (LEBs) with fast ejection using IRIS mission Observations

E. **Tavabi**, S. Koutchmy, L. Golub
Solar Phys. **2015**
http://arxiv.org/ftp/arxiv/papers/1507/1507.06794.pdf
The Interface Region Imaging Spectrograph (IRIS) of the recently commissioned NASA Small Explorer mission provides significantly more complete and higher resolution spectral coverage of the dynamical conditions inside the chromosphere and Transition Region (TR) than has heretofore been available. Near the solar limb high temporal, spatial (0"3) and spectral resolution observations from ultraviolet IRIS spectra reveal high-energy limb event brightenings (LEBs) at low chromospheric height, near 1 Mm height above the limb. They can be characterized as explosive events producing jets. We selected 2 events showing spectra of a confined eruption just off or near the quiet Sun limb, the jet part showing obvious moving material with short duration large Doppler shifts in three directions identified as macro-spicules on slit-jaw (SJ) images in SiIV and HeII 304. The events are analyzed from a sequence of very close rasters taken near the central meridian and the South Pole limb. The processed SJ images and the simultaneously observed fast spectral sequences with large Doppler shifts, with a pair of red shifted elements together with a faster blue shifted element from almost the same position, are analyzed. Shifts correspond to velocities up to 100 km/s in projection on the plane of the limb. The occurrence of erupting spicules and macrospicules from these regions is noticed from images taken before and after the spectra. The cool low-FIP element simultaneous line emissions of the MgII h & k resonance lines do not clearly show a similar signature due to optical thickness effects but SiIV broad band SJ images do. The bidirectional plasma jets ejected from a small reconnection site are interpreted as the result of coronal loop-loop interactions leading to reconnection in nearby sites. **Oct. 10, 2013**

Blue wing enhancement of the chromospheric Mg II h and k lines in a solar flare

Akiko **Tei**, Takahito Sakaue, Tekanori J. Okamoto, Tomoko Kawate, Petr Heinzel, Satoru Ueno, Ayumi Asai, Kiyoshi Ichimoto, Kazunari Shibata
PASJ 70, Issue 6, **2018**
https://arxiv.org/pdf/1803.05237.pdf
We performed coordinated observations of AR 12205, which produced a C-class flare on **2014 November 11**, with the Interface Region Imaging Spectrograph (IRIS) and the Domeless Solar Telescope (DST) at Hida Observatory. Using spectral data in the Si IV 1403 \AA, C II 1335 \AA, and Mg II h and k lines from IRIS and the Ca II K, Ca II 8542 \AA, and Hα lines from DST, we investigated a moving flare kernel during the flare. In the Mg II h line, the leading edge of the flare kernel showed the intensity enhancement in the blue wing, and the smaller intensity of the blue-side peak (h2v) than that of the red-side one (h2r). The blueshift lasted for 9-48 s with a typical speed of 10.1 ± 2.6 km s−1 and it was followed by the high intensity and the large redshift with a speed of up to 51 km s−1 detected in the Mg II h line. The large redshift was a common property for all six lines but the blueshift prior to it was found only in the Mg II lines. A cloud modeling of the Mg II h line suggests that the blue wing enhancement with such peak difference can be caused by a chromospheric-temperature (cool) upflow. We discuss a scenario in which an upflow of cool plasma is lifted up by expanding hot plasma owing to the deep penetration of non-thermal electrons into the chromosphere. Furthermore, we found that the blueshift persisted without any subsequent redshift in the leading edge of the flare kernel during its decaying phase. The cause of such long-lasting blueshift is also discussed. 2014-11-11
RHESSI Science Nugget, No. 321, April 2018 http://sprg.ssl.berkeley.edu/~tohban/wiki/index.php/Blue-wing_enhancement_of_the_Mg_II_h_and_k_lines_in_a_flare

Investigating the Soft X-ray Spectra of Solar Flare Onsets

Anant **Telikicherla**, Thomas N. Woods, Bennet D. Schwab
ApJ **966** 198 **2024**
https://arxiv.org/pdf/2403.05992.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ad37f6/pdf
In this study we present the analysis of six solar flare events that occurred in 2022, using new data from the third-generation Miniature X-Ray Solar Spectrometer (MinXSS), also known as the Dual-zone Aperture X-ray Solar Spectrometer (DAXSS). The primary focus of this study is on the flare's "onset phase", which is characterized by elevated soft X-ray emissions even before the flare's impulsive phase. We analyze the temporal evolution of plasma temperature, emission measure, and elemental abundance factors during the flare onset phase, by fitting the DAXSS

spectra with the Astrophysical Plasma Emission Code (APEC) model. The model fitting results indicate that the flaring-plasma is already at a high temperature (10-15 MK) during the onset period. The temperature rises during the onset phase, followed by a decrease and subsequent increase during the impulsive phase. Elemental abundance factors show a trend of falling below pre-flare values during the onset phase, with some recovery before the impulsive phase. During the impulsive phase, the abundance factors decrease from elevated coronal values to about photospheric values. We also analyze images from the 193 Angstrom channel of the Atmospheric Imaging Assembly (AIA), highlighting the formation or brightening of coronal loop structures during the onset phase. Two distinct onset loop configurations are observed which are referred to as 1-loop and 2-loop onsets. Both DAXSS and AIA observations indicate that the flare onset phase exhibits similar hot coronal plasma properties as the impulsive phase, suggesting that the onset phase may act as a preconditioning effect for some flares. **2022-03-06, 2022-03-15, 2022-03-29, 2022-04-19, 2022-08-15, 2022-08-18**

Space weather: the solar perspective -- an update to Schwenn (2006) Review

Manuela **Temmer**
Living Reviews in Solar Physics **2021**
https://arxiv.org/pdf/2104.04261.pdf
https://link.springer.com/content/pdf/10.1007/s41116-021-00030-3.pdf
The Sun, as an active star, is the driver of energetic phenomena that structure interplanetary space and affect planetary atmospheres. The effects of Space Weather on Earth and the solar system is of increasing importance as human spaceflight is preparing for lunar and Mars missions. This review is focusing on the solar perspective of the Space Weather relevant phenomena, coronal mass ejections (CMEs), flares, solar energetic particles (SEPs), and solar wind stream interaction regions (SIR). With the advent of the STEREO mission (launched in 2006), literally, new perspectives were provided that enabled for the first time to study coronal structures and the evolution of activity phenomena in three dimensions. New imaging capabilities, covering the entire Sun-Earth distance range, allowed to seamlessly connect CMEs and their interplanetary counterparts measured in-situ (so called ICMEs). This vastly increased our knowledge and understanding of the dynamics of interplanetary space due to solar activity and fostered the development of Space Weather forecasting models. Moreover, we are facing challenging times gathering new data from two extraordinary missions, NASA's Parker Solar Probe (launched in 2018) and ESA's Solar Orbiter (launched in 2020), that will in the near future provide more detailed insight into the solar wind evolution and image CMEs from view points never approached before. The current review builds upon the Living Reviews paper by Schwenn from 2006, updating on the Space Weather relevant CME-flare-SEP phenomena from the solar perspective, as observed from multiple viewpoints and their concomitant solar surface signatures**. 5-8 Dec 1981, 13-16 Aug 1982, 12 July 2007, December 12, 2008, December 22, 2009, 10 Jun 2010, June 12-13, 2010, 28 Oct 2003, November 18, 2003, 6-8 Aug 2007, March 7, 2011, August 9, 2011, March 7–11, 2012: May 17, 2012, June 30, 2012, 2-4 Dec 2012, June 14, 2012, February 25, 2014, August 24, 2014, January 1, 2016, September 6, 2017, 6-12 Sep 2017,**

On Flare-CME Characteristics from Sun to Earth Combining Remote-Sensing Image Data with In SituMeasurements Supported by Modeling

Solar Physics July **2017**, 292:93
https://link.springer.com/content/pdf/10.1007%2Fs11207-017-1112-5.pdf
https://arxiv.org/pdf/1703.00694.pdf
We analyze the well-observed flare and coronal mass ejection (CME) from **1 October 2011** (SOL2011-10-01T09:18) covering the complete chain of effects – from Sun to Earth – to better understand the dynamic evolution of the CME and its embedded magnetic field. We study in detail the solar surface and atmosphere associated with the flare and CME using the Solar Dynamics Observatory (SDO) and ground-based instruments. We also track the CME signature off-limb with combined extreme ultraviolet (EUV) and white-light data from the Solar Terrestrial Relations Observatory (STEREO). By applying the graduated cylindrical shell (GCS) reconstruction method and total mass to stereoscopic STEREO-SOHO (Solar and Heliospheric Observatory) coronagraph data, we track the temporal and spatial evolution of the CME in the interplanetary space and derive its geometry and 3D mass. We combine the GCS and Lundquist model results to derive the axial flux and helicity of the magnetic cloud (MC) from in situmeasurements from Wind. This is compared to nonlinear force-free (NLFF) model results, as well as to the reconnected magnetic flux derived from the flare ribbons (flare reconnection flux) and the magnetic flux encompassed by the associated dimming (dimming flux). We find that magnetic reconnection processes were already ongoing before the start of the impulsive flare phase, adding magnetic flux to the flux rope before its final eruption. The dimming flux increases by more than 25% after the end of the flare, indicating that magnetic flux is still added to the flux rope after eruption. Hence, the derived flare reconnection flux is most probably a lower limit for estimating the magnetic flux within the flux rope. We find that the magnetic helicity and axial magnetic flux are lower in the interplanetary space by ~ 50% and 75%, respectively, possibly indicating an erosion process. A CME mass increase of 10% is observed over a range of ~4--

20 R⊙~4--20 R⊙. The temporal evolution of the CME-associated core-dimming regions supports the scenario that fast outflows might supply additional mass to the rear part of the CME.

Relation between CME Acceleration Profile and Flare Energy Release derived from Combined STEREO and RHESSI Observations

Temmer, M.1; Veronig, A.M.1; Vrsnak, B.2
Fraiburg ESP Meeting **2008**, **Presentation**
In the standard flare/CME picture magnetic reconnection occurs in a current sheet formed behind the CME, which may provide a feedback relationship between both phenomena. To study the relationship of the large-scale CME acceleration and the energy release in the associated flare we analyze three well observed events. The observations cover the early (low corona) evolution of the CMEs with the EUVI instruments aboard the twin STEREO spacecraft and the RHESSI hard Xray emission of the associated flare. Since the flare hard X-rays are due to fast electrons, they provide the most direct indicator of the evolution of the flare energy release in the flare. The results are compared to case studies for halo-CMEs where a close synchronization between the CME acceleration and the flare energy release was found (**Temmer et al., ApJ, 2008, 673, L95**).

ACCELERATION IN FAST HALO CMEs AND SYNCHRONIZED FLARE HXR BURSTS

M. **Temmer**, A. M. Veronig, B. Vrsˇnak, J. Rybaˊk, P. Go꞉mo꞉ry, S. Stoiser, and D. Maricˇic
The Astrophysical Journal, 673: L95–L98, **2008, File**
We study two well-observed, fast halo CMEs **(2005.01.17; 2006.07.06)**, covering the full CME kinematics including the initiation and impulsive acceleration phase, and their associated flares. We find a close synchronization between the CME acceleration profile and the flare energy release as indicated by the *RHESSI* hard X-ray flux onsets, as well as peaks occur simultaneously within 5 minutes. These findings indicate a close physical connection between both phenomena and are interpreted in terms of a feedback relationship between the CME dynamics and the reconnection process in the current sheet beneath the CME.

WIDESPREAD NANOFLARE VARIABILITY DETECTED WITH HINODE/X-RAY TELESCOPE IN A SOLAR ACTIVE REGION

Sergio **Terzo**1,4, Fabio Reale1,4, Marco Miceli1,4, James A. Klimchuk2, Ryouhei Kano3 and Saku Tsuneta
2011 ApJ 736 111
It is generally agreed that small impulsive energy bursts called nanoflares are responsible for at least some of the Sun's hot corona, but whether they are the explanation for most of the multimillion-degree plasma has been a matter of ongoing debate. We present here evidence that nanoflares are widespread in an active region observed by the X-Ray Telescope on board the Hinode mission. The distributions of intensity fluctuations have small but important asymmetries, whether taken from individual pixels, multipixel subregions, or the entire active region. Negative fluctuations (corresponding to reduced intensity) are greater in number but weaker in amplitude, so that the median fluctuation is negative compared to a mean of zero. Using Monte Carlo simulations, we show that only part of this asymmetry can be explained by Poisson photon statistics. The remainder is explainable through a tendency for exponentially decreasing intensity, such as would be expected from a cooling plasma produced from a nanoflare. We suggest that nanoflares are a universal heating process within active regions.

On the Coronal Temperature in Solar Microflares

Paola **Testa**1 and Fabio Reale2,3
2020 ApJ 902 31
https://doi.org/10.3847/1538-4357/abb36e
We present a study of solar imaging and spectral observations of a microflare, focusing on the temperature diagnostics provided by the Atmospheric Imaging Assembly (AIA) on board the Solar Dynamics Observatory, and the Extreme-Ultraviolet Imaging Spectrometer (EIS) on board Hinode. Our data analysis, in particular from the emission in the 131 and 94 Å channels, indicates that the heated plasma reaches temperatures of $\gtrsim$10 MK, at odds with a previous analysis of the same event, and we discuss the reason for the discrepancy. A particularly interesting aspect is the likely presence of the Fe xxiii 263.76 Å line, though weak, in EIS spectra in the early phases of the event, supporting the presence of high temperature plasma. Hydrodynamic 1D modeling of a single loop heated with a 3 minute pulse to 12–15 MK reproduces well most observed features along one of the brightening loops, including intensities in the AIA hot channels and their temporal variability, as well as the intensity, Doppler shift, and line width of the EIS Fe xxiii line, and its timing relative to the AIA emission. Overall, we obtain a coherent scenario of a typical microflaring loop system and provide constraints on the intensity of the energy release as well as its spatial and temporal distribution, both along and across the loop.

IRIS Observations of Short-term Variability in Moss Associated with Transient Hot Coronal Loops

Testa, Paola ; Polito, Vanessa ; De Pontieu, Bart
The Astrophysical Journal, Volume 889, Issue 2, id.124, 23 pp. (**2020**)
https://iopscience.iop.org/article/10.3847/1538-4357/ab63cf/pdf
We observed rapid variability (≲60 s) at the footpoints of transient, hot (∼8-10 MK) coronal loops in active region cores, with the Interface Region Imaging Spectrograph (IRIS). The high spatial (∼0"33) and temporal (≲5-10 s) resolution of IRIS is often crucial for the detection of this variability. We show how, in combination with 1D RADYN loop modeling, these IRIS spectral observations of the transition region (TR) and chromosphere provide powerful diagnostics of the properties of coronal heating and energy transport (thermal conduction or nonthermal electrons, NTEs). Our simulations of nanoflare-heated loops indicate that emission in the Mg II triplet can be used as a sensitive diagnostic for nonthermal particles. In our events, we observe a large variety of IRIS spectral properties (intensity, Doppler shifts, broadening, chromospheric/TR line ratios, Mg II triplet emission) even for different footpoints of the same coronal events. In several events, we find spectroscopic evidence for NTEs (e.g., TR blueshifts and Mg II triplet emission), suggesting that particle acceleration can occur even for very small magnetic reconnection events, which are generally below the detection threshold of hard X-ray instruments that provide direct detection of emission of nonthermal particles.

HIGH SPATIAL RESOLUTION Fe xii OBSERVATIONS OF SOLAR ACTIVE REGIONS
Paola **Testa**1, Bart De Pontieu2,3, and Viggo Hansteen
2016 ApJ 827 99
We use UV spectral observations of active regions with the Interface Region Imaging Spectrograph(IRIS) to investigate the properties of the coronal Fe xii 1349.4 Å emission at unprecedented high spatial resolution (~0.33"). We find that by using appropriate observational strategies (i.e., long exposures, lossless compression), Fe xii emission can be studied with IRIS at high spatial and spectral resolution, at least for high-density plasma (e.g., post-flare loops and active region moss). We find that upper transition region (TR; moss) Fe xii emission shows very small average Doppler redshifts (v_D ~ 3 km s−1) as well as modest non-thermal velocities (with an average of ~24 km s−1 and the peak of the distribution at ~15 km s−1). The observed distribution of Doppler shifts appears to be compatible with advanced three-dimensional radiative MHD simulations in which impulsive heating is concentrated at the TR footpoints of a hot corona. While the non-thermal broadening of Fe xii 1349.4 Å peaks at similar values as lower resolution simultaneous Hinode Extreme Ultraviolet Imaging Spectrometer (EIS) measurements of Fe xii195 Å, IRIS observations show a previously undetected tail of increased non-thermal broadening that might be suggestive of the presence of subarcsecond heating events. We find that IRIS andEIS non-thermal line broadening measurements are affected by instrumental effects that can only be removed through careful analysis. Our results also reveal an unexplained discrepancy between observed 195.1/1349.4 Å Fe xii intensity ratios and those predicted by the CHIANTI atomic database.

Evidence of Non-Thermal Particles in Coronal Loops Heated Impulsively by Nanoflares

http://arxiv.org/pdf/1410.6130v1.pdf
The physical processes causing energy exchange between the Sun's hot corona and its cool lower atmosphere remain poorly understood. The chromosphere and transition region (TR) form an interface region between the surface and the corona that is highly sensitive to the coronal heating mechanism. High resolution observations with the Interface Region Imaging Spectrograph (IRIS) reveal rapid variability (about 20 to 60 seconds) of intensity and velocity on small spatial scales at the footpoints of hot dynamic coronal loops. The observations are consistent with numerical simulations of heating by beams of non-thermal electrons, which are generated in small impulsive heating events called "coronal nanoflares". The accelerated electrons deposit a sizable fraction of their energy in the chromosphere and TR. Our analysis provides tight constraints on the properties of such electron beams and new diagnostics for their presence in the nonflaring corona. 2013-11-09

OBSERVING CORONAL NANOFLARES IN ACTIVE REGION MOSS
Paola **Testa**1, Bart De Pontieu2, Juan Martínez-Sykora2,3, Ed DeLuca1, Viggo Hansteen4, Jonathan Cirtain5, Amy Winebarger5, Leon Golub1, Ken Kobayashi5, Kelly Korreck1, Sergey Kuzin6, Robert Walsh7, Craig DeForest8, Alan Title2, and Mark Webe
2013 ApJ 770 L1

The High-resolution Coronal Imager (Hi-C) has provided Fe XII 193Å images of the upper transition region moss at an unprecedented spatial (~0."3-0."4) and temporal (5.5 s) resolution. The Hi-C observations show in some moss regions variability on timescales down to ~15 s, significantly shorter than the minute-scale variability typically found in previous observations of moss, therefore challenging the conclusion of moss being heated in a mostly steady manner. These rapid variability moss regions are located at the footpoints of bright hot coronal loops observed by the Solar Dynamics Observatory/Atmospheric Imaging Assembly in the 94 Å channel, and by the Hinode/X-Ray Telescope. The configuration of these loops is highly dynamic, and suggestive of slipping reconnection. We interpret these events as signatures of heating events associated with reconnection occurring in the overlying hot coronal loops, i.e., coronal nanoflares. We estimate the order of magnitude of the energy in these events to be of at least a few 1023 erg, also supporting the nanoflare scenario. These Hi-C observations suggest that future observations at comparable high spatial and temporal resolution, with more extensive temperature coverage, are required to determine the exact characteristics of the heating mechanism(s).

HINODE/EIS SPECTROSCOPIC VALIDATION OF VERY HOT PLASMA IMAGED WITH THE SOLAR DYNAMICS OBSERVATORY IN NON-FLARING ACTIVE REGION CORES

Paola **Testa**1 and Fabio Reale

2012 ApJ 750 L10

We use coronal imaging observations with the Solar Dynamics Observatory/Atmospheric Imaging Assembly (AIA), and Hinode/Extreme-ultraviolet Imaging Spectrometer (EIS) spectral data to explore the potential of narrowband EUV imaging data for diagnosing the presence of hot (T 5 MK) coronal plasma in active regions. We analyze observations of two active regions (AR 11281, AR 11289) with simultaneous AIA imaging and EIS spectral data, including the Ca XVII line (at 192.8 Å), which is one of the few lines in the EIS spectral bands sensitive to hot coronal plasma even outside flares. After careful co-alignment of the imaging and spectral data, we compare the morphology in a three-color image combining the 171, 335, and 94 Å AIA spectral bands, with the image obtained for Ca XVII emission from the analysis of EIS spectra. We find that in the selected active regions the Ca XVII emission is strong only in very limited areas, showing striking similarities with the features bright in the 94 Å (and 335 Å) AIA channels and weak in the 171 Å band. We conclude that AIA imaging observations of the solar corona can be used to track hot plasma (6-8 MK), and so to study its spatial variability and temporal evolution at high spatial and temporal resolution.

TEMPERATURE DISTRIBUTION OF A NON-FLARING ACTIVE REGION FROM SIMULTANEOUS *HINODE* XRT AND EIS OBSERVATIONS

Paola **Testa**1, Fabio Reale2,3, Enrico Landi4, Edward E. DeLuca1, and Vinay Kashyap1

Astrophysical Journal, 728:30 (12pp), **2011**

We analyze coordinated *Hinode* X-ray Telescope (XRT) and Extreme Ultraviolet Imaging Spectrometer (EIS) observations of a non-flaring active region to investigate the thermal properties of coronal plasma taking advantage of the complementary diagnostics provided by the two instruments. In particular, we want to explore the presence of hot plasma in non-flaring regions. Independent temperature analyses from the XRT multi-filter data set, and the EIS spectra, including the instrument entire wavelength range, provide a cross-check of the different temperature diagnostics techniques applicable to broadband and spectral data, respectively, and insights into cross-calibration of the two instruments. The emission measure distributions, (EM(*T*)), we derive from the two data sets have similar width and peak temperature, but show a systematic shift of the absolute values, the EIS (EM(*T*)) being smaller than the XRT (EM(*T*)) by approximately a factor two. We explore possible causes of this discrepancy, and we discuss the influence of the assumptions for the plasma element abundances. Specifically, we find that the disagreement between the results from the two instruments is significantly mitigated by assuming chemical composition closer to the solar photospheric composition rather than the often adopted “coronal” composition.We find that the data do not provide conclusive evidence on the high temperature (log *T* (K) _ 6.5) tail of the plasma temperature distribution, however, suggesting its presence to a level in agreement with recent findings for other non-flaring regions.

On the reliability of relative helicities deduced from nonlinear force-free coronal models

Julia K. **Thalmann**, X. Sun, K. Moraitis, M. Gupta

A&A 643, A153 **2020**

https://arxiv.org/pdf/2009.05287.pdf

https://doi.org/10.1051/0004-6361/202038921

We study the relative helicity of active region (AR) NOAA~12673 during a ten-hour time interval centered around a preceding X2.2 flare (SOL**2017-09-06**T08:57) and also including an eruptive X9.3 flare that occurred three hours later (SOL**2017-09-06**T11:53). In particular, we aim for a reliable estimate of the normalized self-helicity of the current-carrying magnetic field, the so-called helicity ratio |HJ|/|HV|, a promising candidate to quantity the eruptive potential of solar ARs. Using SDO/HMI vector magnetic field data as an input, we employ nonlinear force-free (NLFF) coronal magnetic field models using an optimization approach. The corresponding relative helicity, and related quantities, are

computed using a finite-volume method. From multiple time series of NLFF models based on different choices of free model parameters, we are able to assess the spread of |HJ|/|HV|, and to estimate its uncertainty. In comparison to earlier works, we favor the non-solenoidal contribution to the free magnetic energy, |Emix|/EJ,s, as selection criterion regarding the required solenoidal quality of the NLFF models for subsequent relative helicity analysis. As a recipe for a reliable estimate of the relative magnetic helicity (and related quantities), we recommend to employ multiple NLFF model time series based on different combinations of free model parameters, to retain only those which satisfy $|Emix|/EJ,s \leq 0.2$ at a certain time instant, to subsequently compute mean estimates, and to use the spread of the individually contributing values as an indication for the uncertainty.

On the Factors Determining the Eruptive Character of Solar Flares

Julia K. **Thalmann**

Magnetic helicity budget of solar active regions prolific of eruptive and confined flares

J. K. **Thalmann**, K. Moraitis, L. Linan, E. Pariat, G. Valori, K. Dalmasse
ApJ **887** 64 **2019**
https://arxiv.org/pdf/1910.06563.pdf
https://doi.org/10.3847/1538-4357/ab4e15
We compare the coronal magnetic energy and helicity of two solar active regions (ARs), prolific in major eruptive (AR~11158) and confined (AR~12192) flaring, and analyze the potential of deduced proxies to forecast upcoming flares. Based on nonlinear force-free (NLFF) coronal magnetic field models with a high degree of solenoidality, and applying three different computational methods to investigate the coronal magnetic helicity, we are able to draw conclusions with a high level of confidence. Based on real observations of two solar ARs we checked trends regarding the potential eruptivity of the active-region corona, as suggested earlier in works that were based on numerical simulations, or solar observations. Our results support that the ratio of current-carrying to total helicity, |HJ|/|HV|, shows a strong ability to indicate the eruptive potential of a solar AR. However, |HJ|/|HV| seems not to be indicative for the magnitude or type of an upcoming flare (confined or eruptive). Interpreted in context with earlier observational studies, our findings furthermore support that the total relative helicity normalized to the magnetic flux at the NLFF model's lower boundary, HV/ϕ2, represents no indicator for the eruptivity. **2011 February 14, 2014 October 24**
HMI Science Nuggets #145 Oct 2020 http://hmi.stanford.edu/hminuggets/?p=3370

Temporal and spatial relationship of flare signatures and the force-free coronal magnetic field

Julia K. **Thalmann**, Astrid M. Veronig, Yang Su
ApJ **826** 143 **2016**
http://arxiv.org/pdf/1605.03703v1.pdf
We investigate the plasma and magnetic environment of active region NOAA 11261 on **2 August 2011** around a GOES M1.4 flare/CME (SOL2011-08-02T06:19). We compare coronal emission at (extreme) ultraviolet and X-ray wavelengths, using SDO AIA and RHESSI images, in order to identify the relative timing and locations of reconnection-related sources. We trace flare ribbon signatures at ultraviolet wavelengths, in order to pin down the intersection of previously reconnected flaring loops at the lower solar atmosphere. These locations are used to calculate field lines from 3D nonlinear force-free magnetic field models, established on the basis of SDO HMI photospheric vector magnetic field maps. With this procedure, we analyze the quasi-static time evolution of the coronal model magnetic field previously involved in magnetic reconnection. This allows us, for the first time, to estimate the elevation speed of the current sheet's lower tip during an on-disk observed flare, as a few kilometers per second. Comparison to post-flare loops observed later above the limb in STEREO EUVI images supports this velocity estimate. Furthermore, we provide evidence for an implosion of parts of the flaring coronal model magnetic field, and identify the corresponding coronal sub-volumes associated to the loss of magnetic energy. Finally, we spatially relate the build up of magnetic energy in the 3D models to highly sheared fields, established due to dynamic relative motions of polarity patches within the active region.

Exceptions to the rule: the X-flares of AR 2192 Lacking Coronal Mass Ejections

Thalmann, J. K.; Su, Y.; Temmer, M.; Veronig, A. M.
Ground-based Solar Observations in the Space Instrumentation Era
ASP Conference Series, Vol. 504, p. 203, **2016**
http://aspbooks.org/publications/504/203.pdf
NOAA Active region (AR) 2192, that was present on the Sun in October 2014, was the largest region which occurred since November 1990 (see Figure 1). The huge size accompanied by a very high activity level, was quite unexpected as it appeared during the unusually weak solar cycle 24. Nevertheless, the AR turned out to be one of the most prolific flaring ARs of cycle 24. It produced in total 6 X, 29 M, 79 C flares during its disk passage from October 18-29, 2014

(see Figure 2). Surprisingly, all flares greater than GOES class M5 and X were confined, i.e. had no coronal mass ejections (CME) associated. All the flare events had some obvious similarity in morphology, as they were located in the core of the AR and revealed only minor separation motion away from the neutral line but a large initial separation of the conjugate flare ribbons. In the paper by Thalmann et al. (2015) we describe the series of flares and give details about the confined X1.6 flare event from October 22, 2014 as well as the single eruptive M4.0 flare event from October 24, 2014. The study of the X1.6 flare revealed a large initial separation of flare ribbons together with recurrent flare brightenings, which were related to two episodes of enhanced hard X-ray emission as derived from RHESSI observations. This suggests that magnetic field structures connected to specific regions were repeatedly involved in the process of reconnection and energy release. Opposite to the central location of the sequence of confined events within the AR, a single eruptive (M4.0) event occurred on the outskirt of the AR in the vicinity of open magnetic fields. Our investigations revealed a predominantly north-south oriented magnetic system of arcade fields overlying the AR that could have preserved the magnetic arcade to erupt, and consequently kept the energy release trapped in a localized volume of magnetic field high up in the corona (as supported by the absence of a lateral motion of the flare ribbons and the recurrent brightenings within them). We conclude that the background magnetic field configuration is an essential parameter for deriving the “eruptiveness” of flare events. Sun et al. (2015) supports this conclusion and derived for this AR a quite slow decay of the strength of the overlying magnetic field (decay index; see Török & Kliem 2005). Interestingly, our magnetic field modellings revealed no flux rope inherent to the AR, indicating that further investigations are needed. In a recent paper by Veronig $ Polanec (2015), who investigated in more detail the X-flares using also ground-based observations in Hα from Kanzelhöhe Observatory (Pötzi et al. 2015), it was shown that such confined events could be explained by the emerging-flux model, where newly emerging small flux tubes reconnect with pre-existing large coronal loops. **October 22, 2014, October 24, 2014**

The Exceptional Aspects of the Confined X-class Flares of Solar Active Region 2192

Julia K. **Thalmann**, Yang Su, Manuela Temmer, Astrid M. Veronig
Proceedings IAU Symposium No. S320, "Solar and Stellar Flares and Their Effects on Planets" **2016**
http://arxiv.org/pdf/1605.03712v1.pdf

During late October 2014, active region NOAA 2192 caused an unusual high level of solar activity, within an otherwise weak solar cycle. While crossing the solar disk, during a period of 11 days, it was the source of 114 flares of GOES class C1.0 and larger, including 29 M- and 6 X-flares. Surprisingly, none of the major flares (GOES class M5.0 and larger) was accompanied by a coronal mass ejection, contrary to statistical tendencies found in the past. From modeling the coronal magnetic field of NOAA 2192 and its surrounding, we suspect that the cause of the confined character of the flares is the strong surrounding and overlying large-scale magnetic field. Furthermore, we find evidence for multiple magnetic reconnection processes within a single flare, during which electrons were accelerated to unusual high energies. **October 22,23,24 2014**

The Confined X-class Flares of Solar Active Region 2192

J.K. **Thalmann**, Y. Su, M. Temmer, A. M. Veronig
ApJL **801** L23 **2015**
http://arxiv.org/pdf/1502.05157v1.pdf
The unusually large NOAA active region 2192, observed in **October 2014**, was outstanding in its productivity of major two-ribbon flares without coronal mass ejections. On a large scale, a predominantly north-south oriented magnetic system of arcade fields served as a strong, also lateral, confinement for a series of large two-ribbon flares originating from the core of the active region. The large initial separation of the flare ribbons, together with an almost absent growth in ribbon separation, suggests a confined reconnection site high up in the corona. Based on a detailed analysis of the confined X1.6 flare on October 22, we show how exceptional the flaring of this active region was. We provide evidence for repeated energy release, indicating that the same magnetic field structures were repeatedly involved in magnetic reconnection. We find that a large number of electrons was accelerated to non-thermal energies, revealing a steep power law spectrum, but that only a small fraction was accelerated to high energies. The total non-thermal energy in electrons derived (on the order of 10^25 J) is considerably higher than that in eruptive flares of class X1, and corresponds to about 10\% of the excess magnetic energy present in the active-region corona. **Oct 19 05:03 UT (X1.1), Oct 22 14:28 UT (X1.6), Oct 24 22:41 UT (X3.1), Oct 25 17:08 UT (X1.0), Oct 26 10:56 UT (X2.0), and Oct 27 14:47 UT (X2.0).**

Forecasting Solar Flares by Data Assimilation in Sandpile Models

Christian **Thibeault**, Antoine Strugarek, Paul Charbonneau, Benoit Tremblay
Solar Phys. **297**, Article number: 125 **2022**
https://arxiv.org/pdf/2206.13583.pdf
https://doi.org/10.1007/s11207-022-02055-9

The prediction of solar flares is still a significant challenge in space weather research, with no techniques currently capable of producing reliable forecasts performing significantly above climatology. In this paper, we present a flare forecasting technique using data assimilation coupled with computationally inexpensive cellular automata called sandpile models. Our data assimilation algorithm uses the simulated annealing method to find an optimal initial condition that reproduces well an energy-release time series. We present and empirically analyze the predictive capabilities of three sandpile models, namely the Lu and Hamilton model (LH) and two deterministically-driven models (D). Despite their stochastic elements, we show that deterministically-driven models display temporal correlations between simulated events, a needed condition for data assimilation. We present our new data assimilation algorithm and demonstrate its success in assimilating synthetic observations produced by the avalanche models themselves. We then apply our method to GOES X-Ray time series for 11 active regions having generated multiple X-class flares in the course of their lifetime. We demonstrate that for such large flares, our data assimilation scheme substantially increases the success of ``All-Clear'' forecasts, as compared to model climatology.

A time dependent relation between EUV solar flare light-curves from lines with differing formation temperatures

Edward M.B. **Thiemann**, Francis G. Eparvier and Thomas N. Woods
J. Space Weather Space Clim. **2017**, 7, A36
https://www.swsc-journal.org/articles/swsc/pdf/2017/01/swsc170050.pdf
https://arxiv.org/pdf/1703.02995.pdf
Extreme ultraviolet (EUV) solar flare emissions evolve in time as the emitting plasma heats and then cools. Although accurately modeling this evolution has been historically difficult, especially for empirical relationships, it is important for understanding processes at the Sun, as well as for their influence on planetary atmospheres. With a goal to improve empirical flare models, a new simple empirical expression is derived to predict how cool emissions evolve based on the evolution of a hotter emission. This technique is initially developed by studying 12 flares in detail observed by the EUV variability experiment (EVE) onboard the Solar Dynamics Observatory (SDO). Then, over 1100 flares observed by EVE are analyzed to validate these relationships. The Cargill and Enthalpy Based Thermal Evolution of Loops (EBTEL) flare cooling models are used to show that this empirical relationship implies the energy radiated by a population of hotter formed ions is approximately proportional to the energy exciting a population of cooler formed ions emitting when the peak formation temperatures of the two lines are up to 72% of each other and above 2 MK. These results have practical implications for improving flare irradiance empirical modeling and for identifying key emission lines for future monitoring of flares for space weather operations; and also provide insight into the cooling processes of flare plasma. **26 March 2002, 14 Aug 2010, 8 March 2011, 15 May 2011, 22 Sept 2011, 2 Oct 2011, 5 March 2012, 7 May 2012, 9 May 2012, 11 May 2012, 17 May 2012, 5 July 2012, 11 Apr 2013**

Center-to-Limb Variability of Hot Coronal EUV Emissions During Solar Flares

Edward **Thiemann**, Phillip Chamberlin, Francis Eparvier, Luke Epp
Solar Phys. 293:19 **2018**
https://arxiv.org/ftp/arxiv/papers/1710/1710.02498.pdf
https://link.springer.com/content/pdf/10.1007%2Fs11207-018-1244-2.pdf
It is generally accepted that densities of quiet sun and active region plasma are sufficiently low to justify the optically thin approximation, and it is commonly used in the analysis of line emissions from plasma in the solar corona. However, densities of solar flare loops are substantially higher, compromising the optically thin approximation. This study begins with a radiative transfer model that uses typical solar flare densities and geometries to show that hot coronal emission lines are not generally optically thin. Further, the model demonstrates that the observed integrated line intensity should exhibit center-to-limb variability (CTLV), with flares observed near the limb being dimmer than those occurring near disk-center. The model predictions are validated with an analysis of nearly 300 flares observed by EVE on SDO that uses 6 lines, with peak formation temperatures between 8.9 and 15.8 MK, to show limb flares are systematically dimmer than disk-center flares. The data are then used to show that the electron column density along the line-of-sight typically increases by 4.44 x 1019 cm-2 for limb flares over the disk-center flare value. It is shown that CTLV of hot coronal emissions reduces the amount of ionizing radiation propagating into the solar system, and changes the relative intensities of lines and bands commonly used for spectral analysis.

RHESSI and General Relativity

Flare particle acceleration in the interaction of twisted coronal flux ropes

J. **Threlfall**, A. W. Hood, P. K. Browning
2018 A&A 611, A40
https://arxiv.org/pdf/1801.02907.pdf
The aim of this work is to investigate and characterise non-thermal particle behaviour in a three-dimensional (3D) magnetohydrodynamical (MHD) model of unstable multi-threaded flaring coronal loops. We have used a numerical scheme which solves the relativistic guiding centre approximation to study the motion of electrons and protons. The scheme uses snapshots from high resolution numerical MHD simulations of coronal loops containing two threads, where a single thread becomes unstable and (in one case) destabilises and merges with an additional thread. The particle responses to the reconnection and fragmentation in MHD simulations of two loop threads are examined in detail. We illustrate the role played by uniform background resistivity and distinguish this from the role of anomalous resistivity using orbits in an MHD simulation where only one thread becomes unstable without destabilising further loop threads. We examine the (scalable) orbit energy gains and final positions recovered at different stages of a second MHD simulation wherein a secondary loop thread is destabilised by (and merges with) the first thread. We compare these results with other theoretical particle acceleration models in the context of observed energetic particle populations during solar flares.

Particle Acceleration Due to Coronal Non-null Magnetic Reconnection

James **Threlfall**, Thomas Neukirch, Clare Elizabeth Parnell
Solar Physics March **2017**, 292:45
Various topological features, for example magnetic null points and separators, have been inferred as likely sites of magnetic reconnection and particle acceleration in the solar atmosphere. In fact, magnetic reconnection is not constrained to solely take place at or near such topological features and may also take place in the absence of such features. Studies of particle acceleration using non-topological reconnection experiments embedded in the solar atmosphere are uncommon. We aim to investigate and characterise particle behaviour in a model of magnetic reconnection which causes an arcade of solar coronal magnetic field to twist and form an erupting flux rope, crucially in the absence of any common topological features where reconnection is often thought to occur. We use a numerical scheme that evolves the gyro-averaged orbit equations of single electrons and protons in time and space, and simulate the gyromotion of particles in a fully analytical global field model. We observe and discuss how the magnetic and electric fields of the model and the initial conditions of each orbit may lead to acceleration of protons and electrons up to 2 MeV in energy (depending on model parameters). We describe the morphology of time-dependent acceleration and impact sites for each particle species and compare our findings to those recovered by topologically based studies of three-dimensional (3D) reconnection and particle acceleration. We also broadly compare aspects of our findings to general observational features typically seen during two-ribbon flare events.

Particle dynamics in a non-flaring solar active region model

J. **Threlfall**, Ph.-A. Bourdin, T. Neukirch, C. E. Parnell
A&A 587, A4 **2016**
http://arxiv.org/pdf/1510.04211v1.pdf
The aim of this work is to investigate and characterise particle behaviour in a (observationally-driven) 3D MHD model of the solar atmosphere above a slowly evolving, non-flaring active region. We use a relativistic guiding-centre particle code to investigate particle acceleration in a single snapshot of the 3D MHD simulation. Despite the lack of flare-like behaviour in the active region, direct acceleration of electrons and protons to non-thermal energies ($\lesssim$420MeV) was found, yielding spectra with high-energy tails which conform to a power law. Examples of particle dynamics, including particle trapping caused by local electric rather than magnetic field effects, are observed and discussed, together with implications for future experiments which simulate non-flaring active region heating and reconnection. **14th Nov 2007**

Particle acceleration at reconnecting separator current layers

J. **Threlfall**, J. E. H. Stevenson, C. E. Parnell, T. Neukirch
A&A 585, A95 (**2016**)
http://arxiv.org/pdf/1510.04215v1.pdf
The aim of this work is to investigate and characterise particle behaviour in a 3D MHD model of a reconnecting magnetic separator. We use a relativistic guiding-centre test-particle code to investigate electron and proton acceleration in snapshots from 3D MHD separator reconnection experiments, and compare the results with findings from an analytical separator reconnection model studied in a previous investigation. The behaviour (and acceleration) of large distributions of particles are examined in detail for both analytical and numerical separator reconnection models. Differences in acceleration sites are recovered and discussed, together with the dependence of final particle energy ranges upon the dimensions of the models and the stage of the (time-dependent) MHD reconnection event. We discuss the implications of these results for observed magnetic separators in the solar corona.

Particle acceleration at a reconnecting magnetic separator

J. **Threlfall**, T. Neukirch, C. E. Parnell, S. Eradat Oskoui
A&A 574, A7 (**2015**)
http://arxiv.org/pdf/1410.6465v1.pdf

While the exact acceleration mechanism of energetic particles during solar flares is (as yet) unknown, magnetic reconnection plays a key role both in the release of stored magnetic energy of the solar corona and the magnetic restructuring during a flare. Recent work has shown that special field lines, called separators, are common sites of reconnection in 3D numerical experiments. To date, 3D separator reconnection sites have received little attention as particle accelerators. We investigate the effectiveness of separator reconnection as a particle acceleration mechanism for electrons and protons. We study the particle acceleration using a relativistic guiding-centre particle code in a time-dependent kinematic model of magnetic reconnection at a separator. The effect upon particle behaviour of initial position, pitch angle and initial kinetic energy are examined in detail, both for specific (single) particle examples and for large distributions of initial conditions. The separator reconnection model contains several free parameters and we study the effect of changing these parameters upon particle acceleration, in particular in view of the final particle energy ranges which agree with observed energy spectra.

First comparison of wave observations from CoMP and AIA/SDO

J. **Threlfall**1, I. De Moortel1, S. W. McIntosh2 and C. Bethge
A&A 556, A124 (**2013**)

Context. Waves have long been thought to contribute to the heating of the solar corona and the generation of the solar wind. Recent observations have demonstrated evidence of quasi-periodic longitudinal disturbances and ubiquitous transverse wave propagation in many different coronal environments.
Aims. This paper investigates signatures of different types of oscillatory behaviour, both above the solar limb and on-disk, by comparing findings from the Coronal Multi-channel Polarimeter (CoMP) and the Atmospheric Imaging Assembly (AIA) on-board the Solar Dynamics Observatory (SDO) for the same active region.
Methods. We study both transverse and longitudinal motion by comparing and contrasting time-distance images of parallel and perpendicular cuts along/across active region fan loops. Comparisons between parallel space-time diagram features in CoMP Doppler velocity and transverse oscillations in AIA images are made, together with space-time analysis of propagating quasi-periodic intensity features seen near the base of loops in AIA.
Results. Signatures of transverse motions are observed along the same magnetic structure using CoMP Doppler velocity (vphase = 600 → 750 km s-1, P = 3 → 6 min) and in AIA/SDO above the limb (P = 3 → 8 min). Quasi-periodic intensity features (vphase = 100 → 200 km s-1, P = 6 → 11 min) also travel along the base of the same structure. On the disk, signatures of both transverse and longitudinal intensity features were observed by AIA, and both show similar properties to signatures found along structures anchored in the same active region three days earlier above the limb. Correlated features are recovered by space-time analysis of neighbouring tracks over perpendicular distances of ≲2.6 Mm.

Nonlinear wave propagation and reconnection at magnetic X-points in the Hall MHD regime

J. **Threlfall**1, C. E. Parnell1, I. De Moortel1, K. G. McClements2 and T. D. Arber
A&A 544, A24 (**2012**)

Context. The highly dynamical, complex nature of the solar atmosphere naturally implies the presence of waves in a topologically varied magnetic environment. Here, the interaction of waves with topological features such as null points is inevitable and potentially important for energetics. The low resistivity of the solar coronal plasma implies that non-magnetohydrodynamic (MHD) effects should be considered in studies of magnetic energy release in this environment.
Aims. This paper investigates the role of the Hall term in the propagation and dissipation of waves, their interaction with 2D magnetic X-points and the nature of the resulting reconnection.
Methods. A Lagrangian remap shock-capturing code (Lare2d) was used to study the evolution of an initial fast magnetoacoustic wave annulus for a range of values of the ion skin depth (δi) in resistive Hall MHD. A magnetic null-point finding algorithm was also used to locate and track the evolution of the multiple null-points that are formed in the system.
Results. Depending on the ratio of ion skin depth to system size, our model demonstrates that Hall effects can play a key role in the wave-null interaction. In particular, the initial fast-wave pulse now consists of whistler and ion-cyclotron components; the dispersive nature of the whistler wave leads to (i) earlier interaction with the null; (ii) the creation of multiple additional, transient nulls and, hence, an increased number of energy release sites. In the Hall regime, the relevant timescales (such as the onset of reconnection and the period of the oscillatory relaxation) of the system are reduced significantly, and the reconnection rate is enhanced.

Implosive Collapse about Magnetic Null Points: A Quantitative Comparison between 2D and 3D Nulls

Jonathan O. **Thurgood**1,2, David I. Pontin1, and James A. McLaughlin2

2018 ApJ 855 50
http://iopscience.iop.org/article/10.3847/1538-4357/aab0a0/pdf
Null collapse is an implosive process whereby MHD waves focus their energy in the vicinity of a null point, forming a current sheet and initiating magnetic reconnection. We consider, for the first time, the case of collapsing 3D magnetic null points in nonlinear, resistive MHD using numerical simulation, exploring key physical aspects of the system as well as performing a detailed parameter study. We find that within a particular plane containing the 3D null, the plasma and current density enhancements resulting from the collapse are quantitatively and qualitatively as per the 2D case in both the linear and nonlinear collapse regimes. However, the scaling with resistivity of the 3D reconnection rate—which is a global quantity—is found to be less favorable when the magnetic null point is more rotationally symmetric, due to the action of increased magnetic back-pressure. Furthermore, we find that, with increasing ambient plasma pressure, the collapse can be throttled, as is the case for 2D nulls. We discuss this pressure-limiting in the context of fast reconnection in the solar atmosphere and suggest mechanisms by which it may be overcome. We also discuss the implications of the results in the context of null collapse as a trigger mechanism of Oscillatory Reconnection, a time-dependent reconnection mechanism, and also within the wider subject of wave–null point interactions. We conclude that, in general, increasingly rotationally asymmetric nulls will be more favorable in terms of magnetic energy release via null collapse than their more symmetric counterparts.

Three-dimensional oscillatory magnetic reconnection

J.O. **Thurgood**, D.I. Pontin, J.A. McLaughlin
ApJ **2017**
https://arxiv.org/pdf/1706.09662.pdf
Here we detail the dynamic evolution of localised reconnection regions about three-dimensional (3D) magnetic null points by using numerical simulation. We demonstrate for the first time that reconnection triggered by the localised collapse of a 3D null point due to an external MHD wave involves a self-generated oscillation, whereby the current sheet and outflow jets undergo a reconnection reversal process during which back-pressure formation at the jet heads acts to prise open the collapsed field before overshooting the equilibrium into an opposite-polarity configuration. The discovery that reconnection at fully 3D nulls can proceed naturally in a time-dependent and periodic fashion is suggestive that oscillatory reconnection mechanisms may play a role in explaining periodicity in astrophysical phenomena associated with magnetic reconnection, such as the observed quasi-periodicity of solar and stellar flare emission. Furthermore, we find a consequence of oscillatory reconnection is the generation of a plethora of freely-propagating MHD waves which escape the vicinity of the reconnection region

Evaluation of different recipes for chromospheric radiative losses in solar flares

J.**Tian**, J.Hong, Y.Li, M.D.Ding
A&A 668, A96 **2022**
https://arxiv.org/pdf/2210.04461
https://www.aanda.org/articles/aa/pdf/2022/12/aa44615-22.pdf
Context. Radiative losses are an indispensable part in the numerical simulation of flares. Detailed calculations could be computationally expensive, especially in the chromosphere. There have been some approximate recipes for chromospheric radiative losses in flares, yet their feasibility in flare simulations needs further evaluation.
Aims. We aim to evaluate the performance of different recipes for chromospheric radiative losses in flare simulations.
Methods. We compare the atmospheric structure and line profiles in beam-heated flares calculated with detailed radiative losses and the approximate recipes.
Results. Both GF90 and HCD22 recipes provide acceptable total radiative losses compared with detailed one, but there are discrepancies in the different atmospheric layers during the different evolutionary phases, which leads to misestimations of temperature and line intensity. The recipe of GF90 overestimates the coolings in the upper chromosphere greatly when temperature exceeds 10^5 K, which also affects the flare evolution and line asymmetries. Radiative heating in the middle chromosphere only functions in the initial stage and could be safely neglected. However, radiative heating from Lyman continuum could dominate near the transition region.

Multi-episode Chromospheric Evaporation Observed in a Solar Flare

H. **Tian**1 and N.-H. Chen
2018 ApJ 856 34 10.3847/1538-4357/aab15a
With observations of the Interface Region Imaging Spectrograph (IRIS), we study chromospheric heating and evaporation during an M1.6 flare SOL**2015-03-12**T11:50. At the flare ribbons, the Mgii 2791.59 Å line shows quasi-periodic short-duration red-wing enhancement, which is likely related to repetitive chromospheric condensation as a result of episodic heating. On the contrary, the Si iv 1402.77 Å line reveals a persistent red-wing asymmetry in both the impulsive and decay phases, suggesting that this line responds to both cooling downflows and chromospheric

condensation. The first two episodes of red-wing enhancement occurred around 11:42 UT and 11:45 UT, when two moving brightenings indicative of heating fronts crossed the IRIS slit. The greatly enhanced red wings of the Si iv and Mg ii lines at these occasions are accompanied by an obvious increase in the line intensities and the HXR flux, suggesting two episodes of energy injection into the lower atmosphere in the form of nonthermal electrons. The Mg ii k/h ratio has a small value of ~1.2 at the ribbons and decreases to ~1.1 at these two occasions. Correspondingly, the Fe xxi 1354 Å line reveals two episodes of chromospheric evaporation, which is characterized as a smooth decrease of the blueshift from ~300 km s−1 to nearly zero within ~3 minutes. The Fexxi 1354 Å line is entirely blueshifted in the first episode, while it appears to contain a nearly stationary component and a blueshifted component in the second episode. Additional episodes of blueshifted Fe xxi emission are found around the northern ribbon in the decay phase, though no obvious response is detected in the Si iv and Mg ii emission. We have also examined the Fe xxiemission at the flare loop top and identified a secondary component with a ~200 km s−1 redshift, which possibly results from the downward moving reconnection outflow. Our analysis also yields a rest wavelength of 1354.0878 ± 0.0072 Å for this Fe xxi line.

Magnetic reconnection at the earliest stage of solar flux emergence

Hui **Tian**, Xiaoshuai Zhu, Hardi Peter, Jie Zhao, Tanmoy Samanta, Yajie Chen

ApJ 854 174 **2018**

https://arxiv.org/pdf/1801.06785.pdf

http://sci-hub.tw/http://iopscience.iop.org/0004-637X/854/2/174/

On **2016 September 20**, the Interface Region Imaging Spectrograph observed an active region during its earliest emerging phase for almost 7 hours. The Helioseismic and Magnetic Imager on board the Solar Dynamics Observatory observed continuous emergence of small-scale magnetic bipoles with a rate of ~1016Mx~s−1. The emergence of magnetic fluxes and interactions between different polarities lead to frequent occurrence of ultraviolet (UV) bursts, which exhibit as intense transient brightenings in the 1400 \AA{} images. In the meantime, discrete small patches with the same magnetic polarity tend to move together and merge, leading to enhancement of the magnetic fields and thus formation of pores (small sunspots) at some locations. The spectra of these UV bursts are characterized by the superposition of several chromospheric absorption lines on the greatly broadened profiles of some emission lines formed at typical transition region temperatures, suggesting heating of the local materials to a few tens of thousands of kelvin in the lower atmosphere by magnetic reconnection. Some bursts reveal blue and red shifts of ~100~km~s−1 at neighboring pixels, indicating the spatially resolved bidirectional reconnection outflows. Many such bursts appear to be associated with the cancellation of magnetic fluxes with a rate of the order of ~1015 Mx~s−1. We also investigate the three-dimensional magnetic field topology through a magneto-hydrostatic model and find that a small fraction of the bursts are associated with bald patches (magnetic dips). Finally, we find that almost all bursts are located in regions of large squashing factor at the height of ~1 Mm, reinforcing our conclusion that these bursts are produced through reconnection in the lower atmosphere.

HMI Science Nuggets #87 Feb **2018** http://hmi.stanford.edu/hminuggets/?p=2275

Multi-episode chromospheric evaporation observed in a solar flare

H. **Tian**, N.-H. Chen

ApJ **2018**

https://arxiv.org/pdf/1801.04370.pdf

With observations of IRIS, we study chromospheric heating and evaporation during an M1.6 flare SOL**2015-03-12**T11:50. At the flare ribbons, the Mg II 2791.59 line shows quasi-periodic short-duration red-wing enhancement, which is likely related to repetitive chromospheric condensation as a result of episodic heating. On the contrary, the Si IV 1402.77 line reveals a persistent red-wing asymmetry in both the impulsive and decay phases, suggesting that this line responds to both cooling downflows and chromospheric condensation. The first two episodes of red-wing enhancement occurred around 11:42 UT and 11:45 UT, when two moving brightenings indicative of heating fronts crossed the IRIS slit. The greatly enhanced red wings of the Si IV and Mg II lines at these occasions are accompanied by an obvious increase in the line intensities and the HXR flux, suggesting two episodes of energy injection into the lower atmosphere in the form of nonthermal electrons. The Mg II k/h ratio has a small value of ~1.2 at the ribbons and decreases to ~1.1 at these two occasions. Correspondingly, the Fe XXI 1354 line reveals two episodes of chromospheric evaporation, which is characterized as a smooth decrease of the blue shift from ~300 km/s to nearly zero within ~3 minutes. The Fe XXI 1354 line is entirely blueshifted in the first episode, while appears to contain a nearly stationary component and a blueshifted component in the second episode. More episodes of blueshifted Fe XXI emission is found around the northern ribbon in the decay phase, though no obvious response is detected in the Si IV and Mg II emission. We have also examined the Fe XXI emission at the flare loop top and identified a secondary component with a ~200 km/s red shift, which possibly results from the downward moving reconnection outflow. Our analysis also suggests a reference wavelength of 1354.0878 Angstrom for this Fe XXI line.

Global sausage oscillation of solar flare loops detected by the Interface Region Imaging Spectrograph

Hui **Tian**, Peter R. Young, Katharine K. Reeves, Tongjiang Wang, Patrick Antolin, Bin Chen, Jiansen He
ApJL 823 L16 **2016**

An observation from the Interface Region Imaging Spectrograph reveals coherent oscillations in the loops of an M1.6 flare on **2015 March 12**. Both the intensity and Doppler shift of Fe~{\sc{xxi}}~1354.08\AA{}~show clear oscillations with a period of ~25 seconds. Remarkably similar oscillations were also detected in the soft X-ray flux recorded by the Geostationary Operational Environmental Satellites (GOES). With an estimated phase speed of ~2420~km~s−1 and a derived electron density of at least 5.4×1010 cm−3, the observed short-period oscillation is most likely the global fast sausage mode of a hot flare loop. We find a phase shift of ~π/2 (1/4 period) between the Doppler shift oscillation and the intensity/GOES oscillations, which is consistent with a recent forward modeling study of the sausage mode. The observed oscillation requires a density contrast between the flare loop and coronal background of a factor ⩾42. The estimated phase speed of the global mode provides an lower limit of the Alfv\'en speed outside the flare loop. We also find an increase of the oscillation period, which might be caused by the separation of the loop footpoints with time.

Temporal evolution of chromospheric evaporation: case studies of the M1.1 flare on 2014 September 6 and X1.6 flare on 2014 September 10

Hui **Tian**, Peter R. Young, Katharine K. Reeves, Bin Chen, Wei Liu, Sean McKillop
ApJ 811 139 **2015**
http://arxiv.org/pdf/1505.02736v1.pdf

Observations from IRIS allow us to study the chromospheric heating and evaporation processes during solar flares with unprecedented high resolution and high cadence. We track the complete evolution of ~11 MK evaporation flows in the M1.1 flare on **2014 September 6 and the X1.6 flare on 2014 September 10**. These hot flows, as indicated by the entirely blueshifted Fe xxi 1354.08 emission line, evolve smoothly with a velocity decreasing from ~200 km/s to almost stationary within a few minutes. The velocity decrease appears to be exponential in time, especially for the X1.6 flare. There is a good correlation between the flow velocity and the energy deposition rate as represented by the RHESSI hard X-Ray flux, or the time derivative of the soft X-Ray flux observed by GOES and the HINODE/XRT, which is in general agreement with models of nonthermal electron heating. The maximum blue shift of Fe xxi appears approximately at the same time as or slightly after the impulsive enhancement of the UV continuum and the Mg ii 2798.8 line emission, demonstrating that the hot evaporation flow is closely related to heating of the lower chromosphere. In the M1.1 flare, the maximum Fe XXI blue shift, the peaks of RHESSI hard X-Ray flux and the time derivative of GOES flux occur at roughly the same time. In the X1.6 flare, the maximum blue shift is found slightly before the peak time of the soft X-Ray derivative, a result that is qualitatively consistent with a recent radiative hydrodynamic simulation (RADYN) of chromospheric evaporation. Finally, while the hot Fe xxi 1354.08 line is entirely blueshifted with no obvious rest component, cool chromospheric and transition region lines like Si iv 1402.77 are often not entirely redshifted but just reveal an obvious enhancement in the red wing of the line profiles at the flare ribbons, suggesting a faster speed of chromospheric condensation than previously thought.

Imaging and spectroscopic observations of magnetic reconnection and chromospheric evaporation in a solar flare

Hui **Tian**, Gang Li, Katharine K. Reeves, John C. Raymond, Fan Guo, Wei Liu, Bin Chen, Nicholas A. Murphy
ApJL **797** 88 **2014**
http://arxiv.org/pdf/1411.2301v1.pdf

Magnetic reconnection is believed to be the dominant energy release mechanism in solar flares. The standard flare model predicts both downward and upward outflow plasmas with speeds close to the coronal Alfv\'{e}n speed. Yet, spectroscopic observations of such outflows, especially the downflows, are extremely rare. With observations of the newly launched Interface Region Imaging Spectrograph (IRIS), we report the detection of greatly redshifted (~125 km s-1 along line of ight) Fe {\sc{xxi}} 1354.08\AA{} emission line with a ~100 km s−1 nonthermal width at the reconnection site of a flare. The redshifted Fe {\sc{xxi}} feature coincides spatially with the loop-top X-Ray source observed by the Reuven Ramaty High Energy Solar Spectroscopic Imager (RHESSI). We interpret this large redshift as the signature of downward-moving reconnection outflow/hot retracting loops. Imaging observations from both IRIS and the Atmospheric Imaging Assembly (AIA) onboard the Solar Dynamics Observatory (SDO) also reveal the eruption and reconnection processes. Fast downward-propagating blobs along these loops are also found from cool emission lines (e.g., Si {\sc{iv}}, O {\sc{iv}}, C {\sc{ii}}, Mg {\sc{ii}}) and images of AIA and IRIS. Furthermore, the entire Fe {\sc{xxi}} line is blueshifted by ~260 km s−1 at the loop footpoints, where the cool lines mentioned above all exhibit obvious redshift, a result that is consistent with the scenario of chromospheric evaporation induced by downward-propagating nonthermal electrons from the reconnection site. **2014 April 19.**

THE SPECTROSCOPIC SIGNATURE OF QUASI-PERIODIC UPFLOWS IN ACTIVE REGION TIMESERIES

Hui **Tian**1, Scott W. McIntosh1 and Bart De Pontieu

2011 ApJ 727 L37

Quasi-periodic propagating disturbances are frequently observed in coronal intensity image sequences. These disturbances have historically been interpreted as being the signature of slow-mode magnetoacoustic waves propagating into the corona. The detailed analysis of Hinode EUV Imaging Spectrometer (EIS) timeseries observations of an active region (known to contain propagating disturbances) shows strongly correlated, quasi-periodic, oscillations in intensity, Doppler shift, and line width. No frequency doubling is visible in the latter. The enhancements in the moments of the line profile are generally accompanied by a faint, quasi-periodically occurring, excess emission at ~100 km s–1 in the blue wing of coronal emission lines. The correspondence of quasi-periodic excess wing emission and the moments of the line profile indicates that repetitive high-velocity upflows are responsible for the oscillatory behavior observed. Furthermore, we show that the same quasi-periodic upflows can be directly identified in a simultaneous image sequence obtained by the Hinode X-Ray Telescope. These results are consistent with the recent assertion of De Pontieu & McIntosh that the wave interpretation of the data is not unique. Indeed, given that several instances are seen to propagate along the direction of the EIS slit that clearly shows in-phase, quasi-periodic variations of intensity, velocity, width (without frequency doubling), and blue wing enhanced emission, this data set would appear to provide a compelling example that upflows are more likely to be the main cause of the quasi-periodicities observed here, as such correspondences are hard to reconcile in the wave paradigm.

ON ASYMMETRY OF MAGNETIC HELICITY IN EMERGING ACTIVE REGIONS: HIGH-RESOLUTION OBSERVATIONS

Lirong **Tian**1, Pascal D´emoulin2, David Alexander1, and Chunming Zhu1

Astrophysical Journal, 727:28 (13pp), **2011** January

We employ the DAVE (differential affine velocity estimator) tracking technique on a time series of Michelson Doppler Imager (MDI)/1 minute high spatial resolution line-of-sight magnetograms to measure the photospheric flow velocity for three newly emerging bipolar active regions (ARs). We separately calculate the magnetic helicity injection rate of the leading and following polarities to confirm or refute the magnetic helicity asymmetry, found by Tian & Alexander using MDI/96 minute low spatial resolution magnetograms. Our results demonstrate that the magnetic helicity asymmetry is robust, being present in the three ARs studied, two of which have an observed balance of the magnetic flux. The magnetic helicity injection rate measured is found to depend little on the window size selected, but does depend on the time interval used between the two successive magnetograms being tracked. It is found that the measurement of the magnetic helicity injection rate performs well for a window size between 12 ↳ 10 and 18 ↳ 15 pixels and at a time interval ⊗*t* = 10 minutes. Moreover, the short-lived magnetic structures, 10–60 minutes, are found to contribute 30%–50% of themagnetic helicity injection rate. Comparing with the results calculated by MDI/96 minute data, we find that the MDI/96 minute data, in general, can outline the main trend of the magnetic properties, but they significantly underestimate the magnetic flux in strong field regions and are not appropriate for quantitative tracking studies, so provide a poor estimate of the amount of magnetic helicity injected into the corona.

On Asymmetry of Magnetic Helicity in Emerging Active Regions: High Resolution Observations

Lirong **Tian**, Pascal Demoulin, David Alexander, Chunming Zhu

E-print Oct **2010**, ApJ

We employ the DAVE (differential affine velocity estimator, Schuck 2005; 2006) tracking technique on a time series of MDI/1m high spatial resolution line-of-sight manetograms to measure the photospheric flow velocity for three newly emerging bipolar active regions. We separately calculate the magnetic helicity injection rate of the leading and following polarities to confirm or refute the magnetic helicity asymmetry, found by Tian & Alexander (2009) using MDI/96m low spatial resolution magnetograms. Our results demonstrate that the magnetic helicity asymmetry is robust being present in the three active regions studied, two of which have an observed balance of the magnetic flux. The magnetic helicity injection rate measured is found to depend little on the window size selected, but does depend on the time interval used between the two successive magnetograms tracked. It is found that the measurement of the magnetic helicity injection rate performs well for a window size between 12X10 and 18X15 pixels, and at a time interval Δt=10 minutes. Moreover, the short-lived magnetic structures, 10-60 minutes, are found to contribute 30-50% of the magnetic helicity injection rate. Comparing with the results calculated by MDI/96m data, we find that the MDI/96m data, in general, can outline the main trend of the magnetic properties, but they significantly underestimate the magnetic flux in strong field region and are not appropriate for quantitative tracking studies, so provide a poor estimate of the amount of magnetic helicity injected into the corona.

ASYMMETRY OF HELICITY INJECTION FLUX IN EMERGING ACTIVE REGIONS
Lirong **Tian** and David Alexander
Astrophysical Journal, 695:1012–1023, **2009** April
http://www.iop.org/EJ/toc/-alert=43190/0004-637X/695/2
Observational and modeling results indicate that typically the leading magnetic field of bipolar active regions (ARs) is often spatially more compact,while more dispersed and fragmented in following polarity. In this paper,we address the origin of this morphological asymmetry, which is not well understood. Although it may be assumed that, in an emerging ∧-shaped flux tube, those portions of the flux tube in which the magnetic field has a higher twist may maintain its coherence more readily, this has not been tested observationally. To assess this possibility, it is important to characterize the nature of the fragmentation and asymmetry in solar ARs and this provides the motivation for this paper. We separately calculate the distribution of the helicity flux injected in the leading and following polarities of 15 emerging bipolar ARs, using the Michelson Doppler Image 96 minute line-of-sight magnetograms and a local correlation tracking technique. We find from this statistical study that the leading (compact) polarity injects several times more helicity flux than the following (fragmented) one (typically 3–10 times). This result suggests that the leading polarity of the ∧-shaped flux tube possesses a much larger amount of twist than the following field prior to emergence. We argue that the helicity asymmetry between the leading and following magnetic field for the ARs studied here results in the observed magnetic field asymmetry of the two polarities due to an imbalance in the magnetic tension of the emerging flux tube. We suggest that the observed imbalance in the helicity distribution results from a difference in the speed of emergence between the leading and following legs of an inclined ∧-shaped flux tube. In addition, there is also the effect of magnetic flux imbalance between the two polarities with the fragmented following polarity displaying spatial fluctuation in both the magnitude and sign of helicity measured.

Origins of coronal energy and helicity in NOAA 10030

Lirong **Tian**1, David Alexander1, and Richard Nightingale2
E-print, April 2008; ApJ, 684:747-756, **2008**
http://www.journals.uchicago.edu/doi/pdf/10.1086/590234
Exploring the origins of coronal helicity and energy, as well as determining the mechanisms that lead to coronal energy release, are fundamental topics in solar physics. Using MDI/96 minute line-of-sight and HSOS vector magnetograms in conjunction with TRACE white light and UV (1600 AA) images and BBSO/H_alpha and SOHO/EIT (195 AA), we find in active region NOAA 10030 that a large positive polarity sunspot, located in the center of the region, exhibited significant counter-clockwise rotation, which continued for six days during the period, **July 12-18, 2002**. This rotating sunspot was related to the formation of inverse-S-shaped filaments, left-handed twist of the vector magnetic fields, and the production of strong negative vertical current, but exhibited little emergence of magnetic flux. In all, five M-class and two X-class flares were produced around this rotating sunspot over the six day period. The observed characteristics of the strongly rotating sunspot suggest that sunspots can undergo strong intrinsic rotation, the source of which may originate below the photosphere and can play a significant role in helicity production and injection and energy buildup in the corona. A sunspot with negative magnetic polarity showed fast and significant emergence in the eastern portion of the active region, and moved north-eastward over several days, but exhibited little rotation. The moving sunspot also exhibited the formation of inverse-S-shaped filaments, left-handed twist of vector magnetic fields and coronal structure, and the production of stronger positive current. The observed characteristics of the emerging sunspot suggest that significant emergence of twisted magnetic fields may not always result in the rotation of the associated sunspots, but do play also a very important role in the coronal helicity accumulation and free-energy build-up.

What is the Most Important Origin of the Coronal Helicity?

Lirong **Tian**
Subsurface and Atmospheric Influences on Solar Activity
ASP Conference Series, Vol. 383, c **2008**
R. Howe, R. W. Komm, K. S. Balasubramaniam, and G. J. D. Petrie, eds.
http://spacibm.rice.edu/~alicetlr/publications/2008b.pdf
23 active regions (ARs) with well-defined SXR sigmoids are selected to study what is the most important origin of the coronal helicity--the emergence of magnetic fields or the photospheric horizontal motions. The redial magnetic flux of each polarity, the helicity injection rate, and total helicity flux (Delta H_{lct}) are calculated using local correlation tracking technique and MDI 96m line-of-sight magnetograms, and the helicity budget of the differential rotation (Delta H_{rot}) is also extimated. It is found that six ARs inject helicity flux greater than 10^{43} Mx^2,(Delta H =Delta H_{lct}-Delta H_{rot}), in a sample of seven ARs with emerging magnetic flux greater than 10^{22} Mx. On the other hand, in sixteen ARs with emerging magnetic flux less than 10^{22} Mx, only 4 ARs injected the helicity flux greater than 10^{43} Mx^2, which denotes the main comtribution of the horizontal motions. The statitical results suggest that the horizontal motions are not important to the coronal helicity injection when there is little magnetic field emergence.

ON THE ORIGIN OF MAGNETIC HELICITY IN THE SOLAR CORONA
Lirong **Tian** and David Alexander
The Astrophysical Journal, 673:532-543, **2008**
http://www.journals.uchicago.edu/doi/pdf/10.1086/524129
Twenty-three active regions associated with pronounced sigmoidal structure in Yohkoh soft X-ray observations are selected to investigate the origin of magnetic helicity in the solar corona.
These statistical results signify that the strong emergence of magnetic field is the most important origin of the coronal helicity, while horizontal motions and differential rotation are insufficient to explain the measured helicity injection flux. Furthermore, the study of the helicity injection in nineteen newly emerging active regions confirms the result on the important role played by strong magnetic flux emergence in controlling the injection of magnetic helicity into the solar corona.

1997 MAY 12 CORONAL MASS EJECTION EVENT.
I. A SIMPLIFIED MODEL OF THE PREERUPTIVE MAGNETIC STRUCTURE
V. S. **Titov**, Z. Mikic, J. A. Linker, and R. Lionello
http://www.journals.uchicago.edu/doi/pdf/10.1086/527280
The Astrophysical Journal, 675:1614Y1628, 2008 March 10
A simple model of the coronal magnetic field prior to the coronal mass ejection (CME) eruption on 1997May 12 is developed. First, the magnetic field is constructed by superimposing a large-scale background field and a localized bipolar field to model the active region (AR) in the current-free approximation. Second, this potential configuration is quasi-statically sheared by photospheric vortex motions applied to two flux concentrations of the AR. Third, the resulting force-free field is then evolved by canceling the photospheric magnetic flux with the help of an appropriate tangential electric field applied to the central part of the AR. To understand the structure of the modeled configuration, we use the field linemapping technique by generalizing it to spherical geometry.We demonstrate that the initial potential configuration contains a hyperbolic flux tube (HFT) which is a union of two intersecting quasi-separatrix layers. This HFT provides a partition of the closed magnetic flux between the AR and the global solar magnetic field. Such a partition is approximate since the entire flux distribution is perfectly continuous. The vortex motions applied to the AR interlock the field lines in the coronal volume to form additionally two newHFTs pinched into thin current layers.Reconnection in these current layers helps to redistribute the magnetic flux and current within the AR in the flux-cancellation phase. In this phase, a magnetic flux rope is formed together with a bald patch separatrix surface wrapping around the rope. Other important implications of the identified structural features of the modeled configuration are also discussed.

Trigger Mechanism of Solar Subflares in a Braided Coronal Magnetic Structure
Sanjiv K. **Tiwari**, Caroline E. Alexander, Amy R. Winebarger, Ronald L. Moore
ApJL, 795 L24 **2014**
http://arxiv.org/pdf/1410.4260v1.pdf
Fine-scale braiding of coronal magnetic loops by continuous footpoint motions may power coronal heating via nanoflares, which are spontaneous fine-scale bursts of internal reconnection. An initial nanoflare may trigger an avalanche of reconnection of the braids, making a microflare or larger subflare. In contrast to this internal triggering of subflares, we observe external triggering of subflares in a braided coronal magnetic field observed by the {\it High-resolution Coronal Imager (Hi-C)}. We track the development of these subflares using 12 s cadence images acquired by {\it SDO}/AIA in 1600, 193, 94 \AA, and registered magnetograms of {\it SDO}/HMI, over four hours centered on the {\it Hi-C} observing time. These data show numerous recurring small-scale brightenings in transition-region emission happening on polarity inversion lines where flux cancellation is occurring. We present in detail an example of an apparent burst of reconnection of two loops in the transition region under the braided coronal field, appropriate for releasing a short reconnected loop downward and a longer reconnected loop upward. The short loop presumably submerges into the photosphere, participating in observed flux cancellation. A subflare in the overlying braided magnetic field is apparently triggered by the disturbance of the braided field by the reconnection-released upward loop. At least 10 subflares observed in this braided structure appear to be triggered this way. How common this external trigger mechanism for coronal subflares is in other active regions, and how important it is for coronal heating in general, remain to be seen. **11July 2012**

MAGNETIC NON-POTENTIALITY OF SOLAR ACTIVE REGIONS AND PEAK X-RAY FLUX OF THE ASSOCIATED FLARES
Sanjiv Kumar **Tiwari**, P. Venkatakrishnan, and Sanjay Gosain
Astrophysical Journal, 721:622–629, **2010** September, **File**
Predicting the severity of solar eruptive phenomena such as flares and coronal mass ejections remains a great

challenge despite concerted efforts to do so over the past several decades. However, the advent of high-quality vector magnetograms obtained from *Hinode* (SOT/SP) has increased the possibility of meeting this challenge. In particular, the spatially averaged signed shear angle (SASSA) seems to be a unique parameter for quantifying the non-potentiality of active regions.We demonstrate the usefulness of the SASSA for predicting flare severity. For this purpose, we present case studies of the evolution of magnetic non-potentiality using 115 vector magnetograms of four active regions, namely, ARs NOAA 10930, 10960, 10961, and 10963 during 2006 December 8–15, 2007 June 3–10, 2007 June 28–July 5, and 2007 July 10–17, respectively. The NOAA ARs 10930 and 10960 were very active and produced X and M class flares, respectively, along with many smaller X-ray flares. On the other hand, the NOAA ARs 10961 and 10963 were relatively less active and produced only very small (mostly A- and B-class) flares. For this study, we have used a large number of high-resolution vector magnetograms obtained from *Hinode* (SOT/SP). Our analysis shows that **the peak X-ray flux of the most intense solar flare emanating from the active regions depends on the magnitude of the SASSA at the time of the flare**. This finding of the existence of a lower limit of the SASSA for a given class of X-ray flares will be very useful for space weather forecasting. We have also studied another non-potentiality parameter called the mean weighted shear angle (MWSA) of the vector magnetograms along with the SASSA. We find that the MWSA does not show such distinction as the SASSA for upper limits of the *GOES* X-ray flux of solar flares; however, both the quantities show similar trends during the evolution of all active regions studied.

Spatially Resolved Plasma Composition Evolution in a Solar Flare -- The Effect of Reconnection Outflow

https://arxiv.org/pdf/2409.18188?

https://www.aanda.org/articles/aa/pdf/2024/11/aa49246-24.pdf

Context. Solar flares exhibit complex variations in elemental abundances compared to photospheric values. These abundance variations, characterized by the first ionization potential (FIP) bias, remain challenging to interpret.
Aims. We aim to (1) examine the spatial and temporal evolution of coronal abundances in the X8.2 flare on **2017 September 10**, and (2) provide a new scenario to interpret the often observed high FIP bias loop top, and provide further insight into differences between spatially resolved and Sun-as-a-star flare composition measurements.
Methods. We analyzed 12 Hinode/Extreme-ultraviolet Imaging Spectrometer (EIS) raster scans spanning 3.5 hours, employing both Ca XIV 193.87 Å/Ar XIV 194.40 Å and Fe XVI 262.98 Å/S XIII 256.69 Å composition diagnostics to derive FIP bias values. We used the Markov Chain Monte Carlo (MCMC) differential emission measure (DEM) method to obtain the distribution of plasma temperatures, which forms the basis for the FIP bias calculations.
Results. Both the Ca/Ar and Fe/S composition diagnostics consistently show that flare loop tops maintain high FIP bias values of > 2–6, with peak phase values exceeding 4, over the extended duration, while footpoints exhibit photospheric FIP bias of ∼1. The consistency between these two diagnostics forms the basis for our interpretation of the abundance variations.
Conclusions. We propose that this variation arises from a combination of two distinct processes: high FIP bias plasma downflows from the plasma sheet confined to loop tops, and chromospheric evaporation filling the loop footpoints with low FIP bias plasma. Mixing between these two sources produces the observed gradient. Our observations show that the localized high FIP bias signature at loop tops is likely diluted by the bright footpoint emission in spatially averaged measurements. The spatially resolved spectroscopic observations enabled by EIS prove critical for revealing this complex abundance variation in loops. Furthermore, our observations show clear evidence that the origin of hot flare plasma in flaring loops consists of a combination of both directly heated plasma in the corona and from ablated chromospheric material; and our results provide valuable insights into the formation and composition of loop top brightenings, also known as EUV knots, which are a common feature at the tops of flare loops.

Reconnection outflow feeds abundance variations.

The Evolution of Plasma Composition During a Solar Flare

Andy S.H. **To**, David M. Long, Deborah Baker, David H. Brooks, Lidia van Driel-Gesztelyi, J. Martin Laming, Gherardo Valori

ApJ **911** 86 **2021**

https://arxiv.org/pdf/2102.09985.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/abe85a/pdf

https://doi.org/10.3847/1538-4357/abe85a

We analyse the coronal elemental abundances during a small flare using Hinode/EIS observations. Compared to the pre-flare elemental abundances, we observed a strong increase in coronal abundance of Ca XIV 193.84 Å, an emission line

with low first ionisation potential (FIP < 10 eV), as quantified by the ratio Ca/Ar during the flare. This is in contrast to the unchanged abundance ratio observed using Si X 258.38 Å/S X 264.23 Å. We propose two different mechanisms to explain the different composition results. Firstly, the small flare-induced heating could have ionised S, but not the noble gas Ar, so that the flare-driven Alfvén waves brought up Si, S and Ca in tandem via the ponderomotive force which acts on ions. Secondly, the location of the flare in strong magnetic fields between two sunspots may suggest fractionation occurred in the low chromosphere, where the background gas is neutral H. In this region, high-FIP S could behave more like a low-FIP than a high-FIP element. The physical interpretations proposed generate new insights into the evolution of plasma abundances in the solar atmosphere during flaring, and suggests that current models must be updated to reflect dynamic rather than just static scenarios. **2-5 Feb 2014**

Flare Hybrids **Review**

M. **Tomczak**, P. Dubieniecki
Solar Physics Volume 290, Issue 12, pp 3611-3623 **2015**
http://arxiv.org/pdf/1504.03165v1.pdf
http://link.springer.com/journal/11207/290/12/page/1
https://link.springer.com/content/pdf/10.1007/s11207-015-0688-x.pdf
Svestka (Solar Phys. 1989, 121, 399) on the basis of the Solar Maximum Mission observations introduced a new class of flares, the so-called flare hybrids. When they start, they look as typical compact flares (phase 1), but later on they look like flares with arcades of magnetic loops (phase 2). We summarize the features of flare hybrids in soft and hard X-rays as well as in extreme-ultraviolet; these allow us to distinguish them from other flares. Additional energy release or long plasma cooling timescales have been suggested as possible cause of phase 2. Estimations of frequency of flare hybrids have been given. Magnetic configurations supporting their origin have been presented. In our opinion, flare hybrids are quite frequent and a difference between lengths of two interacting systems of magnetic loops is a crucial parameter for recognizing their features. **1992-11-05, 1992-09-09, 5 NOV 1992**

Multiperiodicity in quasi-periodic pulsations of flare hard X-rays: a case study

M. **Tomczak**, Z. Szaforz
Central European Astrophysical Bulletin, Cent. Eur. Astrophys. Bull. 38, 111. **2014**
http://arxiv.org/pdf/1412.2173v1.pdf
We present a case study of the solar flare (SOL**2001-10-02**T17:31) that showed quasi-periodic pulsations (QPPs) in hard X-rays with two simultaneously excited periods, P_1 = 26-31 s and P_2 = 110 s. Complete evolution of the flare recorded by the Yohkoh telescopes, together with the patrol SOHO/EIT images, allowed us to identify magnetic structures responsible for particular periods and to propose an overall scenario which is consistent with the available observations. Namely, we suggest that emerging magnetic flux initiated the reconnection with legs of a large arcade of coronal loops that had been present in an active region for several days. The reconnection excited MHD oscillations in both magnetic structures simultaneously: period P_1 was generated in the emerging loop and in a loop being a result of the reconnection; period P_2 occurred in the arcade. Both resonators produced photons of different spectra. We anticipate that multiperiodicity in hard X-rays can be a common feature of flare hybrids, i.e. the events, in which magnetic structures of different sizes interact.

The YOHKOH survey of partially occulted flares in hard X-rays

M. **Tomczak**
A&A 502, 665-678 (**2009**)
Context. Modern solar X-ray imagers do not completely resolve the problem of deriving detailed diagnostics of faint hard X-ray sources in the presence of stronger ones. This is the case for the impulsive phase of solar flares in which footpoint sources are usually stronger than loop-top ones.
Aims. Flares that are partially occulted by the solar limb provide the most hopeful source of knowledge about hard X-ray loop-top sources. This work attempts to fill the gap between the published survey of partially occulted flares observed by RHESSI (Krucker & Lin 2008, ApJ, 673, 1181) and the extensive *Yohkoh* database.
Methods. Among the 1286 flares in the *Yohkoh* Hard X-ray Telescope Flare Catalogue (Sato et al. 2006, Sol. Phys., 236, 351), for which the hard X-ray images were presented, we identified 98 events that occurred behind the solar limb. We investigated their hard X-ray spectra and spatial structure.
Results. In most cases, we found that the hard X-ray spectrum of partially occulted flares consists of two components, non-thermal and thermal, which are cospatial to within 4 arcsec. For rest events, the components are separated, the non-thermal component clearly appearing to be situated higher. The photon energy spectra of the partially occulted flares are systematically steeper than spectra of the non-occulted flares. We can explain this difference as a consequence of intrinsically dissimilar conditions in coronal parts of flares, in comparison with the footpoints that usually dominate the hard X-ray emission of disk flares. At least two reasons for the difference should be taken into consideration: (1)

stronger contamination of hard X-rays by emission from thermal plasma; and (2) different mechanisms in which non-thermal electrons radiate their energy. For events unbiased by the thermal component, the difference, $\Delta\gamma = \bar{\gamma}_{LT} - \bar{\gamma}_{FP}$, equals 1.5. We found a lack of correlation between the altitude of flares and the hard X-ray power-law index γ.
Conclusions. A schematic picture, in which a thin-target mechanism is responsible for the hard X-ray emission of loop-top sources and a thick-target mechanism for emission by footpoint sources, is modified by the presence of some coronal thick-target sources. Some of these sources exhibit evidence of magnetic trapping. For the characteristics of flares is conclusive the local magnetic configuration in which they occur.

Solar Sources of Flares and CMEs **Review**

Shin **Toriumi**
Proceedings of the IAU Symposium No. 388 **2024**
https://arxiv.org/pdf/2409.16353
Strong solar flares and coronal mass ejections (CMEs) are prone to originate within and near active regions (ARs) with a high magnetic complexity. Therefore, to better understand the generation mechanism of flares and the resultant CME eruption and to gain insight into their stellar counterparts, it is crucial to reveal how solar flare-productive ARs are generated and developed. In this review, first, we summarize some general aspects of solar flares and key observational characteristics of such ARs. Then, we discuss a series of flux emergence simulations that were performed to elucidate the subsurface origins of their complexity and introduce state-of-the-art models that consider the effect of turbulent thermal convection. Future flare observations using SOLAR-C, a next-generation high-throughput extreme ultraviolet spectroscopy mission, are also discussed.

Solar Flares and Magnetic Helicity **Review**

Shin **Toriumi**, Sung-Hong Park
A chapter in the AGU book "Helicities in Geophysics, Astrophysics and Beyond" **2022**
https://arxiv.org/pdf/2204.06010.pdf
Solar flares and coronal mass ejections are the largest energy release phenomena in the current solar system. They cause drastic enhancements of electromagnetic waves of various wavelengths and sometimes eject coronal material into the interplanetary space, disturbing the magnetic surroundings of orbiting planets including the Earth. It is generally accepted that solar flares are a phenomenon in which magnetic energy stored in the solar atmosphere above an active region is suddenly released through magnetic reconnection. Therefore, to elucidate the nature of solar flares, it is critical to estimate the complexity of the magnetic field and track its evolution. Magnetic helicity, a measure of the twist of coronal magnetic structures, is thus used to quantify and characterize the complexity of flare-productive active regions. This chapter provides an overview of solar flares and discusses how the different concepts of magnetic helicity are used to understand and predict solar flares. **1997 November 3, 2000 February 27, 2001 October 25, 2007-04-30, 2011 February 14-15, 2014 October 24**

Flux emergence and generation of flare-productive active regions

Shin **Toriumi**
Advances in Space Research **2021**
https://arxiv.org/pdf/2105.09961.pdf
Solar flares and coronal mass ejections are among the most prominent manifestations of the magnetic activity of the Sun. The strongest events of them tend to occur in active regions (ARs) that are large, complex, and dynamically evolving. However, it is not clear what the key observational features of such ARs are, and how these features are produced. This article answers these fundamental questions based on morphological and magnetic characteristics of flare-productive ARs and their evolutionary processes, i.e., large-scale flux emergence and subsequent AR formation, which have been revealed in observational and theoretical studies. We also present the latest modeling of flare-productive ARs achieved using the most realistic flux emergence simulations in a very deep computational domain. Finally, this review discusses the future perspective pertaining to relationships of flaring solar ARs with the global-scale dynamo and stellar superflares. **13 Feb 2011, 7 Mar 2012, 7 Jan 2014, 29 Mar 2014**

Flare-productive active regions **Review**

Shin **Toriumi**, Haimin Wang
Living Reviews in Solar Physics **16**: 3 **2019**
https://arxiv.org/pdf/1904.12027.pdf
sci-hub.do/10.1007/s41116-019-0019-7
Strong solar flares and coronal mass ejections, here defined not only as the bursts of electromagnetic radiation but as the entire process in which magnetic energy is released through magnetic reconnection and plasma instability, emanate from active regions (ARs) in which high magnetic non-potentiality resides in a wide variety of forms. This review focuses on the formation and evolution of flare-productive ARs from both observational and theoretical points of view.

Starting from a general introduction of the genesis of ARs and solar flares, we give an overview of the key observational features during the long-term evolution in the pre-flare state, the rapid changes in the magnetic field associated with the flare occurrence, and the physical mechanisms behind these phenomena. Our picture of flare-productive ARs is summarized as follows: subject to the turbulent convection, the rising magnetic flux in the interior deforms into a complex structure and gains high non-potentiality; as the flux appears on the surface, an AR with large free magnetic energy and helicity is built, which is represented by delta-sunspots, sheared polarity inversion lines, magnetic flux ropes, etc; the flare occurs when sufficient magnetic energy has accumulated, and the drastic coronal evolution affects magnetic fields even in the photosphere. We show that the improvement of observational instruments and modeling capabilities has significantly advanced our understanding in the last decades. Finally, we discuss the outstanding issues and future perspective and further broaden our scope to the possible applications of our knowledge to space-weather forecasting, extreme events in history, and corresponding stellar activities. **1859 September 1, 1946 July 25, 3 August 1972, 2000 Jun 6, 2001 Apr 9, 2001 Aug 25, 2003 Oct 28, 2003 Oct 29, 2003 Nov 2, 2006 Dec 13, February 12, 2007, 5-7 Dec 2007, 12-16 Feb 2011, 2012 March 7, 2012 July 02, 2014 Oct 24, 2015 June 22, 2015 August 19, 3-7 Sep 2017**

Numerical Simulations of Flare-productive Active Regions: delta-sunspots, Sheared Polarity Inversion Lines, Energy Storage, and Predictions

Shin **Toriumi**, Shinsuke Takasao

ApJ **850** 39 **2017**

https://arxiv.org/pdf/1710.08926.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/aa95c2/pdf

Solar active regions (ARs) that produce strong flares and coronal mass ejections (CMEs) are known to have a relatively high non-potentiality and are characterized by delta-sunspots and sheared magnetic structures. In this study, we conduct a series of flux emergence simulations from the convection zone to the corona and model four types of active regions that have been observationally suggested to cause strong flares, namely the Spot-Spot, Spot-Satellite, Quadrupole, and Inter-AR cases. As a result, we confirm that delta-spot formation is due to the complex geometry and interaction of emerging magnetic fields, with finding that the strong-field, high-gradient, highly-sheared polarity inversion line (PIL) is created by the combined effect of the advection, stretching, and compression of magnetic fields. We show that free magnetic energy builds up in the form of a current sheet above the PIL. It is also revealed that photospheric magnetic parameters that predict flare eruptions reflect the stored free energy with high accuracy, while CME-predicting parameters indicate the magnetic relationship between flaring zones and entire ARs.

Magnetic Properties of Solar Active Regions that Govern Large Solar Flares and Eruptions

ApJ **2017 834** 56

https://arxiv.org/pdf/1611.05047v1.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/834/1/56/pdf

Solar flares and coronal mass ejections (CMEs), especially the larger ones, emanate from active regions (ARs). With the aim to understand the magnetic properties that govern such flares and eruptions, we systematically survey all flare events with GOES levels of >=M5.0 within 45 deg from disk center between May 2010 and April 2016. These criteria lead to a total of 51 flares from 29 ARs, for which we analyze the observational data obtained by the Solar Dynamics Observatory. More than 80% of the 29 ARs are found to exhibit delta-sunspots and at least three ARs violate Hale's polarity rule. The flare durations are approximately proportional to the distance between the two flare ribbons, to the total magnetic flux inside the ribbons, and to the ribbon area. From our study, one of the parameters that clearly determine whether a given flare event is CME-eruptive or not is the ribbon area normalized by the sunspot area, which may indicate that the structural relationship between the flaring region and the entire AR controls CME productivity. AR characterization show that even X-class events do not require delta-sunspots or strong-field, high-gradient polarity inversion lines. An investigation of historical observational data suggests the possibility that the largest solar ARs, with magnetic flux of 2x10^23 Mx, might be able to produce "superflares" with energies of order of 10^34 erg. The proportionality between the flare durations and magnetic energies is consistent with stellar flare observations, suggesting a common physical background for solar and stellar flares.

LIGHT BRIDGE IN A DEVELOPING ACTIVE REGION. II. NUMERICAL SIMULATION OF FLUX EMERGENCE AND LIGHT BRIDGE FORMATION

Shin **Toriumi**1, Mark C. M. Cheung2, and Yukio Katsukawa

2015 ApJ 811 138

Light bridges, the bright structure dividing umbrae in sunspot regions, show various activity events. In Paper I, we reported on an analysis of multi-wavelength observations of a light bridge in a developing active region (AR) and concluded that the activity events are caused by magnetic reconnection driven by magnetconvective evolution. The aim of this second paper is to investigate the detailed magnetic and velocity structures and the formation mechanism of light bridges. For this purpose, we analyze numerical simulation data from a radiative magnetohydrodynamics model of an emerging AR. We find that a weakly magnetized plasma upflow in the near-surface layers of the convection zone is entrained between the emerging magnetic bundles that appear as pores at the solar surface. This convective upflow continuously transports horizontal fields to the surface layer and creates a light bridge structure. Due to the magnetic shear between the horizontal fields of the bridge and the vertical fields of the ambient pores, an elongated cusp-shaped current layer is formed above the bridge, which may be favorable for magnetic reconnection. The striking correspondence between the observational results of Paper I and the numerical results of this paper provides a consistent physical picture of light bridges. The dynamic activity phenomena occur as a natural result of the bridge formation and its convective nature, which has much in common with those of umbral dots and penumbral filaments.

LIGHT BRIDGE IN A DEVELOPING ACTIVE REGION. I. OBSERVATION OF LIGHT BRIDGE AND ITS DYNAMIC ACTIVITY PHENOMENA

Shin **Toriumi**1, Yukio Katsukawa1, and Mark C. M. Cheung

2015 ApJ 811 137

http://arxiv.org/pdf/1509.00183v1.pdf

Light bridges, the bright structures that divide the umbra of sunspots and pores into smaller pieces, are known to produce a wide variety of activity events in solar active regions (ARs). It is also known that the light bridges appear in the assembling process of nascent sunspots. The ultimate goal of this series of papers is to reveal the nature of light bridges in developing ARs and the occurrence of activity events associated with the light bridge structures from both observational and numerical approaches. In this first paper, exploiting the observational data obtained by Hinode, the Interface Region Imaging Spectrograph, and the Solar Dynamics Observatory, we investigate the detailed structure of the light bridge in **NOAA AR 11974** and its dynamic activity phenomena. As a result, we find that the light bridge has a weak, horizontal magnetic field, which is transported from the interior by a large-scale convective upflow and is surrounded by strong, vertical fields of adjacent pores. In the chromosphere above the bridge, a transient brightening occurs repeatedly and intermittently, followed by a recurrent dark surge ejection into higher altitudes. Our analysis indicates that the brightening is the plasma heating due to magnetic reconnection at lower altitudes, while the dark surge is the cool, dense plasma ejected from the reconnection region. From the observational results, we conclude that the dynamic activity observed in a light bridge structure such as chromospheric brightenings and dark surge ejections are driven by magnetoconvective evolution within the light bridge and its interaction with the surrounding magnetic fields.

Observations and modeling of the solar flux emergence **Review**

Shin **TORIUMI**

Publ. Astron. Soc. Japan (**2014**) 66 (SP1), S6 (1–10)

http://pasj.oxfordjournals.org/content/66/SP1/S6.full.pdf+html

In a wide variety of magnetic activity phenomena occurring in the Sun, flux emergence is one of the most prominent events. It is important to study flux emergence since this is the process that transports the magnetic flux from the deep interior to the upper atmosphere, creates active regions, and sometimes causes catastrophic flaring eruptions. Recent observations have revealed that flux emergence ranges from the formation of large-scale active regions including sunspots to small-scale events observable only with advanced instruments, covering a very broad spectrum of scale involved. In addition, helioseismology may allow us to investigate the process even before the flux itself appears at the visible surface of the Sun. At the same time, recent development in the numerical modeling of flux emergence opens the door to a further understanding of physical processes, such as resistive and convective emergence. In this paper, we

review the observational and numerical progress in the field of flux emergence study, while focusing particularly on three important aspects: emergence in the interior, the first appearance in the surface layer, and their relation with flaring activity. Based on these studies, we also discuss what should be investigated in the future.

Statistical Analysis of the Horizontal Divergent Flow in Emerging Solar Active Regions

Shin **Toriumi**, Keiji Hayashi, Takaaki Yokoyama
ApJ, **2014**
http://arxiv.org/pdf/1408.2383v1.pdf

Solar active regions (ARs) are thought to be formed by magnetic fields from the convection zone. Our flux emergence simulations revealed that a strong horizontal divergent flow (HDF) of unmagnetized plasma appears at the photosphere before the flux begins to emerge. In our earlier study, we analyzed HMI data for a single AR and confirmed presence of this precursor plasma flow in the actual Sun. In this paper, as an extension of our earlier study, we conducted a statistical analysis of the HDFs to further investigate their characteristics and better determine the properties. From SDO/HMI data, we picked up 23 flux emergence events over a period of 14 months, the total flux of which ranges from 10^{20} to 10^{22} Mx. Out of 23 selected events, 6 clear HDFs were detected by the method we developed in our earlier study, and 7 HDFs detected by visual inspection were added to this statistic analysis. We found that the duration of the HDF is on average 61 minutes and the maximum HDF speed is on average 3.1 km s^{-1}. We also estimated the rising speed of the subsurface magnetic flux to be 0.6-1.4 km s^{-1}. These values are highly consistent with our previous one-event analysis as well as our simulation results. The observation results lead us to the conclusion that the HDF is rather a common feature in the earliest phase of AR emergence. Moreover, our HDF analysis has capability of determining the subsurface properties of emerging fields that cannot be directly measured.
Fig. 7.— ARs analyzed in this study. (Left) SDO/HMI magnetogram.

Formation of a Flare-Productive Active Region: Observation and Numerical Simulation of NOAA AR 11158

S. **Toriumi**, Y. Iida, K. Kusano, Y. Bamba, S. Imada
Solar Phys., Volume 289, Issue 9, pp 3351-3369, **2014**
http://arxiv.org/pdf/1403.4029v1.pdf

We present a comparison of the Solar Dynamics Observatory (SDO) analysis of NOAA Active Region (AR) 11158 and numerical simulations of flux-tube emergence, aiming to investigate the formation process of this flare-productive AR. First, we use SDO/Helioseismic and Magnetic Imager (HMI) magnetograms to investigate the photospheric evolution and Atmospheric Imaging Assembly (AIA) data to analyze the relevant coronal structures. Key features of this quadrupolar region are a long sheared polarity inversion line (PIL) in the central δ-sunspots and a coronal arcade above the PIL. We find that these features are responsible for the production of intense flares, including an X2.2-class event. Based on the observations, we then propose two possible models for the creation of AR 11158 and conduct flux-emergence simulations of the two cases to reproduce this AR. Case 1 is the emergence of a single flux tube, which is split into two in the convection zone and emerges at two locations, while Case 2 is the emergence of two isolated but neighboring tubes. We find that, in Case 1, a sheared PIL and a coronal arcade are created in the middle of the region, which agrees with the AR 11158 observation. However, Case 2 never builds a clear PIL, which deviates from the observation. Therefore, we conclude that the flare-productive AR 11158 is, between the two cases, more likely to be created from a single split emerging flux than from two independent flux bundles.

THE MAGNETIC SYSTEMS TRIGGERING THE M6.6 CLASS SOLAR FLARE IN NOAA ACTIVE REGION 11158

Shin **Toriumi**1,4, Yusuke Iida1,5, Yumi Bamba2, Kanya Kusano2,6, Shinsuke Imada2, and Satoshi Inoue
2013 ApJ 773 128

We report a detailed event analysis of the M6.6 class flare in the active region (AR) NOAA 11158 on **2011 February 13**. AR 11158, which consisted of two major emerging bipoles, showed prominent activity including one X- and several M-class flares. In order to investigate the magnetic structures related to the M6.6 event, particularly the formation process of a flare-triggering magnetic region, we analyzed multiple spacecraft observations and numerical results of a flare simulation. We observed that, in the center of this quadrupolar AR, a highly sheared polarity inversion line (PIL) was formed through proper motions of the major magnetic elements, which built a sheared coronal arcade lying over the PIL. The observations lend support to the interpretation that the target flare was triggered by a localized magnetic region that had an intrusive structure, namely, a positive polarity penetrating into a negative counterpart. The geometrical relationship between the sheared coronal arcade and the triggering region is consistent with the theoretical flare model based on the previous numerical study. We found that the formation of the trigger region was due to the continuous accumulation of small-scale magnetic patches. A few hours before the flare occurred, the series of emerged/advected patches reconnected with a pre-existing field. Finally, the abrupt flare eruption of the M6.6 event

started around 17:30 UT. Our analysis suggests that in the process of triggering flare activity, all magnetic systems on multiple scales are included, not only the entire AR evolution but also the fine magnetic elements.

DETECTION OF THE HORIZONTAL DIVERGENT FLOW PRIOR TO THE SOLAR FLUX EMERGENCE

S. **Toriumi**1, K. Hayashi2, and T. Yokoyama
2012 ApJ 751 154
It is widely accepted that solar active regions including sunspots are formed by the emerging magnetic flux from the deep convection zone. In previous numerical simulations, we found that the horizontal divergent flow (HDF) occurs before the flux emergence at the photospheric height. This paper reports the HDF detection prior to the flux emergence of NOAA AR 11081, which is located away from the disk center. We use SDO/HMI data to study the temporal changes of the Doppler and magnetic patterns from those of the reference quiet Sun. As a result, the HDF appearance is found to come before the flux emergence by about 100 minutes. Also, the horizontal speed of the HDF during this time gap is estimated to be 0.6-1.5 km s–1, up to 2.3 km s–1. The HDF is caused by the plasma escaping horizontally from the rising magnetic flux. And the interval between the HDF and the flux emergence may reflect the latency during which the magnetic flux beneath the solar surface is waiting for the instability onset to the further emergence. Moreover, SMART Hα images show that the chromospheric plages appear about 14 minutes later, located cospatial with the photospheric pores. This indicates that the plages are caused by plasma flowing down along the magnetic fields that connect the pores at their footpoints. One important result of observing the HDF may be the possibility of predicting the sunspot appearances that occur in several hours.

NUMERICAL EXPERIMENTS ON THE TWO-STEP EMERGENCE OF TWISTED MAGNETIC FLUX TUBES IN THE SUN

S. **Toriumi** and T. Yokoyama
2011 ApJ 735 126
We present the new results of the two-dimensional numerical experiments on the cross-sectional evolution of a twisted magnetic flux tube rising from the deeper solar convection zone (–20,000 km) to the corona through the surface. The initial depth is 10 times deeper than most of the previous calculations focusing on the flux emergence from the uppermost convection zone. We find that the evolution is illustrated by the following two-step process. The initial tube rises due to its buoyancy, subject to aerodynamic drag due to the external flow. Because of the azimuthal component of the magnetic field, the tube maintains its coherency and does not deform to become a vortex roll pair. When the flux tube approaches the photosphere and expands sufficiently, the plasma on the rising tube accumulates to suppress the tube's emergence. Therefore, the flux decelerates and extends horizontally beneath the surface. This new finding owes to our large-scale simulation, which simultaneously calculates the dynamics within the interior as well as above the surface. As the magnetic pressure gradient increases around the surface, magnetic buoyancy instability is triggered locally and, as a result, the flux rises further into the solar corona. We also find that the deceleration occurs at a higher altitude than assumed in our previous experiment using magnetic flux sheets. By conducting parametric studies, we investigate the conditions for the two-step emergence of the rising flux tube: field strength 1.5 × 104 G and the twist 5.0 × 10–4 km–1 at –20,000 km depth.

Dependence of the Magnetic Energy of Solar Active Regions on the Twist Intensity of the Initial Flux Tubes

Shin **Toriumi**, Takehiro Miyagoshi, Takaaki Yokoyama, Hiroaki Isobe, and Kazunari Shibata
E-print Jan **2011**, PASJ
We present a series of numerical experiments that model the evolution of magnetic flux tubes with a different amount of initial twist. As a result of calculations, tightly twisted tubes reveal a rapid two-step emergence to the atmosphere with a slight slowdown at the surface, while weakly twisted tubes show a slow two-step emergence waiting longer the secondary instability to be triggered. This picture of the two-step emergence is highly consistent with recent observations. These tubes show multiple magnetic domes above the surface, indicating that the secondary emergence is caused by interchange mode of magnetic buoyancy instability. As for the weakest twist case, the tube exhibits an elongated photospheric structure and never rises into the corona. The formation of the photospheric structure is due to inward magnetic tension force of the azimuthal field component of the rising flux tube (i.e., tube's twist). When the twist is weak, azimuthal field cannot hold the tube's coherency, and the tube extends laterally at the subadiabatic surface. In addition, we newly find that the total magnetic energy measured above the surface depends on the initial twist. Strong twist tubes follow the initial relation between the twist and the magnetic energy, while weak twist tubes deviates from this relation, because these tubes store their magnetic energy in the photospheric structures.

Distribution of Electric Currents in Solar Active Regions

Tibor **Torok**, James E. Leake, Viacheslav S. Titov, Vasilis Archontis, Zoran Mikić, Mark G. Linton, K?vin Dalmasse, Guillaume Aulanier, Bernhard Kliem
E-print, Jan **2014**; **2014** ApJ 782 L10
http://arxiv.org/pdf/1401.2931v1.pdf
There has been a long-lasting debate on the question of whether or not electric currents in solar active regions are neutralized. That is, whether or not the main (or direct) coronal currents connecting the active region polarities are surrounded by shielding (or return) currents of equal total value and opposite direction. Both theory and observations are not yet fully conclusive regarding this question, and numerical simulations have, surprisingly, barely been used to address it. Here we quantify the evolution of electric currents during the formation of a bipolar active region by considering a three-dimensional magnetohydrodynamic simulation of the emergence of a sub-photospheric, current-neutralized magnetic flux rope into the solar atmosphere. We find that a strong deviation from current neutralization develops simultaneously with the onset of significant flux emergence into the corona, accompanied by the development of substantial magnetic shear along the active region's polarity inversion line. After the region has formed and flux emergence has ceased, the strong magnetic fields in the region's center are connected solely by direct currents, and the total direct current is several times larger than the total return current. These results suggest that active regions, the main sources of coronal mass ejections and flares, are born with substantial net currents, in agreement with recent observations. Furthermore, they support eruption models that employ pre-eruption magnetic fields containing such currents.

FAN–SPINE TOPOLOGY FORMATION THROUGH TWO-STEP RECONNECTION DRIVEN BY TWISTED FLUX EMERGENCE
T. **T¨or¨ok**1, G. Aulanier1, B. Schmieder1, K. K. Reeves2, and L. Golub2
Astrophysical Journal, 704:485–495, **2009** October
We address the formation of three-dimensional nullpoint topologies in the solar corona by combining *Hinode/* X-ray Telescope (XRT) observations of a small dynamic limb event, which occurred beside a non-erupting prominence cavity, with a three-dimensional (3D) zero-β magnetohydrodynamics (MHD) simulation. To this end, we model the boundary-driven "kinematic" emergence of a compact, intense, and uniformly twisted flux tube into a potential field arcade that overlies a weakly twisted coronal flux rope. The expansion of the emerging flux in the corona gives rise to the formation of a nullpoint at the interface of the emerging and the pre-existing fields. We unveil a two-step reconnection process at the nullpoint that eventually yields the formation of a broad 3D fan–spine configuration above the emerging bipole. The first reconnection involves emerging fields and a set of large-scale arcade field lines. It results in the launch of a torsional MHD wave that propagates along the arcades, and in the formation of a sheared loop system on one side of the emerging flux. The second reconnection occurs between these newly formed loops and remote arcade fields, and yields the formation of a second loop system on the opposite side of the emerging flux. The two loop systems collectively display an anenome pattern that is located below the fan surface. The flux that surrounds the inner spine field line of the nullpoint retains a fraction of the emerged twist, while the remaining twist is evacuated along the reconnected arcades. The nature and timing of the features which occur in the simulation do qualititatively reproduce those observed by XRT in the particular event studied in this paper. Moreover, the two-step reconnection process suggests a new consistent and generic model for the formation of anemone regions in the solar corona.

Inverse diffraction for the Atmospheric Imaging Assembly in the Solar Dynamics Observatory

Gabriele **Torre**, Richard A Schwartz, Federico Benvenuto, Anna Maria Massone, Michele Piana
Inverse Problems, **2015**
http://arxiv.org/pdf/1501.07805v1.pdf
The Atmospheric Imaging Assembly in the Solar Dynamics Observatory provides full Sun images every 1 seconds in each of 7 Extreme Ultraviolet passbands. However, for a significant amount of these images, saturation affects their most intense core, preventing scientists from a full exploitation of their physical meaning. In this paper we describe a mathematical and automatic procedure for the recovery of information in the primary saturation region based on a correlation/inversion analysis of the diffraction pattern associated to the telescope observations. Further, we suggest an interpolation-based method for determining the image background that allows the recovery of information also in the region of secondary saturation (blooming).
September 6 2011,

EMPIRICAL DETERMINATION OF THE ENERGY LOSS RATE OF ACCELERATED ELECTRONS IN A WELL-OBSERVED SOLAR FLARE
Gabriele **Torre**1, Nicola Pinamonti1, A. Gordon Emslie2, Jingnan Guo1, Anna Maria Massone3, and Michele Piana

2012 ApJ 751 129
We present electron images of an extended solar flare source, deduced from RHESSI hard X-ray imaging spectroscopy data. We apply the electron continuity equation to these maps in order to determine empirically the form of the energy loss rate for the bremsstrahlung-emitting electrons. We show that this form is consistent with an energy transport model involving Coulomb collisions in a target with a temperature of about 2 × 107 K, with a continuous injection of fresh deka-keV electrons at a rate of approximately 10–2 electrons s–1 per ambient electron**.**

A data driven kinetic approach to coronal heating

A. **Toutountzi**1, L. Vlahos1, H. Isliker1, K. Moraitis2, M. Georgoulis2, and G. Chintzoglou
A&A **2016**
http://arxiv.org/pdf/1603.07129v1.pdf
Aims. Coronal heating through the explosive release of magnetic energy remains an open problem in solar physics. Several one-dimensional hydrodynamical models have been developed over the last decade, using simple approaches for the way energy is
deposited and transported in the coronal plasma, namely by inserting “nanoflares” in the form of “hot spots” at random sites and times. Our aim in this work is to investigate the problem from a different perspective.
Methods. With the help of a nonlinear force-free extrapolation method we reconstruct the coronal magnetic field of a well-studied solar active region (NOAA AR 11158) using an observed photospheric vector magnetogram of the region as the required boundary condition. We then determine the locations, energy contents, and volumes of unstable areas (i.e., areas prone to releasing energy) within the active-region corona. These areas include strong gradients in the magnetic field and are naturally connected to three-dimensional current sheets. The statistical distributions of these volumes, their fractal structure and corresponding fractal dimension as well as their electric currentdensity distribution are then inferred. Further adopting a simple model for the resistivity, we estimate the key characteristics of the fractally distributed electric fields. We then follow the behavior of thousands of particles (electrons and ions), obeying an initial Maxwellian distribution with temperature 10 eV, monitoring their trajectories and energization obtained by encountering the electric fields enveloped by unstable volumes. For computational convenience, the spatial resolution of the magnetic field reconstruction (hundreds of km) is much coarser than the particles’ mean free path, which is 0.1 − 1 km in the low corona.
Results. The presence of collisions traps the bulk of the plasma around the unstable current sheets (UCS) and only a tail of the distribution of the electrons and ions gain substantial energy. Assuming that the distance between the UCS can be as small as the collisional mean free path, we find that the low active-region corona is heated to 100-200 eV, corresponding to temperatures in excess of 2 MK, within tens of seconds for electrons and thousands of seconds for ions. Our main result is that fractally distributed nanoflares inside the active region, following the statistical properties of the extrapolated magnetic fields, can heat electrons and ions with minor enhancements of the local resistivity due to the fragmentation of electric fields inside the driven complex magnetic topology.
Conclusions. The active region solar corona can be naturally heated by fractally distributed swarms of nanoflares that we simulate here as energy dissipation episodes in UCS. This could be extended for the quiet Sun corona, provided that currently undetected nanoflares are sufficient in number and occurrence frequency. February 11-16, 2011

Plasma Motions and Turbulent Magnetic Diffusivity of Active Region AR 12158 Using a Minimum Energy Functional and Non-Force-Free Reconstructions of Vector Magnetograms

Benoit **Tremblay**, Alain Vincent
Solar Phys. January **2017**, 292:2
We present a generalization of the resistive minimum-energy fit (MEF-R: Tremblay and Vincent, *Solar Phys.* **290**, 437, 2015) for non-force-free (NFF) magnetic fields. InMEF-R, an extremum principle is used to infer two-dimensional maps of plasma motions [$\boldsymbol{v}(x, y)$] and magnetic eddy diffusivity [$\eta_{\mathrm{eddy}}(x, y)$] at the photosphere. These reconstructions could be used as boundary conditions in data-driven simulations or in data assimilation. The algorithm is validated using the analytical model of a resistive expanding spheromak by Rakowski, Laming, and Lyutikov (*Astrophys. J.* **730**, 30, 2011). We study the flaring Active Region AR 12158 using a series of magnetograms and Dopplergrams provided by the *Helioseismic and Magnetic Imager* (HMI) onboard the *Solar Dynamics Observatory* (SDO). The results are discussed for a non-force-free magnetic-field reconstruction [$\boldsymbol{B}_{\mathrm{NFF}}$] (Hu and Dasgupta in *Solar Phys.* **247**, 87, 2008). We found that the vertical plasma velocities [$v_z(x, y)$] inferred using MEF-R are very similar to the observed Doppler velocities [$v_r(x, y)$]. Finally, we study the potential spatial correlation between microturbulent velocities and significant values of $\eta_{\mathrm{eddy}}(x, y)$. **10 September 2014**

Reconstruct Photospheric Velocity and Magnetic Diffusivity in Active Regions from Observed Magnetograms and Dopplergrams

Benoit **Tremblay**, Alain Vincent
Solar Phys. February **2015**, Volume 290, Issue 2, pp 437-466
We introduce MEF-R, a generalization of the minimum energy fit (MEF; Longcope, Astrophys. J.612, 1181, 2004) to a non-ideal (resistive) gas. The new technique requires both vector magnetograms and Doppler velocities as input fields.

However, in the case of active regions observed only with the Michelson–Doppler Imager (MDI) onboard the Solar and Heliospheric Observatory (SOHO) such as AR 9077, we have only access to line-of-sight magnetograms. We reconstruct two-dimensional maps of the magnetic diffusivity η(x,y) together with velocity components v x (x,y), v y (x,y), and v z (x,y) under the linear force-free magnetic field approximation. Computed maps for v z (x,y) very well match the Doppler velocities v r (x,y). We find the average value $\langle\eta\rangle \approx 108$ m2 s−1 with a standard deviation of ≈ 1010 m2 s−1. Such high values of η(x,y) are to be expected at some places since our magnetic diffusivity is actually eddy-diffusivity. Inside AR 9077, the maps of η(x,y) do not resemble closely the maps from classical models of the magnetic diffusivity, but they are closer to η as a function of temperature than to ηas a function of electric current density.

Transient Formation of Loops in the Core of an Active Region

Durgesh **Tripathi**1
2021 ApJ 909 105
https://doi.org/10.3847/1538-4357/abdd2e
We study the formation of transient loops in the core of the AR 11890. For this purpose, we have used the observations recorded by the Atmospheric Imaging Assembly (AIA) and the Interface Region Imaging Spectrograph (IRIS). For photospheric field configuration, we have used the line-of-sight (LOS) magnetograms obtained from the Helioseismic and Magnetic Imager. The transient is simultaneously observed in all the UV and EUV channels of AIA and the three slit-jaw images from IRIS. The coexistence of the transient in all AIA and IRIS SJI channels suggests the transient's multithermal nature. The transient consists of short loops located at the base of the transient, as well as long loops. A differential emission measure analysis shows that the transient has a clumpy structure. The highest emission observed at the base is within the temperature bin of $\log T = 6.65$–6.95. We observe the longer loops at a similar temperature, albeit very feeble. Using LOS magnetograms, we conclude that the magnetic reconnection may have caused the transient. Our observations further suggest that the physics of the formation of such transients may be similar to those of typical coronal jets, albeit in different topological configurations. Such multiwavelength observations shed light on the formation of hot plasma in the solar corona and provide further essential constraints on modeling the thermodynamics of such transients.

EMISSION MEASURE DISTRIBUTION AND HEATING OF TWO ACTIVE REGION CORES

Durgesh **Tripathi**1,2, James A. Klimchuk3 and Helen E. Mason
2011 ApJ 740 111
Using data from the Extreme-ultraviolet Imaging Spectrometer aboard Hinode, we have studied the coronal plasma in the core of two active regions. Concentrating on the area between opposite polarity moss, we found emission measure distributions having an approximate power-law form EMT 2.4 from log T = 5.5 up to a peak at log T = 6.55. We show that the observations compare very favorably with a simple model of nanoflare-heated loop strands. They also appear to be consistent with more sophisticated nanoflare models. However, in the absence of additional constraints, steady heating is also a viable explanation.

EVIDENCE OF IMPULSIVE HEATING IN ACTIVE REGION CORE LOOPS

Durgesh **Tripathi**1, Helen E. Mason1, and James A. Klimchuk2
Astrophysical Journal, 723:713–718, **2010**
Using a full spectral scan of an active region from the Extreme-Ultraviolet Imaging Spectrometer (EIS) we have obtained emission measure EM(T) distributions in two different moss regions within the same active region.We have compared these with theoretical transition region EMs derived for three limiting cases, namely, static equilibrium, strong condensation, and strong evaporation from Klimchuk et al. The EM distributions in both the moss regions are strikingly similar and show a monotonically increasing trend from log T [K] = 5.15–6.3. Using photospheric abundances, we obtain a consistent EM distribution for all ions. Comparing the observed and theoretical EM distributions, we find that the observed EM distribution is best explained by the strong condensation case (EM_{con}), suggesting that a downward enthalpy flux plays an important and possibly dominant role in powering the transition region moss emission. The downflows could be due to unresolved coronal plasma that is cooling and draining after having been impulsively heated. This supports the idea that the hot loops (with temperatures of 3–5 MK) seen in the core of active regions are heated by nanoflares.

Temperature Tomography of a Coronal Sigmoid Supporting the Gradual Formation of a Flux Rope

Durgesh **Tripathi**1, Bernhard Kliem, Helen E. Mason1, Peter R. Young3, 5, and Lucie M. Green

E-print, April **2009,** Astrophysical Journal, 698:L27–L32, **2009, File**
Multi-wavelength observations of a sigmoidal (S-shaped) solar coronal source by the EUV Imaging Spectrometer and the X-ray Telescope aboard the **Hinode spacecraft and by the EUV Imager aboard STEREO** are reported. The data reveal the coexistence of a pair of J-shaped hot arcs at temperatures T>2 MK with an S-shaped structure at somewhat lower temperatures T~1.3 MK. The middle section of the S-shaped structure runs along the polarity inversion line of the photospheric field, bridging the gap between the arcs. Flux cancellation occurs at the same location in the photosphere. The sigmoid forms in the gradual decay phase of the active region, which does not experience an eruption. These findings correspond to the expected signatures of a flux rope forming, or being augmented, gradually by a topology transformation inside a magnetic arcade. In such a transformation, the plasma on newly formed helical field lines in the outer flux shell of the rope (S-shaped in projection) is expected to enter a cooling phase once the reconnection of their parent field line pairs (double-J shaped in projection) is complete. Thus, the data support the conjecture that flux ropes can exist in the corona prior to eruptive activity.

A bright coronal downflow seen in multi-wavelength observations: evidence of a bifurcating flux-rope?

D. **Tripathi**, S.K. Solanki, H.E. Mason, D.F. Webb
E-print, July **2007**
To study the origin and characteristics of a bright coronal downflow seen after a coronal mass ejection associated with erupting prominences on 5~March 2000.
The origin of the downflow was likely to have been magnetic reconnection taking place inside the erupting flux rope that led to its bifurcation.

EIT and TRACE responses to flare plasma –

Soar Phys. **2015**
http://arxiv.org/pdf/1509.06336v1.pdf
Solar observations in the infrared domain can bring important clues on the response of the low solar atmosphere to primary energy released during flares. At present the infrared continuum has been detected at 30 THz (10 μm) in only a few flares. In this work we present a detailed multi-frequency analysis of SOL2012-03-13, including observations at radio millimeter and sub-millimeter wavelengths, in hard X-rays (HXR), gamma-rays (GR), H-alpha, and white-light. HXR/GR spectral analysis shows that the event is a GR line flare and allows estimating the numbers of and energy contents in electrons, protons and alpha particles produced during the flare. The energy spectrum of the electrons producing the HXR/GR continuum is consistent with a broken power-law with an energy break at ~800 keV. It is shown that the high-energy part (above ~800 keV) of this distribution is responsible for the high-frequency radio emission (> 20 GHz) detected during the flare. By comparing the 30 THz emission expected from semi-empirical and time-independent models of the quiet and flare atmospheres, we find that most (~80%) of the observed 30 THz radiation can be attributed to thermal free-free emission of an optically-thin source. Using the F2 flare atmospheric model this thin source is found to be at temperatures T~8000 K and is located well above the minimum temperature region. We argue that the chromospheric heating, which results in 80% of the 30 THz excess radiation, can be due to energy deposition by non-thermal flare accelerated electrons, protons and alpha particles. The remaining 20% of the 30 THz excess emission is found to be radiated from an optically-thick atmospheric layer at T~5000 K, below the temperature minimum region, where direct heating by non-thermal particles is insufficient to account for the observed infrared radiation.

Dreicer electric field definition and runaway electrons in solar flares

Yu.T. **Tsap**, A.V. Stepanov, Yu.G. Kopylova
Research in Astron. Astrophys. **2024**
https://arxiv.org/pdf/2401.04591.pdf
We analyse electron acceleration by a large-scale electric field E in a collisional hydrogen plasma under the solar flare coronal conditions based on approaches proposed by Dreicer and Spitzer for the dynamic friction force of electrons. The Dreicer electric field EDr is determined as a critical electric field at which the entire electron population runs away. Two regimes of strong (E≲EDr) and weak (E≪EDr) electric field are discussed. It is shown that the commonly used formal definition of the Dreicer field leads to an overestimation of its value by about five times. The critical velocity at which the electrons of the ``tail" of the Maxwell distribution become runaway under the action of the sub-Dreiser electric fields turns out to be underestimated by 3–√ times in some works because the Coulomb collisions between

runaway and thermal electrons are not taken into account. The electron acceleration by sub-Dreicer electric fields generated in the solar corona faces difficulties.

Electron acceleration and hard X-ray emission from SOL2013-11-09

On the origin of 140 GHz emission from the 4 July 2012 solar flare

Yuriy T. **Tsap**, Victoria V. Smirnova, Alexander S. Morgachev, Galina G. Motorina, Eduard P. Kontar, Valery G. Nagnibeda, Polina V. Strekalova
Advances in Space Research, V. 57, I. 7, p. 1449-1455 **2016**; DOI: 10.1016/j.asr.2015.12.037
http://arxiv.org/pdf/1604.01530v1.pdf
The sub-THz event observed on the **4 July 2012** with the Bauman Moscow State Technical University Radio Telescope RT-7.5 at 93 and 140~GHz as well as Kislovodsk and Metsahovi radio telescopes, Radio Solar Telescope Network (RSTN), GOES, RHESSI, and SDO orbital stations is analyzed. The spectral flux between 93 and 140 GHz has been observed increasing with frequency. On the basis of the SDO/AIA data the differential emission measure has been calculated. It is shown that the thermal coronal plasma with the temperature above 0.5~MK cannot be responsible for the observed sub-THz flare emission. The non-thermal gyrosynchrotron mechanism can be responsible for the microwave emission near 10~GHz but the observed millimeter spectral characteristics are likely to be produced by the thermal bremsstrahlung emission from plasma with a temperature of about 0.1~MK.

Chromospheric evaporation and pitch angle diffusion of trapped electrons in solar flare coronal loops

Yuriy T. **Tsap**, Yulia G. Kopylov, , Alexander V. Stepanov
Advances in Space Research, Volume 55, Issue 3, 1 February **2015**, Pages 791–794
http://www.sciencedirect.com/science/article/pii/S0273117714002841
The peculiarities of time delays between the peaks of hard X-ray and microwave emissions within the framework of the trap-plus-precipitation model are studied. Using the continuity equation it has been shown that time delays strongly depend on the chromospheric evaporation in the case of the Coulomb pitch angle diffusion of trapped electrons into the loss–cone. Based on the obtained results the origin of time delays as well as the role of Coulomb collisions in flare coronal loops are discussed.

Reconnection fluxes in eruptive and confined flares and implications for superflares on the Sun

Johannes **Tschernitz**, Astrid M. Veronig, Julia K. Thalmann, Jürgen Hinterreiter, Werner Pötzi
2018 *ApJ* **853** 41
https://arxiv.org/pdf/1712.04701.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/aaa199/pdf
We use Hα filtergrams from Kanzelh¨ohe Observatory together with SDO HMI and SOHO MDI magnetograms to derive magnetic reconnection fluxes and rates. The flare reconnection flux is strongly correlated with the peak of the GOES 1-8 ˚A soft X-ray flux (c=0.92, in log-log space), both for confined and eruptive flares. Confined flares of a certain GOES class exhibit smaller ribbon areas but larger magnetic flux densities in the flare ribbons (by a factor of 2). In the largest events, up to ≈50% of the magnetic flux of the active region (AR) causing the flare is involved in the flare magnetic reconnection. These findings allow us to extrapolate toward the largest solar flares possible. A complex solar AR hosting a magnetic flux of 2·1023 Mx, which is in line with the largest AR fluxes directly measured, is capable of producing an X80 flare, which corresponds to a bolometric energy of about 7 · 1032 ergs. Using a magnetic flux estimate of 6 · 1023 Mx for the largest solar AR observed, we find that flares of GOES class ≈X500 could be produced (Ebol ≈ 3 · 1033 ergs). These estimates suggest that the present day's Sun is capable of producing flares and related

space weather events that may be more than an order of magnitude stronger than have been observed to date. **2011 November 9, 2014 May 10**

Extreme Value Analysis of Solar Flare Events

T. **Tsiftsi** V. De la Luz
Space Weather 16?, 12, 1984-1996 **2018**
http://sci-hub.tw/10.1029/2018SW001958
Space weather events such as solar flares can be harmful for life and infrastructure on Earth or in near-Earth orbit. In this paper we employ extreme value theory to model extreme solar flare events; extreme value theory offers the appropriate tools for the study and estimation of probabilities for extrapolation to ranges outside of those that have already been observed. In this work the data points used are inherently independent and realistic confidence intervals are offered with respect to the estimates of future solar flare events. The data used in this study are peak X-ray fluxes provided by National Oceanic and Atmospheric Administration that form a series of distinct flare events. The expected return levels for Carrington- or Halloween storm-like events were calculated with the outcome that the existing data predict similar events happening in 110 and 38 years, respectively, which are consistent with the results and inferences provided by Elvidge and Angling (2018, https://doi.org/10.1002/2017SW001727). We also make a preliminary analysis of the implications of solar seasonality and found its effect on extreme flare events to be statistically insignificant.

Particle acceleration by sub-proton cyclotron frequency spectrum of dispersive Alfven waves in inhomogeneous solar coronal plasmas

D. **Tsiklauri**
MNRAS **2024**
https://arxiv.org/pdf/2312.14616.pdf
The problem of explaining observed soft X-ray fluxes during solar flares, which invokes acceleration of large fraction of electrons, if the acceleration takes places at the solar coronal loop-top, can potentially be solved by postulating that flare at loop-top creates dispersive Alfven waves (DAWs) which propagate towards the foot-points. As DAWs move in progressively denser parts of the loop (due to gravitational stratification) the large fraction of electrons is no longer needed. Here we extend our previous results by considering f−1 frequency spectrum of DAWs and add He++ ions using fully kinetic particle-in-cell (PIC) simulations. We consider cases when transverse density gradient is in the range 4−40c/ωpe and DAW driving frequency is 0.3−0.6ωcp. We find that (i) The frequency spectrum case does not affect electron acceleration fraction in the like-to-like cases, but few times larger percentage of He++ heating is seen due to ion cyclotron resonance; (ii) In cases when counter propagating DAWs collide multiple-times, much larger electron and ion acceleration fractions are found, but the process is intermittent in time. This is because intensive heating (temperature increase) makes the-above-thermal-fraction smaller; Also more isotropic velocity distributions are seen; (iii) Development of kink oscillations occurs when DAWs collide; (iv) Scaling of the magnetic fluctuations power spectrum steepening in the higher-density regions is seen, due to wave refraction. Our PIC runs produce much steeper slopes than the orginal spectrum, indicating that the electron-scale physics has a notable effect of DAW spectrum evolution.

Three dimensional particle-in-cell simulation of particle acceleration by circularly polarised inertial Alfven waves in a transversely inhomogeneous plasma

D. **Tsiklauri**
E-print, Aug **2012**; Physics of Plasmas, in-press, September 2012 issue
The process of particle acceleration by left-hand, circularly polarised inertial Alfvén waves (IAW) in a transversely inhomogeneous plasma is studied using 3D particle-in-cell simulation. A cylindrical tube with, transverse to the background magnetic field, inhomogeneity scale of the order of ion inertial length is considered on which IAWs with frequency 0.3 omegaci are launched that are allowed to develop three wavelength. As a result time-varying parallel electric fields are generated in the density gradient regions which accelerate electrons in the parallel to magnetic field direction. Driven perpendicular electric field of IAWs also heats ions in the transverse direction. Such numerical setup is relevant for solar flaring loops and earth auroral zone. This first, 3D, fully-kinetic simulation demonstrates electron acceleration efficiency in the density inhomogeneity regions, along the magnetic field, of the order of 45% and ion heating, in the transverse to the magnetic field direction, of 75%. The latter is a factor of two times higher than the previous 2.5D analogous study and is in accordance with solar flare particle acceleration observations. We find that the generated parallel electric field is localised in the density inhomogeneity region and rotates in the same direction and with the same angular frequency as the initially launched IAW. Our numerical simulations seem also to suggest that the "knee" often found in the solar flare electron spectra can alternatively be interpreted as the Landau damping (Cerenkov resonance effect) of IAWs due to the wave-particle interactions.

Two-dimensional time evolution of beam-plasma instability in the presence of binary collisions

S. F. **Tigik**1, L. F. Ziebell1, P. H. Yoon2,3 and E. P. Kontar
A&A 586, A19 (**2016**) **Open Access**
http://www.aanda.org/articles/aa/pdf/2016/02/aa27271-15.pdf
Energetic electrons produced during solar flares are known to be responsible for generating solar type III radio bursts. The radio emission is a byproduct of Langmuir wave generation via beam-plasma interaction and nonlinear wave-wave and wave-particle interaction processes. In addition to type III radio bursts, electrons traveling downwards toward the chromosphere lead to the hard X-ray emission via electron-ion collisions. Recently, the role of Langmuir waves on the X-ray-producing electrons has been identified as important, because Langmuir waves may alter the electron distribution, thereby affecting the X-ray profile. Both Coulomb collisions and wave-particle interactions lead electrons to scattering and energy exchange that necessitates considering the two-dimensional (2D) problem in velocity space. The present paper investigates the influence of binary collisions on the beam-plasma instability development in 2D in order to elucidate the nonlinear dynamics of Langmuir waves and binary collisions. The significance of the present findings in the context of solar physics is discussed.

Millimeter and X-Ray Emission from the 5 July 2012 Solar Flare

Y. T. **Tsap**, V. V. Smirnova, G. G. Motorina, A. S. Morgachev, S. A. Kuznetsov, V. G. Nagnibeda, V. S. Ryzhov
Solar Physics March **2018**, 293:50
http://sci-hub.tw/http://link.springer.com/10.1007/s11207-018-1269-6
The **5 July 2012** solar flare SOL2012-07-05T11:44 (11:39 – 11:49 UT) with an increasing millimeter spectrum between 93 and 140 GHz is considered. We use space and ground-based observations in X-ray, extreme ultraviolet, microwave, and millimeter wave ranges obtained with the Reuven Ramaty High-Energy Solar Spectroscopic Imager, Solar Dynamics Observatory(SDO), Geostationary Operational Environmental Satellite, Radio Solar Telescope Network, and Bauman Moscow State Technical University millimeter radio telescope RT-7.5. The main parameters of thermal and accelerated electrons were determined through X-ray spectral fitting assuming the homogeneous thermal source and thick-target model. From the data of the Atmospheric Imaging Assembly/SDO and differential-emission-measure calculations it is shown that the thermal coronal plasma gives a negligible contribution to the millimeter flare emission. Model calculations suggest that the observed increase of millimeter spectral flux with frequency is determined by gyrosynchrotron emission of high-energy (≳300≳300 keV) electrons in the chromosphere. The consequences of the results are discussed in the light of the flare-energy-release mechanisms.

On the origin of 140 GHz emission from the 4 July 2012 solar flare

2016
http://arxiv.org/pdf/1604.01530v1.pdf
The sub-THz event observed on the **4 July 2012** with the Bauman Moscow State Technical University Radio Telescope RT-7.5 at 93 and 140~GHz as well as Kislovodsk and Mets\"ahovi radio telescopes, Radio Solar Telescope Network (RSTN), GOES, RHESSI, and SDO orbital stations is analyzed. The spectral flux between 93 and 140 GHz has been observed increasing with frequency. On the basis of the SDO/AIA data the differential emission measure has been calculated. It is shown that the thermal coronal plasma with the temperature above 0.5~MK cannot be responsible for the observed sub-THz flare emission. The non-thermal gyrosynchrotron mechanism can be responsible for the microwave emission near 10~GHz but the observed millimeter spectral characteristics are likely to be produced by the thermal bremsstrahlung emission from plasma with a temperature of about 0.1~MK.

Extreme Value Analysis of Solar Flare Events

Thomai **Tsiftsi**, Victor De la Luz
Space Weather **2018**
https://arxiv.org/pdf/1802.06100.pdf
Space weather events such as solar flares can be harmful for life and infrastructure on earth or in near-earth orbit. In this paper we employ extreme value theory (EVT) to model extreme solar flare events; EVT offers the appropriate tools for the study and estimation of probabilities for extrapolation to ranges outside of those that have already been observed. In the past such phenomena have been modelled as following a power law which may gives poor estimates of such events due to overestimation. The data used in the study were X-ray fluxes from NOAA/GOES and the expected return levels for Carrington or Halloween like events were calculated with the outcome that the existing data predict similar events happening in 110 and 38 years respectively.

Electron plasma wake field acceleration in solar coronal and chromospheric plasmas

David **Tsiklauri** (Queen Mary University of London)
Phys. Plasmas **2017**
https://arxiv.org/pdf/1706.05265.pdf
Three dimensional, particle-in-cell, fully electromagnetic simulations of electron plasma wake field acceleration applicable to solar atmosphere are presented. It is established that injecting driving and trailing electron bunches into solar coronal and chromospheric plasmas, results in electric fields (−(20−5)×106 V/m), leading to acceleration of the trailing bunch up to 52 MeV, starting from initial 36 MeV. The results provide one of potentially important mechanisms for the extreme energetic solar flare electrons, invoking plasma wake field acceleration.

Online Catalog of Activity Events of Solar Cycle 24 Related to Active Regions.

Tsvetkov, T., Nakeva, Y. & Petrov, N.
Sol Phys 299, 125 (**2024**).
https://doi.org/10.1007/s11207-024-02351-6
We present a statistical study on the relationship of solar dynamic events (solar flares and coronal mass ejections) with active regions during Solar Cycle 24 (December 2008–December 2019). Combining data from NOAA Space Weather Prediction Center and observations of Large Angle and Spectrometric Coronagraph (LASCO) onboard the Solar and Heliospheric Observatory (SOHO) spacecraft, we found that more than a half of the coronal mass ejections were generated inside active regions. Geostationary Operational Environmental Satellite (GOES) soft X-ray flare listing data completed our study showing that almost 83% of Solar Cycle 24 flares are connected with active regions. Finally, we summarize the details for the related phenomena into an online catalog based on a list of all 1533 active regions that produced at least one flare and/or coronal mass ejection during Solar Cycle 24 and explore their properties like flare class, coronal mass ejection speed, and angular width paying special attention to the most powerful and threatful to Earth solar events.

Superflares, chromospheric activities and photometric variabilities of solar-type stars from the second-year observation of TESS and spectra of LAMOST

Zuo-Lin **Tu**, Ming Yang, H.-F. Wang, F. Y. Wang
ApJS **253** 35 **2021**
https://arxiv.org/pdf/2101.02901.pdf
https://iopscience.iop.org/article/10.3847/1538-4365/abda3c/pdf
https://doi.org/10.3847/1538-4365/abda3c
In this work, 1272 superflares on 311 stars are collected from 22,539 solar-type stars from the second-year observation of Transiting Exoplanet Survey Satellite ({\em TESS}), which almost covered northern hemisphere of the sky. Three superflare stars contain hot Jupiter candidates or ultra short-period planet candidates. We obtain $\gamma=-1.76\pm0.11$ of the correlation between flare frequency and flare energy ($dN/dE \propto E^{-\gamma}$) for all superflares, and get $\beta=0.42\pm0.01$ of the correlation between superflare duration and energy ($T_{duration} \propto E^{\beta}$), which supports that similar mechanism is shared by stellar superflares and solar flares. Stellar photometric variability (Rvar) is estimated for all solar-type stars, and the relation of $E \propto Rvar^{3/2}$ is included. Indicator of chromospheric activity (S-index) is obtained by using data from the Large Sky Area Multi-Object Fiber Spectroscopic Telescope (LAMOST) for 7454 solar-type stars. Distributions of these two properties indicate that the Sun is generally less active than superflare stars. We find that saturation-like feature of $Rvar \sim 0.1$ may be the reason for superflare energy saturating around 1036 erg. TIC93277807 was captured by {\em TESS} first-year mission and generated the most energetic superflare. This superflare is valuable and unique to be treated as an extreme event, which may be generated by different mechanisms rather than that of other superflares.

THE MAGNETIC ENERGY-HELICITY DIAGRAM OF SOLAR ACTIVE REGIONS

Kostas **Tziotziou**1, Manolis K. Georgoulis1,3, and Nour-Eddine Raouafi
2012 ApJ 759 L4
Using a recently proposed nonlinear force-free method designed for single-vector magnetograms of solar active regions, we calculate the instantaneous free magnetic energy and relative magnetic helicity budgets in 162 vector magnetograms corresponding to 42 different active regions. We find a statistically robust, monotonic correlation between the free magnetic energy and the relative magnetic helicity in the studied regions. This correlation implies that magnetic helicity, in addition to free magnetic energy, may be an essential ingredient for major solar eruptions. Eruptive active regions appear well segregated from non-eruptive ones in both free energy and relative helicity with major (at least M-class) flares occurring in active regions with free energy and relative helicity exceeding 4 × 1031 erg and 2 × 1042 Mx2, respectively. The helicity threshold agrees well with estimates of the helicity contents of typical coronal mass ejections.

OBSERVATIONS OF MULTIPLE SURGES ASSOCIATED WITH MAGNETIC ACTIVITIES IN AR 10484 ON 2003 OCTOBER 25

Wahab **Uddin**1, B. Schmieder2, R. Chandra3, Abhishek K. Srivastava1, Pankaj Kumar4, and S. Bisht

2012 ApJ 752 70

We present a multi-wavelength study of recurrent surges observed in Hα, UV (Solar and Heliospheric Observatory (SOHO)/EIT), and Radio (Learmonth, Australia) from the super-active region NOAA 10484 on 2003 October 25. Several bright structures visible in Hα and UV corresponding to subflares are also observed at the base of each surge. Type III bursts are triggered and RHESSI X-ray sources are evident with surge activity. The major surge consists of bunches of ejective paths forming a fan-shaped region with an angular size of (65°) during its maximum phase. The ejection speed reaches up to ~200 km s–1. The SOHO/Michelson Doppler Imager magnetograms reveal that a large dipole emerges from the east side of the active region on 2003 October 18-20, a few days before the surges. **On 2003 October 25,** the major sunspots were surrounded by "moat regions" with moving magnetic features (MMFs). Parasitic fragmented positive polarities were pushed by the ambient dispersion motion of the MMFs and annihilated with negative polarities at the borders of the moat region of the following spot to produce flares and surges. A topology analysis of the global Sun using Potential Field Source Surface shows that the fan structures visible in the EIT 171 Å images follow magnetic field lines connecting the present active region to a preceding active region in the southeast. Radio observations of Type III bursts indicate that they are coincident with the surges, suggesting that magnetic reconnection is the driver mechanism. The magnetic energy released by the reconnection is transformed into plasma heating and provides the kinetic energy for the ejections. A lack of a radio signature in the high corona suggests that the surges are confined to follow the closed field lines in the fans. We conclude that these cool surges may have some local heating effects in the closed loops, but probably play a minor role in global coronal heating and the surge material does not escape to the solar wind.

Extremely Energetic 4B/X17.2 Flare and Associated Phenomena

Wahab **Uddin**∗, Ramesh Chandra & Syed Salman Ali

J. Astrophys. Astr. (**2006**) **27,** 267–276

http://www.ias.ac.in/jaa/junsep2006/JAA22.pdf

We observed 4B/X17.2 flare in H*α* from super-active region NOAA 10486 at ARIES, Nainital. This is one of the largest flares of current solar cycle 23, which occurred near the Sun's center and produced extremely energetic emission almost at allwavelengths from γ -ray to radiowaves. The flare is associated with a bright/fast full-halo earth directed CME, strong type II, type III and type IV radio bursts, an intense proton event and GLE. This flare is well observed bySOHO,RHESSI andTRACE. Our H*α* observations show the stretching/de-twisting and eruption of helically twisted S shaped (sigmoid) filament in the south–west direction of the active region with bright shock front followed by rapid increase in intensity and area of the gigantic flare. The flare shows almost similar evolution in H*α*, EUV and UV. We measure the speed of H*α* ribbon separation and the mean value is ∼ 70 km s−1. This is used together with photospheric magnetic field to infer a magnetic reconnection rate at three HXR sources at the flare maximum. In this paper, we also discuss the energetics of active region filament, flare and associated CME.

Orientation of X-Ray Bright Points in the Quiet Sun

K. **Ueda**, R. Kano, S. Tsuneta & H. Shibahashi

Solar Phys., 261, No. 1, Page: 77 – 85, **2010**

Thanks to the high-resolution images from the X-ray telescope (XRT) aboard the *Hinode* satellite, X-ray bright points (XBPs) in the quiet region of the Sun are resolved and can be seen to have complex loop-like structures. We measure the orientation of such loop structures for 488 XBPs picked up in 26 snapshot X-ray images near the disk center. The distribution of the orientation is slightly but clearly biased to the east−west direction: the random distribution is rejected with a significance level of 1% by the χ^2-test. The distribution is similar to the orientation distribution for the bipolar magnetic fields. The XBP orientation is, however, much more random than that of the bipolar magnetic fields with similar size. 24% of the XBPs are due to emerging bipoles, while the remaining 76% are due to chance encounters of opposite polarities.

DETERMINING HEATING TIME SCALES IN SOLAR ACTIVE REGION CORES FROM AIA/*SDO* FE XVIII IMAGES

IGNACIO **UGARTE-URRA**1 AND HARRY P. WARREN2

E-print, Jan **2014**; **2014** ApJ 783 12

We present a study of the frequency of transient brightenings in the core of solar active regions as observed in the Fe XVIII line component of AIA/*SDO* 94 °A filter images. The Fe XVIII emission is isolated using an

empirical correction to remove the contribution of “warm” emission to this channel. Comparing with simultaneous observations from EIS/*Hinode*, we find that the variability observed in Fe XVIII is strongly correlated with the emission from lines formed at similar temperatures. We examine the evolution of loops in the cores of active regions at various stages of evolution. Using a newly developed event detection algorithm we characterize the distribution of event frequency, duration, and magnitude in these active regions. These distributions are similar for regions of similar age and show a consistent pattern as the regions age. This suggests that these characteristics are important constraints for models of solar active regions. We find that the typical frequency of the intensity fluctuations is about 1400 s for any given line-of-sight, i.e. about 2–3 events per hour. Using the EBTEL 0D hydrodynamic model, however, we show that this only sets a lower limit on the heating frequency along that line-of-sight. **2011/08/04, 2011/11/08, 2011/12/05, 2012/04/22, 2012/05/18**

TEMPORAL VARIABILITY OF ACTIVE REGION OUTFLOWS

Ignacio **Ugarte-Urra**1 and Harry P. Warren2
2011 ApJ 730 37
Recent observations from the Extreme-ultraviolet Imaging Spectrometer (EIS) on board Hinode have shown that low-density areas on the periphery of active regions are characterized by strong blueshifts in the emission of spectral lines formed at 1 MK. These Doppler shifts have been associated with outward propagating disturbances observed with extreme-ultraviolet and soft X-ray imagers. Since these instruments can have broad temperature responses, we investigate these intensity fluctuations using the monochromatic imaging capabilities of the EIS wide slit (slot) and confirm their 1 MK nature. We also look into their spectral temporal variability using narrow slit observations and present the first Doppler movies of the outflow regions. We find that the Fe XII 195.119 Å blueshifted spectral profiles at their footpoints exhibit transient blue wing enhancements on timescales as short as the 5 minute cadence. We have also looked at the fan peripheral loops observed at 0.6 MK in Si VII 275.368 Å in those regions and find no sign of the recurrent outward propagating disturbances with velocities of 40-130 km s–1 seen in Fe XII. We do observe downward trends (15-20 km s–1) consistent with the characteristic redshifts measured at their footpoints. We, therefore, find no evidence that the structures at these two temperatures and the intensity fluctuations they exhibit are related to one another.

Active Region Transition Region Loop Populations and Their Relationship to the Corona

Ignacio **Ugarte-Urra**, Harry P. Warren, and David H. Brooks
ApJ 695, 642-651, **2009**
http://www.iop.org/EJ/toc/-alert=43190/0004-637X/695/1
The relationships among coronal loop structures at different temperatures are not settled. Previous studies have suggested that coronal loops in the core of an active region (AR) are not seen cooling through lower temperatures and therefore are steadily heated. If loops were cooling, the transition regionwould be an ideal temperature regime to look for a signature of their evolution. The Extreme-ultraviolet Imaging Spectrometer on ***Hinode*** provides monochromatic images of the solar transition region and corona at an unprecedented cadence and spatial resolution, making it an ideal instrument to shed light on this issue. Analysis of observations of AR 10978 taken in 2007 December 8–19 indicates that there are two dominant loop populations in the AR: (1) core multitemperature loops that undergo a continuous process of heating and cooling in the full observed temperature range 0.4–2.5MK and even higher as shown by the X-Ray Telescope and (2) peripheral loops which evolve mostly in the temperature range 0.4–1.3MK. Loops at transition region temperatures can reach heights of 150 Mm in the corona above the limb and develop downflows with velocities in the range of 39–105 km s^{-1}.

Solar extreme ultraviolet variability as a proxy for nanoflare heating diagnostics

Artem **Ulyanov**, Anton Reva, Alexey Kirichenko, Ivan Loboda and Sergey Bogachev
A&A 683, A88 (**2024**)
https://www.aanda.org/articles/aa/pdf/2024/03/aa48425-23.pdf
Aims. We aim to improve the existing techniques to probe the nanoflare hypothesis for the coronal heating problem. For this purpose, we propose using the solar extreme ultraviolet (EUV) emission variability registered with modern space-based imagers.
Methods. We followed a novel model-based approach. As a starting point, we used the EBTEL 0d hydrodynamic model. We integrated the arising system of stochastic differential equations to calculate the covariance matrix for plasma parameters. We then employed a Taylor expansion technique to relate model parameters with observable EUV intensity variation statistics.
Results. We found that in the high-frequency approximation, the variability of the EUV emission is defined by the dimensionless factor ϖ, which is inversely proportional to the frequency. We calculated the factor ϖ throughout the solar disk and found that it does not exceed 0.01, except for the finite number of compact regions. The distribution of ϖ follows the power law with an index of ≈ -2.6. To validate our approach, we used it to probe the temperature of

the coronal plasma. We show that the line-of-sight temperature distribution is close to homogeneous with a mode of ≈1.25 MK, which is in perfect agreement with the results of the spectroscopic diagnostics.

Direct Evidence for Magnetic Reconnection in a Solar EUV Nanoflare

Artem S. **Ulyanov**, Sergey A. Bogachev, Ivan P. Loboda, Anton A. Reva, Alexey S. Kirichenko
Solar Physics September **2019**, 294:128
https://link.springer.com/content/pdf/10.1007%2Fs11207-019-1472-0.pdf
sci-hub.se/10.1007/s11207-019-1472-0
We provide observational evidence that the mechanism of solar EUV nanoflares may be close to the standard flare model. The object of our study was a nanoflare on **25 February 2011**, for which we determined a plasma temperature of 3.1 MK, a total thermal energy of 6.2×1025 erg, and an electric-current distribution that reaches its maximum at a height of ≈1.5 Mm. Despite the lack of spatial resolution, we reconstructed the 3D magnetic configuration for this event in the potential and non-linear force-free-field interpolations. As a result, we identified four null-points, two of which were coincident with the region of maximal energy release. The nanoflare was initiated by a new small-scale magnetic flux, which appeared on the photosphere about 15 – 20 minutes before the nanoflare. The total free energy stored in the region before the nanoflare was ≈8.9×1025 erg. Only about two-thirds of this amount was transferred into the plasma heating and EUV radiation. We posit that the remaining energy could be transferred during particle acceleration and plasma motions, which are still inaccessible for direct observations in nanoflares.

Examining Flux Tube Interactions as a Cause of Sub-alfvénic Outflow

John **Unverferth**1 and Dana Longcope2
2021 ApJ 923 248
https://iopscience.iop.org/article/10.3847/1538-4357/ac312e/pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ac312e/pdf
https://doi.org/10.3847/1538-4357/ac312e
In accepted models, magnetic tension drives reconnected magnetic flux away from the reconnection site at the local Alfvén speed. Numerous observational signatures of these outflows have been identified in solar flares, notable among them being supra-arcade downflows (SADs), almost none move at the Alfvén speed as predicted by models. Well-studied examples of SADs or SAD loops found in the flare of **2017 September 10** (SOL2017-09-10T15:35:00) move at a quarter or less of the expected Alfvén speed. Among those reasons posited to explain such discrepancies is the possibility that reconnected flux experiences a drag force during its outflow. Drag has not been included in previous reconnection models. Here, we develop the first such model in order to test the possibility that drag can explain sub-alfveńic reconnection outflows. Our model uses thin flux tube dynamics, previously shown to match features of flare observations other than outflow speed, including for the 2017 September 10 flare. We supplement the dynamics with a drag force representing the tube's interaction with surrounding plasma through the formation of a wake. The wake's width appears as a parameter in the force. We perform simulations, varying the drag parameter and synthesizing EUV observations, to test whether a drag force can produce a reasonable fit to observed features of the September 10 flare. We find that that slower retraction increases the brightness of emission and lowers the temperature of the synthetic plasma sheet. With proper choice of parameters the drag enables the simulation to agree reasonably with the observations.

Modeling Observable Differences in Flare Loop Evolution due to Reconnection Location and Current Sheet Structure

John **Unverferth** and Dana Longcope
2020 ApJ 894 148
https://doi.org/10.3847/1538-4357/ab88cf
Flare reconnection is expected to occur at some point within a large-scale coronal current sheet. The structure of the magnetic field outside this sheet is almost certain to affect the flare, especially its energy release. Different models for reconnection have invoked different structures for the current sheet's magnetic field and different locations for the reconnection electric field within it. Models invoking Petschek-type reconnection often use a uniform field. Others invoke a field bounded by two Y-points with a field strength maximum between them and propose this maximum as the site of the reconnection electric field. Still other models, such as the collapsing trap model, require that the field strength peak at or near the edge of the current sheet and propose that reconnection occurs above this peak. At present there is no agreement as to where reconnection might occur within a global current sheet. We study the post-reconnection dynamics under all these scenarios, seeking potentially observable differences between them. We find that reconnection occurring above the point of strongest field leads to the highest density and the highest emission measure of the hottest material. This scenario offers a possible explanation of superhot coronal sources seen in some flares.

Effects of the Canopy and Flux Tube Anchoring on Evaporation Flow of a Solar Flare

John **Unverferth** and Dana Longcope
2018 ApJ 859 170

Spectroscopic observations of flare ribbons typically show chromospheric evaporation flows, which are subsonic for their high temperatures. This contrasts with many numerical simulations where evaporation is typically supersonic. These simulations typically assume flow along a flux tube with a uniform cross-sectional area. A simple model of the magnetic canopy, however, includes many regions of low magnetic field strength, where flux tubes achieve local maxima in their cross-sectional area. These are analgous to a chamber in a flow tube. We find that one-third of all field lines in a model have some form of chamber through which evaporation flow must pass. Using a one-dimensional isothermal hydrodynamic code, we simulated supersonic flow through an assortment of chambers and found that a subset of solutions exhibit a stationary standing shock within the chamber. These shocked solutions have slower and denser upflows than a flow through a uniform tube would. We use our solution to construct synthetic spectral lines and find that the shocked solutions show higher emission and lower Doppler shifts. When these synthetic lines are combined into an ensemble representing a single canopy cell, the composite line appears slower, even subsonic, than expected due to the outsized contribution from shocked solutions.

Nanoflare Heating of the Solar Corona Observed in X-rays

Vishal **Upendran**, Durgesh Tripathi, N.P.S. Mithun, Santosh Vadawale, Anil Bhardwaj
ApJ Letters **2022**
https://arxiv.org/pdf/2211.02324.pdf
The existence of the million-degree corona above the cooler photosphere is an unsolved problem in astrophysics. Detailed study of quiescent corona that exists regardless of the phase of the solar cycle may provide fruitful hints towards resolving this conundrum. However, the properties of heating mechanisms can be obtained only statistically in these regions due to their unresolved nature. Here, we develop a two-step inversion scheme based on the machine learning scheme of Upendran & Tripathi (2021a) for the empirical impulsive heating model of Pauluhn & Solanki (2007), and apply it to disk integrated flux measurements of the quiet corona as measured by the X-ray solar monitor (XSM) onboard Chandrayaan - 2. We use data in three energy passbands, viz., 1 - 1.3 keV, 1.3 - 2.3 keV, and 1 - 2.3 keV, and estimate the typical impulsive event frequencies, timescales, amplitudes, and the distribution of amplitudes. We find that the impulsive events occur at a frequency of ≈25 events per minute with a typical lifetime of ≈10 minutes. They are characterized by a power law distribution with a slope $\alpha \leq 2.0$. The typical amplitudes of these events lie in an energy range of 1021 - 1024 ergs, with a typical radiative loss of about ≈103 erg cm−2 s−1 in the energy range of 1 - 2.3 keV. These results provide further constraints on the properties of sub-pixel impulsive events in maintaining the quiet solar corona.

The First AGILE Solar Flare Catalog

Alessandro **Ursi**, Nicolò Parmiggiani, Mauro Messerotti, Alberto Pellizzoni, Carlotta Pittori, Francesco Longo, Francesco Verrecchia, Andrea Argan, Andrea Bulgarelli, Marco Tavani, Patrizio Tempesta, Fabio D'Amico
ApJS **267** 9 **2023**
https://arxiv.org/pdf/2305.14957.pdf
https://iopscience.iop.org/article/10.3847/1538-4365/acd4b6/pdf
We report the Astrorivelatore Gamma ad Immagini LEggero (AGILE) observations of solar flares, detected by the on board anticoincidence system in the 80-200 keV energy range, from 2007 May 1st to 2022 August 31st. In more than 15 yr, AGILE detected 5003 X-ray, minute-lasting transients, compatible with a solar origin. A cross-correlation of these transients with the Geostationary Operational Environmental Satellites (GOES) official solar flare database allowed to associate an intensity class (i.e., B, C, M, or X) to 3572 of them, for which we investigated the main temporal and intensity parameters. The AGILE data clearly revealed the solar activity covering the last stages of the 23rd cycle, the whole 24th cycle, and the beginning of the current 25th cycle. In order to compare our results with other space missions operating in the high-energy range, we also analyzed the public lists of solar flares reported by RHESSI and Fermi Gamma-ray Burst Monitor. This catalog reports 1424 events not contained in the GOES official dataset, which, after statistical comparisons, are compatible with low-intensity, short-duration solar flares.
Besides providing a further dataset of solar flares detected in the hard X-ray range, this study allowed to point out two main features: a longer persistence of the decay phase in the high-energy regime, with respect to the soft X-rays, and a tendency of the flare maximum to be reached earlier in the soft X-rays with respect to the hard X-rays. ***Both these aspects support a two-phase acceleration mechanism of electrons in the solar atmosphere.*** **2013 April 24**

Extreme Solar Events: Setting up a Paradigm **Review**

Usoskin, I., Miyake, F., Baroni, M. et al.
Space Sci Rev 219, 73 (**2023**).
https://doi.org/10.1007/s11214-023-01018-1
https://link.springer.com/content/pdf/10.1007/s11214-023-01018-1.pdf **File**
The Sun is magnetically active and often produces eruptive events on different energetic and temporal scales. Until recently, the upper limit of such events was unknown and believed to be roughly represented by direct instrumental observations. However, two types of extreme events were discovered recently: extreme solar energetic particle events on the multi-millennial time scale and super-flares on sun-like stars. Both discoveries imply that the Sun might rarely

produce events, called extreme solar events (ESE), whose energy could be orders of magnitude greater than anything we have observed during recent decades. During the years following these discoveries, great progress has been achieved in collecting observational evidence, uncovering new events, making statistical analyses, and developing theoretical modelling. The ESE paradigm lives and is being developed. On the other hand, many outstanding questions still remain open and new ones emerge. Here we present an overview of the current state of the art and the forming paradigm of ESE from different points of view: solar physics, stellar–solar projections, cosmogenic-isotope data, modelling, historical data, as well as terrestrial, technological and societal effects of ESEs. Special focus is paid to open questions and further developments. This review is based on the joint work of the International Space Science Institute (ISSI) team #510 (2020–2022). 7176 BCE and 5259 BCE, **5410 BCE, 1279 CE, 1052 CE, 1859, 4-6 Dec 2006, 13 Dec 2006**

The size distribution of magnetic bright points derived from Hinode/SOT observations

D. **Utz**1, A. Hanslmeier1, C. Möstl1, 2, R. Muller3, A. Veronig1, and H. Muthsam4
A&A 498, 289-293 (2009), DOI: 10.1051/0004-6361/200810867
Context. Magnetic bright points (MBPs) are small-scale magnetic features in the solar photosphere. They may be a possible source of coronal heating by rapid footpoint motions that cause magnetohydrodynamical waves. The number and size distribution are of vital importance in estimating the small scale-magnetic-field energy.
Aims. The size distribution of MBPs is derived for G-band images acquired by the Hinode/SOT instrument.
Methods. For identification purposes, a new automated segmentation and identification algorithm was developed.
Results. For a sampling of 0.108 arcsec/pixel, we derived a mean diameter of $^{(218 \pm 48)}$ km for the MBPs. For the full resolved data set with a sampling of 0.054 arcsec/pixel, the size distribution shifted to a mean diameter of $^{(166 \pm 31)}$ km. The determined diameters are consistent with earlier published values. The shift is most probably due to the different spatial sampling.
Conclusions. We conclude that the smallest magnetic elements in the solar photosphere cannot yet be resolved by G-band observations. The influence of discretisation effects (sampling) has also not yet been investigated sufficiently.

Magnetic Reconnection Onset via Disruption of a Forming Current Sheet by the Tearing Instability

Dmitri A. **Uzdensky**, Nuno F. Loureiro
2014
http://arxiv.org/pdf/1411.4295v1.pdf
The recent realization that Sweet-Parker current sheets are violently unstable to the secondary tearing (plasmoid) instability implies that such current sheets cannot occur in real systems. This suggests that, in order to understand the onset of magnetic reconnection, one needs to consider the growth of the tearing instability in a current layer as it is being formed. Such an analysis is performed here in the context of nonlinear resistive MHD for a generic time-dependent equilibrium representing a gradually forming current sheet. It is shown that two regimes, single-island and multi-island, are possible, depending on the rate of current sheet formation. A simple model is used to compute the criterion for transition between these two regimes, as well as the reconnection onset time and the current sheet parameters at that moment. For typical solar corona parameters this model yields results consistent with observations.

Observations of the Quiet Sun During the Deepest Solar Minimum of the Past Century with Chandrayaan-2 XSM -- Sub-A Class Microflares Outside Active Regions

Santosh V. **Vadawale**, N. P. S. Mithun, Biswajit Mondal, Aveek Sarkar, P. Janardhan, Bhuwan Joshi, Anil Bhardwaj, M. Shanmugam, Arpit R. Patel, Hitesh Kumar L. Adalja, Shiv Kumar Goyal, Tinkal Ladiya, Neeraj Kumar Tiwari, Nishant Singh, Sushil Kumar

https://doi.org/10.3847/2041-8213/abf0b0
Solar flares, with energies ranging over several orders of magnitude, result from impulsive release of energy due to magnetic reconnection in the corona. Barring a handful, almost all microflares observed in X-rays are associated with the solar active regions. Here we present, for the first time, a comprehensive analysis of a large sample of quiet Sun microflares observed in soft X-rays by the Solar X-ray Monitor (XSM) on board the Chandrayaan-2 mission during the 2019-20 solar minimum. A total of 98 microflares having peak flux below GOES A-level were observed by the XSM during observations spanning 76 days. By using the derived plasma temperature and emission measure of these events obtained by fitting the XSM spectra along with volume estimates from concurrent imaging observations in EUV with the Solar Dynamics Observatory/Atmospheric Imaging Assembly (SDO/AIA), we estimated their thermal energies to be ranging from 3e26 to 6e27 erg. We present the frequency distribution of the quiet Sun microflares with energy and discuss the implications of these observations of small-scale magnetic reconnection events outside active regions on coronal heating. **12-29 Sep 2019, 24 Feb-24 Mar 2020**

Particle Acceleration Mechanisms **Tutorial** **Review**

Rami **Vainio** and Alexandr Afanasiev

In: O.E. Malandraki, N.B. Crosby (eds.), Solar Particle Radiation Storms Forecasting and Analysis Chapter 3, **2018**

https://link.springer.com/content/pdf/10.1007%2F978-3-319-60051-2.pdf

File Malandraki_Crosby_SEPs_Forecasting and Analysis_Book.pdf

This chapter provides a short tutorial review on particle acceleration in dynamic electromagnetic fields under scenarios relevant to the problem of particle acceleration in the solar corona and solar wind during solar eruptions. It concentrates on fundamental aspects of the acceleration process and refrains from presenting detailed modeling of the specific conditions in solar eruptive plasmas. All particle acceleration mechanisms (in the solar corona) are related to electric fields that can persist in the highly conductive plasma: either electrostatic (or potential) or inductive related to temporally variable magnetic fields through Faraday's law. Mechanisms involving both kinds of fields are included in the tutorial.

Solar flare catalog from 3 years of Chandrayaan-2 XSM observations

Aravind Bharathi **Valluvan**, Ashwin Goyal, Devansh Jain, Abhinna Sundar Samantaray, Abhilash Sarwade, Kasiviswanathan Sankarasubramanian

Solar Phys. Volume 299, article number 8 **2024**

https://arxiv.org/pdf/2312.09191.pdf

https://doi.org/10.1007/s11207-023-02244-0

We present a catalog of 6266 solar flares detected by the X-Ray Solar Monitor onboard the Chandrayaan-2 lunar orbiter between 1.55 and 12.4 keV (1 and 8 Å) **from 2019 September 12 to 2022 November 4**, including 1469 type A flares. The catalog represents the first large sample, including both type A, hot thermal flares, and type B, impulsive flares, with a sub-A class sensitive instrument. We also detect 213 sub-A and 1330 A class flares. Individual flares are fit with an exponentially-modified Gaussian function and multi-flare groups are decomposed into individual flares. We validate our findings with flare catalogs made using visual inspection as well as automatic pipelines on Geostationary Operational Environmental Satellite and Solar Dynamics Observatory data. We find a clear bimodality in the ratio of the width to decay time between type A and B flares. We infer a power-law index of $\alpha_F=1.92\pm0.09$ for the background-subtracted peak flux distribution of XSM flares, which is consistent with the value ~2 reported in the literature. We also infer $\alpha_F=1.90\pm0.09$ for type B, and $\alpha_F=1.94\pm0.08$ for type A flares, which has previously not been reported in the literature. These comparable values hint at a similarity in their generative processes.

Time Evolution of Force-Free Parameter and Free Magnetic Energy in Active Region NOAA 10365

G. **Valori**, P. Romano, A. Malanushenko, I. Ermolli, F. Giorgi, K. Steed, L. van Driel-Gesztelyi, F. Zuccarello, J.-M. Malherbe

Solar Phys., February **2015**, Volume 290, Issue 2, pp 491-506

We describe the variation of the accumulated coronal helicity derived from the magnetic helicity flux through the photosphere in active region (AR) NOAA 10365, where several large flares and coronal mass ejections (CMEs) occurred. We used SOHO/MDI full-disk line-of-sight magnetograms to measure the helicity flux, and the integral of GOES X-ray flux as a proxy of the coronal energy variations due to flares or CMEs. Using the linear force-free field model, we transformed the accumulated helicity flux into a time sequence of the force-free parameter α accounting for flares or CMEs via the proxy derived from GOES observations. This method can be used to derive the value of α at different times during the AR evolution, and is a partial alternative to the commonly used match of field lines with EUV loops. By combining the accumulated helicity obtained from the observations with the linear force-free theory, we describe the main phases of the emergence process of the AR, and relate them temporally with the occurrence of flares or CMEs. Additionally, a comparison with the loop-matching method of fixing alpha at each time independently shows that the proposed method may be helpful in avoiding unrealistic or undetermined values of alpha that may originate from an insufficient quality of the image used to identify coronal loops at a given time. For the relative intensity of the considered events, the linear force-free field theory implies that there is a direct correlation between the released energy on the one hand and the product of the coronal helicity with the variation of α due to the event on the other. Therefore, the higher the value of the accumulated coronal helicity, the smaller the force-free parameter variation required to produce the same decrease in the free energy during the CMEs.

Reconnection brightenings in the quiet solar photosphere

Luc H. M. Rouppe **van der Voort**, Robert J. Rutten, Gregal J. M. Vissers

A&A **2016**

http://arxiv.org/pdf/1606.03675v1.pdf

We describe a new quiet-Sun phenomenon which we call "Quiet-Sun Ellerman-like Brightenings" (QSEB). QSEBs are similar to Ellerman bombs (EB) in some respects but differ significantly in others. EBs are transient brightenings of the wings of the Balmer H-alpha line that mark strong-field photospheric reconnection in complex active regions. QSEBs are similar but smaller and less intense Balmer-wing brightenings that occur in quiet areas away from active regions. In the H-alpha wing we measure typical lengths of less than 0.5 arcsec, widths of 0.21 arcsec, and lifetimes of less than a minute. We discovered them using high-quality H-alpha imaging spectrometry from the Swedish 1-m Solar Telescope (SST) and show that in lesser-quality data they cannot be distinguished from more ubiquitous facular brightenings, nor in the ultraviolet diagnostics currently available from space platforms. We add evidence from concurrent SST spectropolarimetry that QSEBs also mark photospheric reconnection events, but in quiet regions on the solar surface.

Quasi-periodic pulsations in solar and stellar flares: an overview of recent results **Review**

Tom **Van Doorsselaere**, Elena G. Kupriyanova, Ding Yuan
Solar Phys. Volume 291, Issue 11, pp 3143–3164 **2016**
http://arxiv.org/pdf/1609.02689v1.pdf
https://perswww.kuleuven.be/~u0041608/docs/2016qppreview.pdf
Quasi-periodic pulsations (or QPPs) are periodic intensity variations in the flare emission, across all wavelength bands. In this paper, we review the observational and modelling achievements since the previous review on this topic by Nakariakov & Melnikov (2009). In recent years, it has become clear that QPPs are an inherent feature of solar flares, because almost all flares exhibit QPPs. Moreover, it is now firmly established that QPPs often show multiple periods. We also review possible mechanisms for generating QPPs. Up to now, it has not been possible to conclusively identify the triggering mechanism or cause of QPPs. The lack of this identification currently hampers possible seismological inferences of flare plasma parameters. QPPs in stellar flares have been detected for a long time, and the high quality data of the Kepler mission allows to study the QPP more systematically. However, it has not been conclusively shown whether the time scales of stellar QPPs are different or the same as those in solar flares.

LYRA OBSERVATIONS OF TWO OSCILLATION MODES IN A SINGLE FLARE

T. **Van Doorsselaere**1,5, A. De Groof2, J. Zender3, D. Berghmans4 and M. Goossens
2011 ApJ 740 90
We analyze light curves from the LYRA irradiance experiment on board PROBA2 during the flare of **2010 February 8**. We see both long- and short-period oscillations during the flare. The long-period oscillation is interpreted in terms of standing slow sausage modes; the short-period oscillation is thought to be a standing fast sausage mode. The simultaneous presence of two oscillation modes in the same flaring structure allows for new coronal seismological applications. The periods are used to find seismological estimates of the plasma-β and the density contrast of the flaring loop. Also the wave mode number is estimated from the observed periods.

Evolution of Active Regions **Review**

van Driel-Gesztelyi, Lidia and Green, Lucie M.
Living Reviews in Solar Physics PUB.NO. lrsp-2015-1, Sept **2015**
http://solarphysics.livingreviews.org/Articles/lrsp-2015-1/
The evolution of active regions (AR) from their emergence through their long decay process is of fundamental importance in solar physics. Since large-scale flux is generated by the deep-seated dynamo, the observed characteristics of flux emergence and that of the subsequent decay provide vital clues as well as boundary conditions for dynamo models. Throughout their evolution, ARs are centres of magnetic activity, with the level and type of activity phenomena being dependent on the evolutionary stage of the AR. As new flux emerges into a pre-existing magnetic environment, its evolution leads to re-configuration of small-and large-scale magnetic connectivities. The decay process of ARs spreads the once-concentrated magnetic flux over an ever-increasing area. Though most of the flux disappears through small-scale cancellation processes, it is the remnant of large-scale AR fields that is able to reverse the polarity of the poles and build up new polar fields. In this Living Review the emphasis is put on what we have learned from observations, which is put in the context of modelling and simulation efforts when interpreting them. For another, modelling-focused Living Review on the sub-surface evolution and emergence of magnetic flux see Fan (2009). In this first version we focus on the evolution of dominantly bipolar ARs.

Shock-drift accelerated electrons and n-distribution

M. **Vandas** and M. Karlický
A&A 591, A127 (**2016**)
Aims. By analyzing soft X-ray spectra observed during the impulsive phase of several solar flares, the n-distribution function of superthermal electrons has been detected. In the paper we try to answer the question of whether electrons with this type of distribution function can be produced in a shock, e.g. in a flare termination shock.
Methods. We use analytical and numerical methods to compute distribution functions of electrons accelerated by a shock.

Results. We analytically derive the distribution functions of reflected electrons at quasi-perpendicular shocks. We also consider the influence of the electrostatic cross-shock potential, shock curvature, and the role of the upstream seed population on these distributions. The computed distributions are compared with the n-distributions. We found that a high-energy part of the distribution of electrons reflected at a quasi-perpendicular shock can be very well fitted by the n-distribution in all the cases we studied. This provides a chance to detect the flare termination shock.

Active region upflows: 1. Multi-instrument observations

K. **Vanninathan**, M.S. Madjarska, K. Galsgaard, Z. Huang, J.G. Doyle
A&A **2015**
http://arxiv.org/pdf/1509.05624v1.pdf
Upflows at the edges of active regions (ARs) are studied by spatially and temporally combining multi-instrument observations obtained with EIS/Hinode, AIA and HMI/SDO and IBIS/NSO, to derive their plasma parameters. This information is used for benchmarking data-driven modelling of the upflows (Galsgaard et al., 2015). The studied AR upflow displays blueshifted emission of 5-20 km/s in Fe XII and Fe XIII and its average electron density is 1.8x10^9 cm^3 at 1 MK. The time variation of the density shows no significant change (in a 3sigma error). The plasma density along a single loop drops by 50% over a distance of 20000 km. We find a second velocity component in the blue wing of the Fe XII and Fe XIII lines at 105 km/s. This component is persistent during the whole observing period of 3.5 hours with variations of only 15 km/s. We also study the evolution of the photospheric magnetic field and find that magnetic flux diffusion is responsible for the formation of the upflow region. High cadence Halpha observations of the chromosphere at the footpoints of the upflow region show no significant jet-like (spicule/rapid blue excursion) activity to account for several hours/days of plasma upflow. Using an image enhancement technique, we show that the coronal structures seen in the AIA 193A channel is comparable to the EIS Fe XII images, while images in the AIA 171A channel reveals additional loops that are a result of contribution from cooler emission to this channel. Our results suggest that at chromospheric heights there are no signatures that support the possible contribution of spicules to AR upflows. We suggest that magnetic flux diffusion is responsible for the formation of the coronal upflows. The existence of two velocity components possibly indicate the presence of two different flows which are produced by two different physical mechanisms, e.g. magnetic reconnection and pressure-driven.

Evidence for a White-light Flare on 10 September 1886

J.M. **Vaquero**, M. Vázquez, J. Sánchez Almeida
Solar Phys. 292:33 **2017**
https://arxiv.org/pdf/1701.05910v1.pdf
We present evidence for the occurrence of a white-light flare on **10 September 1886**. It represents the third of such rare events reported in the history of astronomy. The flare was mentioned by Valderrama (1886, L'Astronomie 5, 388). In this article we have used the original logbook of the observer, J. Valderrama y Aguilar, an amateur astronomer that lived in Madrid and Santa Cruz de Tenerife at that time.

Modifications of thick-target model: re-acceleration of electron beams by static and stochastic electric fields

M. **Varady**1,2, M. Karlický2, Z. Moravec1 and J. Kašparová
A&A 563, A51 (**2014**)
Context. The collisional thick-target model (CTTM) of the impulsive phase of solar flares, together with the famous Carmichael, Sturrock, Hirayama, and Kopp-Pneuman (CSHKP) model, presented for many years a “standard” model, which straightforwardly explained many observational aspects of flares. On the other hand, many critical issues appear when the concept is scrutinised theoretically or with the new generation of hard X-ray (HXR) observations. The famous “electron number problem” or problems related to transport of enormous particle fluxes though the corona represent only two of them. To resolve the discrepancies, several modifications of the CTTM appeared.
Aims. We study two of them based on the global and local re-acceleration of non-thermal electrons by static and stochastic electric fields during their transport from the coronal acceleration site to the thick-target region in the chromosphere. We concentrate on a comparison of the non-thermal electron distribution functions, chromospheric energy deposits, and HXR spectra obtained for both considered modifications with the CTTM itself.
Methods. The results were obtained using a relativistic test-particle approach. We simulated the transport of non-thermal electrons with a power-law spectrum including the influence of scattering, energy losses, magnetic mirroring, and also the effects of the electric fields corresponding to both modifications of the CTTM.
Results. We show that both modifications of the CTTM change the outcome of the chromospheric bombardment in several aspects. The modifications lead to an increase in chromospheric energy deposit, change of its spatial distribution, and a substantial increase in the corresponding HXR spectrum intensity.
Conclusions. The re-acceleration in both models reduces the demands on the efficiency of the primary coronal accelerator, on the electron fluxes transported from the corona downwards, and on the total number of accelerated coronal electrons during flares.

Confinedness of an X3.1 class solar flare occurred in NOAA 12192: Analysis from multi-instruments observations

N. **Vasantharaju**, F. Zuccarello, F. Ferrente, S. L. Guglielmino
ApJ **950** 183 **2023**
https://arxiv.org/pdf/2304.12156.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/accfff/pdf
The non-association of coronal mass ejections with high energetic flares is sparse. For this reason, the magnetic conditions required for the confinedness of major flares is a topic of active research. Using multi-instrument observations, we investigated the evolution and effects of confinedness in an X3.1 flare, which occurred in active region (AR) 12192. The decrease of net fluxes in the brightening regions, near the footpoints of the multi-sigmoidal AR in photosphere and chromosphere, indicative of flux cancellation favouring tether-cutting reconnection (TCR), is observed using the magnetic field observations of HMI/SDO and SOT/Hinode, respectively. The analysis of spectropolarimetric data obtained by the Interferometric Bidimensional Spectrometer over the brightening regions suggests untwisting of field lines, which further supports TCR. Filaments near polarity inversion line region, resulted from TCR of low lying sheared loops, undergo merging and form an elongated filament. The temperature and density differences between footpoints of the merged filament, revealed by DEM analysis, caused streaming and counter-streaming of plasma flow along the filament and unloads at its footpoints with an average velocity of ≈ 40 km s−1. This results in decrease of mass of the filament (density decreased by >50%), leading to its rise and expansion outwards. However, due to strong strapping flux, the filament separates itself instead of erupting. Further, the evolution of non-potential parameters describes the characteristics of confinedness of the flare. Our study suggests that the sigmoid-filament system exhibits upward catastrophe due to mass unloading, but gets suppressed by strong confinement of external poloidal field. **24 October 2014**

Magnetic Imprints of Eruptive and Noneruptive Solar Flares as Observed by Solar Dynamics Observatory

N. **Vasantharaju**1,2, P. Vemareddy1, B. Ravindra1, and V. H. Doddamani3
2022 ApJ 927 86
https://iopscience.iop.org/article/10.3847/1538-4357/ac4d8c/pdf
The abrupt and permanent changes of the photospheric magnetic field in the localized regions of active regions during solar flares, called magnetic imprints (MIs), have been observed for nearly the past three decades. The well-known coronal implosion model is assumed to explain such flare-associated changes but the complete physical understanding is still missing and debatable. In this study, we made a systematic analysis of flare-related changes of the photospheric magnetic field during 21 flares (14 eruptive and seven noneruptive) using the 135 s cadence vector magnetogram data obtained from the Helioseismic and Magnetic Imager. The MI regions for eruptive flares are found to be strongly localized, whereas the majority of noneruptive events (>70%) have scattered imprint regions. To quantify the strength of the MIs, we derived the integrated change of horizontal field and the total change of Lorentz force over an area. These quantities correlate well with the flare strength, irrespective of whether flares are eruptive or not, or have a short or long duration. Further, the free energy (FE), determined from virial theorem estimates, exhibits a statistically significant downward trend that starts around the flare time and is observed in the majority of flares. The change of FE during flares does not depend on eruptivity but has a strong positive correlation (≈0.8) with the Lorentz force change, indicating that part of the FE released would penetrate the photosphere. While these results strongly favor the idea of significant feedback from the corona on the photospheric magnetic field, the characteristics of MIs are quite indistinguishable from flares being eruptive or not. **15 Feb 2011, 9 Mar 2011, 30 Jul 2011, 6 Mar 2012, 11 Apr 2013, 28 oct 2013, 8 Nov 2013, 2 Feb 2014, 24 Oct 2014, 23 May 2015, 22 Jun 2015,**

Statistical study of magnetic non-potential measures in confined and eruptive flares

N. **Vasantharaju**, P. Vemareddy, B. Ravindra, V. H. Doddamani
ApJ **860** 58 **2018**
https://arxiv.org/pdf/1805.02348.pdf
Using the HMI/SDO vector magnetic field observations, we studied the relation of degree of magnetic non-potentiality with the observed flare/CME in active regions. From a sample of 77 flare/CME cases, we found a general relation that degree of non-potentiality is positively correlated with the flare strength and the associated CME speeds. Since the magnetic flux in the flare-ribbon area is more related to the reconnection, we trace the strong gradient polarity inversion line (SGPIL), Schrijver's R value manually along the flare-ribbon extent. Manually detected SGPIL length and R values show higher correlation with the flare strength and CME speed than the automatically traced values without flare-ribbon information. It highlights the difficulty of predicting the flare strength and CME speed a priori from the pre-flare magnetograms used in flare prediction models. Although the total, potential magnetic energy proxies show weak positive correlation, the decrease in free energy exhibits higher correlation (0.56) with the flare strength and CME speed. Moreover, the eruptive flares have threshold of SGPIL length (31Mm), R value (1.6×1019Mx), free-energy decrease (2×1031erg) compared to confined ones. In 90\% eruptive flares, the decay-index curve is steeper

reaching ncrit=1.5 within 42Mm, whereas it is beyond 42Mm in >70% confined flares. While indicating the improved statistics in the predictive capability of the AR eruptive behavior with the flare-ribbon information, our study provides threshold magnetic properties for a flare to be eruptive. **15 Feb 2011, March 7, 2012**

Nature of helicity injection in non-erupting solar active regions

P. **Vemareddy**
MNRAS **2022**
https://arxiv.org/pdf/2208.03228
Using time-sequence vector magnetic field and coronal observations from \textit{Solar Dynamics Observatory}, we report the observations of the magnetic field evolution and coronal activity in four emerging active regions (ARs). The ARs emerge with leading polarity being the same as for the majority of ARs in a hemisphere of solar cycle 24. After emergence, the magnetic polarities separate each other without building a sheared polarity inversion line. In all four ARs, the magnetic fields are driven by foot point motions such that the sign of the helicity injection (dH/dt) in the first half of the evolution is changed to the opposite sign in the later part of the observation time. This successive injection of opposite helicity is also consistent with the sign of mean force-free twist parameter (αav). Further, the EUV light curves of the ARs in 94Å~and GOES X-ray flux reveal flaring activity below C-class magnitude. Importantly, the white-light coronagraph images in conjunction with the AR images in AIA 94 Å~delineate the absence of associated CMEs with the studied ARs. These observations imply that the ARs with successive injection of opposite sign magnetic helicity are not favorable to twisted flux rope formation with excess coronal helicity, and therefore are unable to launch CMEs, according to recent reports. This study provides the characteristics of helicity flux evolution in the ARs referring to the conservative property of magnetic helicity and more such studies would help to quantify the eruptive capability of a given AR. **17–22 Apr, 2012, 24–29 Jul, 2015, 25–30 Mar, 2017, 29 Mar–03 Apr, 2017**

Magnetic Structure in Successively Erupting Active Regions: Comparison of Flare-Ribbons with Quasi-Separatrix Layers

P. **Vemareddy**
Front. Phys 9:749479 **2021**
https://arxiv.org/pdf/2109.14583.pdf
https://www.frontiersin.org/articles/10.3389/fphy.2021.749479/pdf
https://doi.org/10.3389/fphy.2021.749479
This paper studies the magnetic topology of successively erupting active regions (ARs) 11429 and 12371. Employing vector magnetic field observations from Helioseismic and Magnetic Imager, the pre-eruptive magnetic structure is reconstructed by a model of non-linear force-free field (NLFFF). For all the five CMEs from these ARs, the pre-eruptive magnetic structure identifies an inverse-S sigmoid consistent with the coronal plasma tracers in EUV observations. In all the eruption cases, the quasi-separatrix layers (QSLs) of Large Q values are continuously enclosing core field bipolar regions in which inverse-S shaped flare ribbons are observed. These QSLs essentially represent the large connectivity gradients between the domains of twisted core flux within the inner bipolar region and the surrounding potential like arcade. It is consistent with the observed field structure largely with the sheared arcade. The QSL maps in the chromosphere are compared with the flare-ribbons observed at the peak time of the flares. The flare ribbons are largely inverse-S shape morphology with their continuity of visibility is missing in the observations. For the CMEs in the AR 12371, the QSLs outline the flare ribbons as a combination of two inverse J-shape sections with their straight parts being separated. These QSLs are typical with the weakly twisted flux rope. Similarly, for the CMEs in the AR 11429, the QSLs are co-spatial with the flare ribbons both in the middle of the PIL and in the hook sections. In the frame work of standard model of eruptions, the observed flare ribbons are the characteristic of the pre-eruptive magnetic structure being sigmoid which is reproduced by {\bf the} NLFFF model with a weakly twisted flux rope at the core. **7-11 Mar 2012, 17-25 Jun 2015**

Relation of Non-neutralized electric currents and the activity in active regions

P. **Vemareddy**
RHESSI Science Nuggets #386 Oct **2020**

Degree of electric current neutralization and the activity in solar active regions

P. **Vemareddy**
MNRAS Volume 486, Issue 4, July **2019**, Pages 4936–4946,
https://arxiv.org/pdf/1904.02648.pdf
https://watermark.silverchair.com/stz1020.pdf

Using time-sequence vector magnetic field observation from Helioseismic and Magnetic Imager, we examined the connection of non-neutralized currents and the observed activity in 20 solar active regions (ARs). The net current in a given magnetic polarity is algebraic sum of direct current (DC) and return current (RC) and the ratio |DC/RC| is a measure of degree of net current neutralization (NCN). In the emerging ARs, the non-neutrality of these currents builds with the onset of flux emergence, following the relaxation to neutrality during the separation motion of bipolar regions. Accordingly, some emerging ARs are source regions of CMEs occurring at the time of higher level non-neutrality. ARs in the post-emergence phase can be CME productive provided they have interacting bipolar regions with converging and shearing motions. In these cases, the net current evolves with higher level (>1.3) of non-neutrality. Differently, the |DC/RC| in flaring and quiet ARs vary near unity. In all the AR samples, the |DC/RC| is higher for chiral current density than that for vertical current density. Owing to the fact that the non-neutralized currents arise in the vicinity of sheared polarity-inversion-lines (SPILs), the profiles of the total length of SPIL segments and the degree of NCN follow each other with a positive correlation. We find that the SPIL is localized as small segments in flaring-ARs, whereas it is long continuous in CME-producing ARs. These observations demonstrate the dividing line between the CMEs and flares with the difference being in global or local nature of magnetic shear in the AR that reflected in non-neutralized currents. **Table** 1. Details of the active regions in this study (2012-2016)

Very fast helicity injection leading to critically stable state and large eruptive activity in solar active region NOAA 12673

P. **Vemareddy**

ApJ **872** 182 **2019**

https://arxiv.org/abs/1901.09358

https://doi.org/10.3847/1538-4357/ab0200

Using the photospheric magnetic and coronal observations of Solar Dynamics Observatory, we studied the build-up and eruption of coronal non-potential magnetic structure in emerging active region (AR) 12673. The velocity field derived from tracked vector-magnetograms indicates persistent shear and converging motions of flux regions about the polarity inversion line (PIL). A major helicity injection occurs during rapid flux emergence consistent with the very fast flux emergence phase. While this helicity flux builds-up the sigmoid by September 4, the helicity injection by the continued shear and converging motions in the later evolution contributes to sigmoid sustenance and its core field twist as a manifestation of the flux rope which erupts after exceeding critical value of twist. Moreover, the total length of sheared PIL segments correlates with the non-neutralized current and maintains a higher value in both the polarity regions as a signature of eruptive capability of the AR according to the flux rope models. The modelled magnetic field qualitatively reproduces the sigmoidal structure capturing major features like twisted core flux as flux rope, and hook-shaped parts connecting at the middle of the PIL. Study of quasi-separatrix-layers reveals that the sheared arcade, enclosing the flux rope, is stressed to a critically stable state and its coronal height becomes doubled from September 4-6. While demonstrating the fast injection of helicity per unit flux as the crucial factor for severe space-weather events, this study explains the formation of the flux rope and recurrent eruptive nature of the AR by the critically stable state of sheared arcade early on September 6. **4-6 Sept 2017**

Study of Three-Dimensional Magnetic Structure and the Successive Eruptive Nature of Active Region 12371

P. **Vemareddy**, P. Demóulin

ApJ **2018**

https://arxiv.org/pdf/1803.04728.pdf

We study the magnetic structure of successively erupting sigmoid in active region 12371 by modeling the quasi-static coronal field evolution with non-linear force-free field (NLFFF) equilibria. HMI/SDO vector magnetograms are used as input to the NLFFF model. In all eruption events, the modeled structure resembles the observed pre-eruptive coronal sigmoid and the NLFFF core-field is a combination of double inverse J-shaped and inverse-S field-lines with dips touching the photosphere. Such field-lines are formed by flux-cancellation reconnection of opposite-J field-lines at bald-patch locations. It implies the formation of a weakly twisted flux-rope from large scale sheared arcade field lines. Later on, this flux-rope undergo coronal tether-cutting reconnection until a CME is triggered. The modeled structure captured these major features of sigmoid-to-arcade-to-sigmoid transformation, that is being recurrent under continuous photospheric flux motions. Calculations of the field-line twist reveal a fractional increase followed by a decrease of the number of pixels having a range of twist. This traces the buildup process of a twisted core-field by slow photospheric motions and the relaxation after eruption, respectively. Our study infers that the large eruptivity of this AR is due to a steep decrease of the background coronal field meeting the torus instability criteria at low height (\approx 40 Mm) in contrast to non-eruptive ARs. **18-25 June, 2015**

Successive Injection of Opposite Magnetic Helicity in Solar Active Region NOAA 11928

P. **Vemareddy**, P. Démoulin

A&A **2016**
https://arxiv.org/pdf/1611.00699v1.pdf
Understanding the nature and evolution of the photospheric helicity flux transfer is a key to reveal the role of magnetic helicity in coronal dynamics of solar active regions. Using SDO/HMI photospheric vector magnetograms and the derived flow velocity field, we computed boundary driven helicity flux with a 12 minute cadence during the emergence of AR 11928. Accounting the foot point connectivity defined by non-linear force-free magnetic extrapolations, we derived and analyzed the corrected distribution of helicity flux maps. The photospheric helicity flux injection is found to changes sign during the steady emergence of the AR. This reversal is confirmed with the evolution of the photospheric electric currents and with the coronal connectivity as observed in EUV wavelengths with SDO/AIA. During about the three first days of emergence, the AR coronal helicity is positive while later on the field configuration is close to a potential field. As theoretically expected, the magnetic helicity cancelation is associated to enhanced coronal activity. The study suggests a boundary driven transformation of the chirality in the global AR magnetic structure. This may be the result of the emergence of a flux rope with positive twist around its apex while it has negative twist in its legs. The origin of such mixed helicity flux rope in the convective zone is challenging for models.

Flux Emergence in the Solar Active Region NOAA 11158: The Evolution of Net Current

P. **Vemareddy**, P. Venkatakrishnan, S. Karthikreddy
Research in Astronomy and Astrophysics, Vol 15, No 9 1547-1558 (**2015**)
http://arxiv.org/pdf/1502.05458v1.pdf
We present a detailed investigation on the evolution of observed net vertical current using a time series of vector magnetograms of the active region (AR) NOAA 11158 obtained from Helioseismic Magnetic Imager. We also discuss the relation of net current to the observed eruptive events. The AR evolved from βγ to βγδ configuration over a period of 6 days. The AR had two sub-regions of activity with opposite chirality: one dominated by sunspot rotation producing a strong CME, the other showing large shear motions producing a strong flare. The net current in each polarity over the CME producing sub-region increased to a maximum and then decreased when the sunspots got separated. The time profile of net current in this sub-region followed the time profile of the rotation rate of the S-polarity sunspot of the same sub-region. The net current in the flaring sub-region showed a sudden increase at the time of the strong flare and remained unchanged till the end of the observation, while the sunspots maintained their close proximity. The systematic evolution of the observed net current is seen to follow the time evolution of total length of strongly sheared polarity inversion lines in both the sub-regions. The observed photospheric net current could be explained as an inevitable product of the emergence of a twisted flux rope, from a higher pressure confinement below the photosphere into the lower pressure environment of the photosphere. **February 13-16, 2011**

Quasi-Static 3D-Magnetic Field Evolution in Solar Active Region NOAA 11166 Associated with X1.5 Flare

P. **Vemareddy**, and T. Wiegelmann
E-print, July **2014**; ApJ, **2014** 792 40
http://arxiv.org/pdf/1406.7823v1.pdf
We study the quasi-static evolution of coronal magnetic fields constructed from the Non Linear Force Free Field (NLFFF) approximation aiming to understand the relation between the magnetic field topology and ribbon emission during an X1.5 flare in active region (AR) NOAA 11166. The flare with a quasi-elliptical, and two remote ribbons occurred on **March 9, 2011** at 23:13UT over a positive flux region surrounded by negative flux at the center of the bipolar AR. Our analysis of the coronal magnetic structure with potential and NLFFF solutions unveiled the existence of a single magnetic null point associated with a fan-spine topology and is co-spatial with the hard X-ray source. The footpoints of the fan separatrix surface agree with the inner edge of the quasi-elliptical ribbon and the outer spine is linked to one of the remote ribbons. During the evolution, the slow footpoint motions stressed the fieldlines along the polarity inversion line and caused electric current layers in the corona around the fan separatrix surface. These current layers trigger magnetic reconnection as a consequence of dissipating currents, which are visible as cusped shape structures at lower heights. The reconnection process reorganised the magnetic field topology whose signatures are observed at the separatrices/QSL structure both in the photosphere and corona during the pre-to-post flare evolution. In agreement with previous numerical studies, our results suggest that the line-tied footpoint motions perturb the fan-spine system and cause null point reconnection, which eventually causes the flare emission at the footpoints of the fieldlines.

ON THE INJECTION OF HELICITY BY THE SHEARING MOTION OF FLUXES IN RELATION TO FLARES AND CORONAL MASS EJECTIONS

P. **Vemareddy**1, A. Ambastha1, R. A. Maurya2, and J. Chae
2012 ApJ 761 86
http://arxiv.org/pdf/1202.5195v2.pdf

An investigation of helicity injection by photospheric shear motions is carried out for two active regions (ARs), NOAA 11158 and 11166, using line-of-sight magnetic field observations obtained from the Helioseismic and Magnetic Imager on board the Solar Dynamics Observatory. We derived the horizontal velocities in the ARs from the differential affine velocity estimator (DAVE) technique. Persistent strong shear motions at maximum velocities in the range of 0.6-0.9 km s–1 along the magnetic polarity inversion line and outward flows from the peripheral regions of the sunspots were observed in the two ARs. The helicities injected in NOAA 11158 and 11166 during their six-day evolution period were estimated as 14.16 × 1042 Mx2 and 9.5 × 1042 Mx2, respectively. The estimated injection rates decreased up to 13% by increasing the time interval between the magnetograms from 12 minutes to 36 minutes, and increased up to 9% by decreasing the DAVE window size from 21 × 18 to 9 × 6 pixel2, resulting in 10% variation in the accumulated helicity. In both ARs, the flare-prone regions (R2) had inhomogeneous helicity flux distribution with mixed helicities of both signs and coronal mass ejection (CME) prone regions had almost homogeneous distribution of helicity flux dominated by a single sign. The temporal profiles of helicity injection showed impulsive variations during some flares/CMEs due to negative helicity injection into the dominant region of positive helicity flux. A quantitative analysis reveals a marginally significant association of helicity flux with CMEs but not flares in AR 11158, while for the AR 11166, we find a marginally significant association of helicity flux with flares but not CMEs, providing evidence of the role of helicity injection at localized sites of the events. These short-term variations of helicity flux are further discussed in view of possible flare-related effects. This study suggests that flux motions and spatial distribution of helicity injection are important to understanding the complex nature of the magnetic flux system of the AR, and how it can lead to conditions favorable for eruptive events.

ON THE ROLE OF ROTATING SUNSPOTS IN THE ACTIVITY OF SOLAR ACTIVE REGION NOAA 11158

P. **Vemareddy**1, A. Ambastha1, and R. A. Maurya
2012 ApJ 761 60
http://arxiv.org/pdf/1210.3912v1.pdf

We study the role of rotating sunspots in relation to the evolution of various physical parameters characterizing the non-potentiality of the active region (AR) NOAA 11158 and its eruptive events using the magnetic field data from the Helioseismic and Magnetic Imager (HMI) and multi-wavelength observations from the Atmospheric Imaging Assembly (AIA) on board the Solar Dynamics Observatory. From the evolutionary study of HMI intensity and AIA channels, it is observed that the AR consists of two major rotating sunspots, one connected to a flare-prone region and another with coronal mass ejection (CME). The constructed space-time intensity maps reveal that the sunspots exhibited peak rotation rates coinciding with the occurrence of major eruptive events. Further, temporal profiles of twist parameters, namely, average shear angle, αav, αbest, derived from HMI vector magnetograms, and the rate of helicity injection, obtained from the horizontal flux motions of HMI line-of-sight magnetograms, correspond well with the rotational profile of the sunspot in the CME-prone region, giving predominant evidence of rotational motion causing magnetic non-potentiality. Moreover, the mean value of free energy from the virial theorem calculated at the photospheric level shows a clear step-down decrease at the onset time of the flares revealing unambiguous evidence of energy release intermittently that is stored by flux emergence and/or motions in pre-flare phases. Additionally, distribution of helicity injection is homogeneous in the CME-prone region while in the flare-prone region it is not and often changes sign. This study provides a clear picture that both proper and rotational motions of the observed fluxes played significant roles in enhancing the magnetic non-potentiality of the AR by injecting helicity, twisting the magnetic fields and thereby increasing the free energy, leading to favorable conditions for the observed transient activity.

Filament Eruption in NOAA 11093 Leading to a Two-Ribbon M1.0 Class Flare and CME

P. **Vemareddy**, R. A. Maurya and A. Ambastha
Solar Physics, Volume 277, Number 2, 337-354, **2012**
http://arxiv.org/pdf/1103.3168v2.pdf

We present a multi-wavelength analysis of an eruption event that occurred in active region NOAA 11093 on **7 August 2010**, using data obtained from SDO, STEREO, RHESSI, and the GONG Hα network telescope. From these observations, we inferred that an upward slow rising motion of an inverse S-shaped filament lying along the polarity inversion line resulted in a CME subsequent to a two-ribbon flare. Interaction of overlying field lines across the filament with the side-lobe field lines, associated EUV brightening, and flux emergence/cancelation around the filament were the observational signatures of the processes leading to its destabilization and the onset of eruption. Moreover, the time profile of the rising motion of the filament/flux rope corresponded well with flare characteristics, viz., the reconnection rate and hard X-ray emission profiles. The flux rope was accelerated to the maximum velocity as a CME at the peak phase of the flare, followed by deceleration to an average velocity of 590 km s−1. We suggest that the observed emergence/cancelation of magnetic fluxes near the filament caused it to rise, resulting in the tethers to cut and

reconnection to take place beneath the filament; in agreement with the tether-cutting model. The corresponding increase/decrease in positive/negative photospheric fluxes found in the post-peak phase of the eruption provides unambiguous evidence of reconnection as a consequence of tether cutting.

Solar Flare Distributions: Lognormal Instead of Power Law?

Cis **Verbeeck**1, Emil Kraaikamp1, Daniel F. Ryan2, and Olena Podladchikova1
Astrophysical Journal, 884:50 (16pp), **2019**
https://iopscience.iop.org/article/10.3847/1538-4357/ab3425/pdf
In many statistical solar flare studies, power laws are claimed and exponents derived by fitting a line to a log–log histogram. It is well known that this approach is statistically unstable, and very large statistics are needed to produce reliable exponent estimates. This may explain part of the observed divergence in power-law exponents in various studies. Moreover, the question is seldom addressed to what extent the data really do support power-law behavior. In this paper, we perform a comprehensive study of 6924 flares detected in SDO/AIA 9.4 nm images by the Solar Demon flare detection software between 2010 May 13 and 2018 March 16 and 9601 flares detected during the same period in GOES/XRS data by the LYRAFF flare detection software. We apply robust statistics to the SDO/AIA 9.4 nm peak intensity and the GOES/XRS raw peak flux, background-subtracted peak flux, and background-subtracted fluence and find clear indications that most background-corrected data are not well described by a power law and that all are better described by a lognormal distribution, while the raw GOES/XRS peak flux is best described by a power law. This may explain the success of power-law fits in flare studies using uncorrected data. The behavior of flare distributions has important implications for large-scale science questions such as coronal heating and the nature of solar flares. The apparent lognormal character of flare distributions in our data sets suggests that the assumed power-law nature of flares and its consequences need to be reexamined with great care.2014-03-29

A Multi-wavelength Analysis of Active Regions and Sunspots by Comparison of Automatic Detection Algorithms

C. **Verbeeck**, P. A. Higgins, T. Colak, F. T. Watson, V. Delouille, B. Mampaey, R. Qahwaji
Solar Physics, March **2013**, Volume 283, Issue 1, pp 67-95
Since the Solar Dynamics Observatory (SDO) began recording ≈ 1 TB of data per day, there has been an increased need to automatically extract features and events for further analysis. Here we compare the overall detection performance, correlations between extracted properties, and usability for feature tracking of four solar feature-detection algorithms: the Solar Monitor Active Region Tracker (SMART) detects active regions in line-of-sight magnetograms; the Automated Solar Activity Prediction code (ASAP) detects sunspots and pores in white-light continuum images; the Sunspot Tracking And Recognition Algorithm (STARA) detects sunspots in white-light continuum images; the Spatial Possibilistic Clustering Algorithm (SPoCA) automatically segments solar EUV images into active regions (AR), coronal holes (CH), and quiet Sun (QS). One month of data from the Solar and Heliospheric Observatory (SOHO)/Michelson Doppler Imager (MDI) and SOHO/Extreme Ultraviolet Imaging Telescope (EIT) instruments during **12 May – 23 June 2003** is analysed. The overall detection performance of each algorithm is benchmarked against National Oceanic and Atmospheric Administration (NOAA) and Solar Influences Data Analysis Center (SIDC) catalogues using various feature properties such as total sunspot area, which shows good agreement, and the number of features detected, which shows poor agreement. Principal Component Analysis indicates a clear distinction between photospheric properties, which are highly correlated to the first component and account for 52.86% of variability in the data set, and coronal properties, which are moderately correlated to both the first and second principal components. Finally, case studies of NOAA 10377 and 10365 are conducted to determine algorithm stability for tracking the evolution of individual features. We find that magnetic flux and total sunspot area are the best indicators of active-region emergence. Additionally, for NOAA 10365, it is shown that the onset of flaring occurs during both periods of magnetic-flux emergence and complexity development.

On the origin of two X-class flares in active region NOAA 12673 - Shear flows and head-on collision of new and pre-existing flux

M. **Verma**
A&A 612, A101 **2018**
https://arxiv.org/pdf/1801.08368.pdf
Flare-prolific active region NOAA 12673 produced consecutive X2.2 and X9.3 flares on **06/09/2017**. To scrutinize the morphological, magnetic, and horizontal flow properties associated with these flares, a 7-hour time-series was used consisting of continuum images, line-of-sight/vector magnetograms, and 1600 {\AA} UV images. These data were acquired with the SDO HMI and AIA. The white-light flare emission differed for both flares, while the X2.2 flare displayed localized, confined flare kernels, the X9.3 flare exhibited a two-ribbon structure. In contrast, the excess UV emission exhibited a similar structure for both flares, but with larger areal extent for the X9.3 flare. These two flares represented a scenario, where the first confined flare acted as precursor, setting up the stage for the more extended flare. Difference maps for continuum and magnetograms revealed locations of significant changes, i.e., penumbral decay and umbral strengthening. The curved magnetic polarity inversion line in the {\delta}-spot was the fulcrum of most changes.

Horizontal proper motions were computed using the DAVE4VM. Persistent flow features included (1) strong shear flows along the polarity inversion line, where the negative, parasitic polarity tried to bypass the majority, positive-polarity part of the {\delta}-spot in the north, (2) a group of positive-polarity spots, which moved around the {\delta}-spot in the south, moving away from the {\delta}-spot with significant horizontal flow speeds, and (3) intense moat flows partially surrounding the penumbra of several sunspots, which became weaker in regions with penumbral decay. The enhanced flare activity has its origin in the head-on collision of newly emerging flux with an already existing regular, {\alpha}-spot.

Flows in and around active region NOAA12118 observed with the GREGOR solar telescope and SDO/HMI

M. **Verma**, C. Denker, H. Balthasar, C. Kuckein, S.J. González Manrique, M. Sobotka,
ASP Conf. Series - Coimbra solar physics meeting: Grounds-based solar observations in the space instrumentation era , I. Dorotovic, C. Fischer, and M. Temmer (eds.) **2016**
http://arxiv.org/pdf/1603.01109v1.pdf
Accurate measurements of magnetic and velocity fields in and around solar active regions are key to unlocking the mysteries of the formation and the decay of sunspots. High spatial resolution image and spectral sequences with a high cadence obtained with the GREGOR solar telescope give us an opportunity to scrutinize 3-D flow fields with local correlation tracking and imaging spectroscopy. We present GREGOR early science data acquired in 2014 July - August with the GREGOR Fabry-P\'erot Interferometer and the Blue Imaging Channel. Time-series of blue continuum (? 450.6 nm) images of the small active region NOAA 12118 were restored with the speckle masking technique to derive horizontal proper motions and to track the evolution of morphological changes. In addition, high-resolution observations are discussed in the context of synoptic data from the Solar Dynamics Observatory. **2014 July 18**.

Horizontal flow fields observed in Hinode G-band images
III. The decay of a satellite sunspot and the role of magnetic flux removal in flaring

M. **Verma** and C. Denker
A&A 545, A92 (**2012**)
Context. Emergence of magnetic flux plays an important role in the initiation of flares. However, the role of submerging magnetic flux in prompting flares is more ambiguous, not the least because of the scarcity of observations.
Aims. The flare-prolific active region NOAA 10930 offered both a developing δ-spot and a decaying satellite sunspot of opposite polarity. The objective of this study is to characterize the photometric decay of the satellite sunspot as well as the evolution of photospheric and chromospheric horizontal proper motions in its surroundings.
Methods. We apply the local correlation tracking technique to a 16-h time-series of Hinode G-band and Ca ii H images and study the horizontal proper motions in the vicinity of the satellite sunspot on 2006 December 7. Decorrelation times were computed to measure the lifetime of solar features in intensity and flow maps.
Results. We observed shear flows in the dominant umbral cores of the satellite sunspot. These flows vanished once the penumbra had disappeared. This slow penumbral decay had an average rate of 152 Mm2 day-1 over an 11-h period. Typical lifetimes of intensity features derived from an autocorrelation analysis are 3–5 min for granulation, 25–35 min for G-band bright points, and up to 200−235 min for penumbrae, umbrae, and pores. Long-lived intensity features (i.e., the dominant umbral cores) are not related to long-lived flow features in the northern part of the sunspot, where flux removal, slowly decaying penumbrae, and persistent horizontal flows of up to 1 km s-1 contribute to the erosion of the sunspot. Finally, the restructuring of magnetic field topology was responsible for a homologous M2.0 flare, which shared many characteristics with an X6.5 flare on the previous day.
Conclusions. Notwithstanding the prominent role of δ-spots in flaring, we conclude based on the decomposition of the satellite sunspot, the evolution of the surrounding flow fields, and the timing of the M2.0 flare that the vanishing magnetic flux in the decaying satellite sunspot played an instrumental role in triggering the homologous M2.0 flare and the eruption of a small Hα filament. The strong magnetic field gradients of the neighboring δ-spot merely provided the vehicle for the strongest flare emission about 10 min after the onset of the flare.

Can we predict solar flares?

Astrid M. **Veronig**
Science 31 Jul **2020**: Vol. 369, Issue 6503, pp. 504-505
DOI: 10.1126/science.abb6150
https://sci-hub.tw/10.1126/science.abb6150
https://science.sciencemag.org/content/369/6503/504
Flares from the Sun are the strongest explosions in our Solar System. They can cause severe space weather disturbances, posing a hazard to astronauts and technological systems in space and on the ground. Solar flares have an immediate impact in the form of enhanced radiation and energetic particles in as little as 8 min after the start of the event. Reliable prediction methods for flares are needed to provide longer warning times. However, pinning down the flare onset conditions is necessary for reliable predictions and is still a struggle (1). On page 587 of this issue, Kusano et al. (2) introduce a method to predict and successfully test for large imminent flares.

Magnetic Reconnection Rates and Energy Release in a Confined X-class Flare

A.M. **Veronig**, W. Polanec

Solar Phys. Volume 290, Issue 10, pp 2923-2942 **2015**

http://arxiv.org/pdf/1509.07089v1.pdf

We study the energy-release process in the confined X1.6 flare that occurred on **22 October 2014** in AR 12171. Magnetic-reconnection rates and reconnection fluxes are derived from three different data sets: space-based data from the Atmospheric Imaging Assembly (AIA) 1600 {\AA} filter onboard the Solar Dynamics Observatory (SDO) and ground-based Hα and Ca II K filtergrams from Kanzelh\"ohe Observatory. The magnetic-reconnection rates determined from the three data sets all closely resemble the temporal profile of the hard X-rays measured by the Ramaty High Energy Solar Spectroscopic Imager (RHESSI), which are a proxy for the flare energy released into high-energy electrons. The total magnetic-reconnection flux derived lies between 4.1×1021 Mx (AIA 1600 {\AA}) and 7.9×1021 Mx (Hα), which corresponds to about 2 to 4% of the total unsigned flux of the strong source AR. Comparison of the magnetic-reconnection flux dependence on the GOES class for 27 eruptive events collected from previous studies (covering B to >X10 class flares) reveals a correlation coefficient of ≈0.8 in double-logarithmic space. The confined X1.6 class flare under study lies well within the distribution of the eruptive flares. The event shows a large initial separation of the flare ribbons and no separation motion during the flare. In addition, we note enhanced emission at flare-ribbon structures and hot loops connecting these structures before the event starts. These observations are consistent with the emerging-flux model, where newly emerging small flux tubes reconnect with pre-existing large coronal loops.

MULTIWAVELENGTH IMAGING AND SPECTROSCOPY OF CHROMOSPHERIC EVAPORATION IN AN M-CLASS SOLAR FLARE

A. M. **Veronig** 1, J. Rybák 2, P. Gömöry 2,3, S. Berkebile-Stoiser 1, M. Temmer 1,4, W. Otruba 3, B. Vršnak 5, W. Pötzi 3 and D. Baumgartner

2010 ApJ 719 655

We study spectroscopic observations of chromospheric evaporation mass flows in comparison with the energy input by electron beams derived from hard X-ray (HXR) data for the white-light M2.5 flare of **2006 July 6**. The event was captured in high-cadence spectroscopic observing mode by SOHO/CDS combined with high-cadence imaging at various wavelengths in the visible, extreme ultraviolet, and X-ray domain during the joint observing campaign JOP171. During the flare peak, we observe downflows in the He I and O V lines formed in the chromosphere and transition region, respectively, and simultaneous upflows in the hot coronal Si XII line. The energy deposition rate by electron beams derived from RHESSI HXR observations is suggestive of explosive chromospheric evaporation, consistent with the observed plasma motions. However, for a later distinct X-ray burst, where the site of the strongest energy deposition is exactly located on the Coronal Diagnostics Spectrometer (CDS) slit, the situation is intriguing. The O V transition region line spectra show the evolution of double components, indicative of the superposition of a stationary plasma volume and upflowing plasma elements with high velocities (up to 280 km s–1) in single CDS pixels on the flare ribbon. However, the energy input by electrons during this period is too small to drive explosive chromospheric evaporation. These unexpected findings indicate that the flaring transition region is much more dynamic, complex, and fine structured than is captured in single-loop hydrodynamic simulations.

Temporal aspects and frequency distributions of solar soft X-ray flares

A. **Veronig**1, M. Temmer1, A. Hanslmeier1, W. Otruba2, and M. Messerotti3

A&A 382, 1070–1080 (**2002**)

DOI: 10.1051/0004-6361:20011694

https://sci-hub.ru/10.1051/0004-6361:20011694

A statistical analysis of almost 50 000 soft X-ray (SXR) flares observed by GOES during the period 1976–2000 is presented. On the basis of this extensive data set, statistics on temporal properties of soft X-ray flares, such as duration, rise and decay times with regard to the SXR flare classes is presented. Correlations among distinct flare parameters, i.e. SXR peak flux, fluence and characteristic times, and frequency distributions of flare occurrence as function of the peak flux, the fluence and the duration are derived. We discuss the results of the analysis with respect to statistical flare models, the idea of coronal heating by nanoflares, and elaborate on implications of the obtained results on the Neupert effect in solar flares.

A Survey of Nanoflare Properties in Active Regions Observed with the Solar Dynamics Observatory

Nicholeen M. **Viall** and James A. Klimchuk

2017 ApJ 842 108

http://iopscience.iop.org.sci-hub.cc/0004-637X/842/2/108/

In this paper, we examine 15 different active regions (ARs) observed with the Solar Dynamics Observatory and analyze their nanoflare properties. We have recently developed a technique that systematically identifies and measures plasma temperature dynamics by computing time lags between light curves. The time lag method tests whether the plasma is maintained at a steady temperature, or if it is dynamic, undergoing heating and cooling cycles. An important aspect of our technique is that it analyzes both observationally distinct coronal loops as well as the much more prevalent diffuse emission between them. We find that the widespread cooling reported previously for NOAA AR 11082 is a generic property of all ARs. The results are consistent with impulsive nanoflare heating followed by slower cooling. Only occasionally, however, is there full cooling from above 7 MK to well below 1 MK. More often, the plasma cools to approximately 1–2 MK before being reheated by another nanoflare. These same 15 ARs were first studied by Warren et al. We find that the degree of cooling is not well correlated with the reported slopes of the emission measure distribution. We also conclude that the Fe xviii emitting plasma that they measured is mostly in a state of cooling. These results support the idea that nanoflares have a distribution of energies and frequencies, with the average delay between successive events on an individual flux tube being comparable to the plasma cooling timescale.

The Transition Region Response to a Coronal Nanoflare: Forward Modeling and Observations in SDO/AIA

Nicholeen M. **Viall** and James A. Klimchuk

2015 ApJ 799 58

The corona and transition region (TR) are fundamentally coupled through the processes of thermal conduction and mass exchange. It is not possible to understand one without the other. Yet the temperature-dependent emissions from the two locations behave quite differently in the aftermath of an impulsive heating event such as a coronal nanoflare. Whereas the corona cools sequentially, emitting first at higher temperatures and then at lower temperatures, the TR is multithermal and the emission at all temperatures responds in unison. We have previously applied the automated time lag technique of Viall & Klimchuk to disk observations of an active region (AR) made by the Atmospheric Imaging Assembly (AIA) on the Solar Dynamics Observatory. Lines of sight passing through coronal plasma show clear evidence for post-nanoflare cooling, while lines of sight intersecting the TR footpoints of coronal strands show zero time lag. In this paper, we use the EBTEL hydrodynamics code to demonstrate that this is precisely the expected behavior when the corona is heated by nanoflares. We also apply the time lag technique for the first time to off-limb observations of an AR. Since TR emission is not present above the limb, the occurrence of zero time lags is greatly diminished, supporting the conclusion that zero time lags measured on the disk are due to TR plasma. Lastly, we show that the "coronal" channels in AIA can be dominated by bright TR emission. When defined in a physically meaningful way, the TR reaches a temperature of roughly 60% the peak temperature in a flux tube. The TR resulting from impulsive heating can extend to 3 MK and higher, well within the range of the "coronal" AIA channels.

Table 1 ARs are Ordered in Increasing Total Unsigned Magnetic Flux, Following WWB2012 (2010-2011)

PATTERNS OF NANOFLARE STORM HEATING EXHIBITED BY AN ACTIVE REGION OBSERVED WITH SOLAR DYNAMICS OBSERVATORY/ATMOSPHERIC IMAGING ASSEMBLY

Nicholeen M. **Viall** and James A. Klimchuk

2011 ApJ 738 24, **2011**

It is largely agreed that many coronal loops—those observed at a temperature of about 1 MK—are bundles of unresolved strands that are heated by storms of impulsive nanoflares. The nature of coronal heating in hotter loops and in the very important but largely ignored diffuse component of active regions is much less clear. Are these regions also heated impulsively, or is the heating quasi-steady? The spectacular new data from the Atmospheric Imaging Assembly (AIA) telescopes on the Solar Dynamics Observatory offer an excellent opportunity to address this question. We analyze the light curves of coronal loops and the diffuse corona in six different AIA channels and compare them with the predicted light curves from theoretical models. Light curves in the different AIA channels reach their peak intensities with predictable orderings as a function the nanoflare storm properties. We show that while some sets of light curves exhibit clear evidence of cooling after nanoflare storms, other cases are less straightforward to interpret. Complications arise because of line-of-sight integration through many different structures, the broadband nature of the AIA channels, and because physical properties can change substantially depending on the magnitude of the energy release. Nevertheless, the light curves exhibit predictable and understandable patterns consistent with impulsive nanoflare heating.

SMESE: A SMall Explorer for Solar Eruptions

Stellar flares, superflares and coronal mass ejections -- entering the Big data era **Review**

Krisztián **Vida**, Zsolt Kővári, Martin Leitzinger, Petra Odert, Katalin Oláh, Bálint Seli, Levente Kriskovics, Robert Greimel, Anna Görgei
Universe **2024**
https://arxiv.org/pdf/2407.16446
Flares, sometimes accompanied by coronal mass ejections (CMEs), are the result of sudden changes in the magnetic field of stars with high energy release through magnetic reconnection, which can be observed across a wide range of the electromagnetic spectrum from radio waves to the optical range to X-rays. In our observational review, we attempt to collect some fundamental new results, which can largely be linked to the Big data era that has arrived due to the expansion of space photometric observations of the last two decades. We list the different types of stars showing flare activity, their observation strategies, and discuss how their main stellar properties relate to the characteristics of the flares (or even CMEs) they emit. Our goal is to focus, without claiming to be complete, on those results that may in one way or another challenge the "standard" flare model based on the solar paradigm. **2024 May 10**

FOXSI-2 Solar Microflares II: Hard X-ray Imaging Spectroscopy and Flare Energetics

Juliana T. **Vievering**, Lindsay Glesener, P. S. Athiray, Juan Camilo Buitrago-Casas, Sophie Musset, Daniel Ryan, Shin-nosuke Ishikawa, Jessie Duncan, Steven Christe, Säm Krucker
2021 *ApJ* **913** 15
https://arxiv.org/pdf/2011.04753.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/abf145/pdf
https://doi.org/10.3847/1538-4357/abf145
We study the nature of energy release and transfer for two sub-A class solar microflares observed during the second flight of the Focusing Optics X-ray Solar Imager (FOXSI-2) sounding rocket experiment on **2014 December 11**. FOXSI is the first solar-dedicated instrument to utilize focusing optics to image the Sun in the hard X-ray (HXR) regime, sensitive to the energy range 4-20 keV. Through spectral analysis of the two microflares using an optically thin isothermal plasma model, we find evidence for plasma heated to temperatures of ~10 MK and emissions measures down to ~1044 cm−3. Though nonthermal emission was not detected for the FOXSI-2 microflares, a study of the parameter space for possible hidden nonthermal components shows that there could be enough energy in nonthermal electrons to account for the thermal energy in microflare 1, indicating that this flare is plausibly consistent with the standard thick-target model. With a solar-optimized design and improvements in HXR focusing optics, FOXSI-2 offers approximately five times greater sensitivity at 10 keV than the Nuclear Spectroscopic Telescope Array (NuSTAR) for typical microflare observations and allows for the first direct imaging spectroscopy of solar HXRs with an angular resolution at scales relevant for microflares. Harnessing these improved capabilities to study the evolution of small-scale events, we find evidence for spatial and temporal complexity during a sub-A class flare. These studies in combination with contemporanous observations by the Atmospheric Imaging Assembly onboard the Solar Dynamics Observatory (SDO/AIA) indicate that the evolution of these small microflares is more similar to that of large flares than to the single burst of energy expected for a nanoflare.
RHESSI Nuggets #396 Dec **2020** https://sprg.ssl.berkeley.edu/~tohban/wiki/index.php/Investigation_of_Small-Scale_Energy_Releases_in_Hard_X-rays_with_%E2%80%8BFOXSI

ENERGETIC PARTICLES IN THE SOLAR ATMOSPHERE **Review**

N. **Vilmer**1 and S. Musset2
SF2A-2019: Proceedings of the Annual meeting of the French Society of Astronomy and Astrophysics. Eds.: P. Di Matteo, O. Creevey, A. Crida, G. Kordopatis, J. Malzac, J.-B. Marquette, M. N'Diaye, O. Venot, **2019**, pp 283-289
http://sf2a.eu/proceedings/2019/2019/vilmer.pdf
http://sf2a.eu/proceedings/2019/2019sf2a.conf..0283V.pdf
The Sun is an efficient particle accelerator. These particles play a major role in the active Sun because they contain a large amount of the magnetic energy released during flares. Energetic electrons and ions interact with the solar atmosphere and produce high-energy X-rays and γ-rays. Energetic particles can also escape to the corona and interplanetary medium and may eventually reach the Earth's orbit. It is currently admitted that solar flares are powered by magnetic energy previously stored in the coronal magnetic field and that magnetic energy release is likely to occur on coronal current sheets along regions of strong gradient of magnetic connectivity. Particle transport from the

acceleration region to the emission sites must also be considered to infer properties of the accelerated particles (and thus of the acceleration processes) from the observations of their radiation. In this paper, we will present the results of some recent studies using RHESSI observations: relationship found in some flares between ribbons of electric currents observed at the photospheric level and the flare energetic electrons traced by their X-ray emissions. We will also present some results on electron transport in solar flares and comment on the role of scattering in this process. We will finally describe some recent results from FERMI/LAT observations on the production of GeV protons in connection with solar flares and/or coronal mass ejections. **23 July 2002, 21 May 2004, 15 Feb 2011, 2014 February 25**

Energetic electrons in the solar atmosphere as diagnosed from their radio and Hard X-ray signatures.

Nicole **Vilmer**∗1 and Hamish Reid
CESRA **2016** p.66
http://cesra2016.sciencesconf.org/conference/cesra2016/pages/CESRA2016_prog_abs_book_v3.pdf
Efficient particle acceleration is observed in association with solar flares. X-ray and radio emissions provide valuable information on the properties of electron acceleration, interaction and propagation in the solar atmosphere. In particular, radio emission from electron beams produced in association with solar flares provides crucial information on the relationship and connections between energetic electrons in the corona and electrons measured in situ. In this talk, we will address the question of the relation between escaping electrons that generate type III emissions in the corona and in the interplanetary medium and electrons confined to the lower atmosphere of the Sun that produce HXRs. We will present here the results of a study based on ten years of data (2002-2011) starting with a selection of 'coronal' type III bursts above 100 MHz. We use X-ray flare information from RHESSI (flares above 6 keV) to produce a list of more than 300 coronal type III bursts associated with X-ray emissions (see Reid and Vilmer, 2016). For these associated events, we will characterize the relative timings, the X-ray and radio intensities and the associated GOES class. We will also examine the percentage of the 'coronal' type III bursts associated with an interplanetary signature (i.e. an interplanetary type III burst detected below 12 MHz by the Wind/Waves experiment) and whether the association between coronal types III and interplanetary types III depends on the characteristics of the propagating electron beams. We will further describe how these studies can be continued in the future using the combination of ground-based measurements with Solar Orbiter and Solar Probe + observations.

Properties of Energetic Ions in the Solar Atmosphere from γ-Ray and Neutron Observations

N. **Vilmer**, A. L. MacKinnon and G. J. Hurford
Space Sci. Rev., 159:167–224, **2011, File** **A Review**
Gamma-rays and neutrons are the only sources of information on energetic ions present during solar flares and on properties of these ions when they interact in the solar atmosphere. The production of γ-rays and neutrons results from convolution of the nuclear cross-sections with the ion distribution functions in the atmosphere. The observed γ-ray and neutron fluxes thus provide useful diagnostics for the properties of energetic ions, yielding strong constraints on acceleration mechanisms as well as properties of the interaction sites. The problem of ion transport between the accelerating and interaction sites must also be addressed to infer as much information as possible on the properties of the primary ion accelerator. In the last couple of decades, both theoretical and observational developments have led to substantial progress in understanding the origin of solar γ-rays and neutrons. This chapter reviews recent developments in the study of solar γ-rays and of solar neutrons at the time of the RHESSI era. The unprecedented quality of the RHESSI data reveals γ-ray line shapes for the first time and provides γ-ray images. Our previous understanding of the properties of energetic ions based on measurements from the former solar cycles is also summarized. The new results—obtained owing both to the gain in spectral resolution (both with RHESSI and with the non solar-dedicated INTEGRAL/SPI instrument) and to the pioneering imaging technique in the γ-ray domain—are presented in the context of this previous knowledge. Still open questions are emphasized in the last section of the chapter and future perspectives on this field are briefly discussed.

Numerical Simulation of a Solar Active Region. I: Bastille Day Flare

Alain **Vincent**, Paul Charbonneau and Caroline Dubé
Solar Physics, Volume 278, Number 2 (**2012**), 367-391
We present three-dimensional unsteady modeling and numerical simulations of a coronal active region, carried out within the compressible single-fluid MHD approximation. We focus on AR 9077 on **14 July 2000**, and the triggering of the X5.7 GOES X-ray class "Bastille Day" flare. We simulate only the lower corona, although we include a virtual photosphere and chromosphere below. The boundary conditions at the base of this layer are set using temperature maps from line intensities and line-of-sight magnetograms (SOHO/MDI). From the latter, we generate vector magnetograms using the force-free approximation; these vector magnetograms are then used to produce the boundary condition on the

velocity field using a minimum energy principle (Longcope, Astrophys. J. 612, 1181, 2004). The reconnection process is modeled through a dynamical hyper-resistivity which is activated when the current exceeds a critical value (Klimas et al., J. Geophys. Res. 109, 2218, 2004). Comparing the time series of X-ray fluxes recorded by GOES with modeled time series of various mean physical variables such as current density, Poynting energy flux, or radiative loss inside the active region, we can demonstrate that the model properly captures the evolution of an active region over a day and, in particular, is able to explain the initiation of the flare at the observed time.

Non-LTE inversions of a confined X2.2 flare: I. Vector magnetic field in the photosphere and chromosphere

G. J. M. **Vissers**, S. Danilovic, J. de la Cruz Rodriguez, J. Leenaarts, R. Morosin, C. J. Diaz Baso, A. Reid, J. Pomoell, D. J. Price, S. Inoue

A&A 645, A1 **2021**

https://arxiv.org/pdf/2009.01537.pdf

https://doi.org/10.1051/0004-6361/202038900

Context. Obtaining an accurate measurement of magnetic field vector in the solar atmosphere is essential for studying changes in field topology during flares and reliably modelling space weather.

Aims. We tackle this problem by applying various inversion methods to a confined X2.2 flare that occurred in NOAA AR 12673 on **6 September 2017** and comparing the photospheric and chromospheric magnetic field vector with the results of two numerical models of this event.

Methods. We obtained the photospheric magnetic field from Milne-Eddington and (non-)local thermal equilibrium (non-LTE) inversions of Hinode SOT/SP Fe I 6301.5 Å and 6302.5 Å. The chromospheric field was obtained from a spatially regularised weak-field approximation (WFA) and non-LTE inversions of Ca II 8542 Å observed with CRISP at the Swedish 1 m Solar Telescope. We investigated the field strengths and photosphere-to-chromosphere shear in the field vector.

Results. The LTE- and non-LTE-inferred photospheric magnetic field components are strongly correlated across several optical depths in the atmosphere, with a tendency towards a stronger field and higher temperatures in the non-LTE inversions. For the chromospheric field, the non-LTE inversions correlate well with the spatially regularised WFA, especially in terms of the line-of-sight field strength and field vector orientation. The photosphere exhibits coherent strong-field patches of over 4.5 kG, co-located with similar concentrations exceeding 3 kG in the chromosphere. The obtained field strengths are up to two to three times higher than in the numerical models, while the photosphere-to-chromosphere shear close to the polarity inversion line is more concentrated and structured.

Conclusions. In the photosphere, the assumption of LTE for Fe I line formation does not yield significantly different magnetic field results in comparison to the non-LTE case, while Milne-Eddington inversions fail to reproduce the magnetic field vector orientation where Fe I is in emission. In the chromosphere, the non-LTE-inferred field is excellently approximated by the spatially regularised WFA. Our inversions confirm the locations of flux rope footpoints that have been predicted by numerical models. However, pre-processing and lower spatial resolution lead to weaker and smoother field in the models than what our data indicate. This highlights the need for higher spatial resolution in the models to better constrain pre-eruptive flux ropes.

Ellerman bombs at high resolution III. Simultaneous observations with IRIS and SST

Gregal J. M. **Vissers**, Luc H. M. Rouppe van der Voort, Robert J. Rutten, Mats Carlsson, Bart De Pontieu

ApJ 812 11 **2015**

http://arxiv.org/pdf/1507.00435v1.pdf

Ellerman bombs are transient brightenings of the extended wings of the solar Balmer lines in emerging active regions. We describe their properties in the ultraviolet lines sampled by the Interface Region Imaging Spectrograph (IRIS), using simultaneous imaging spectroscopy in Hα with the Swedish 1-m Solar Telescope (SST) and ultraviolet images from the Solar Dynamics Observatory for Ellerman bomb detection and identification. We select multiple co-observed Ellerman bombs for detailed analysis. The IRIS spectra strengthen the view that Ellerman bombs mark reconnection between bipolar kilogauss fluxtubes with the reconnection and the resulting bi-directional jet located within the solar photosphere and shielded by overlying chromospheric fibrils in the cores of strong lines. The spectra suggest that the reconnecting photospheric gas underneath is heated sufficiently to momentarily reach stages of ionization normally assigned to the transition region and the corona. We also analyze similar outburst phenomena that we classify as small flaring arch filaments and ascribe to higher-located reconnection. They have different morphology and produce hot arches in million-Kelvin diagnostics. **2013 Sep 6, 2014 Jun 14, 2014 Jun 15**

Variation of the electron flux spectrum along a solar flare loop as inferred from STIX hard X-ray observations

Anna **Volpara**, Paolo Massa, Sam Krucker, A Gordon Emslie, Michele Piana, Anna Maria Massone

A&A 684, A185 (**2024**)

https://arxiv.org/pdf/2311.07148.pdf
Regularized imaging spectroscopy was introduced for the construction of electron flux images at different energies from count visibilities recorded by the Reuven Ramaty High Energy Solar Spectroscopic Imager (RHESSI). In this work we seek to extend this approach to data from the Spectrometer/Telescope for Imaging X-rays (STIX) on-board the Solar Orbiter mission. Our aims are to demonstrate the feasibility of regularized imaging spectroscopy as a method for analysis of STIX data, and also to show how such analysis can lead to insights into the physical processes affecting the nonthermal electrons responsible for the hard X-ray emission observed by STIX. STIX records imaging data in an intrinsically different manner from RHESSI. Rather than sweeping the angular frequency plane in a set of concentric circles (one circle per detector), STIX uses 30 collimators, each corresponding to a specific angular frequency. In this paper we derive an appropriate modification of the previous computational approach for the analysis of the visibilities observed by STIX. This approach also allows for the observed count data to be placed into non-uniformly-spaced energy bins. We show that the regularized imaging spectroscopy approach is not only feasible for analysis of the visibilities observed by STIX, but also more reliable. Application of the regularized imaging spectroscopy technique to several well-observed flares reveals details of the variation of the electron flux spectrum throughout the flare sources. We conclude that the visibility-based regularized imaging spectroscopy approach is well-suited to analysis of STIX data. We also use STIX electron flux spectral images to track, for the first time, the behavior of the accelerated electrons during their path from the acceleration site in the solar corona toward the chromosphere . **2021-05-08, 2022-09-29**

Role of electron inertia and reconnection dynamics in a stressed X-point collapse with a guide-field

J. Graf **von der Pahlen** and D. Tsiklauri
A&A 595, A84 (**2016**)
Aims. In previous simulations of collisionless 2D magnetic reconnection it was consistently found that the term in the generalised Ohm’s law that breaks the frozen-in condition is the divergence of the electron pressure tensor’s non-gyrotropic components. The motivation for this study is to investigate the effect of the variation of the guide-field on the reconnection mechanism in simulations of X-point collapse, and the related changes in reconnection dynamics.
Methods. A fully relativistic particle-in-cell (PIC) code was used to model X-point collapse with a guide-field in two and three spatial dimensions.
Results. We show that in a 2D X-point collapse with a guide-field close to the strength of the in-plane field, the increased induced shear flows along the diffusion region lead to a new reconnection regime in which electron inertial terms play a dominant role at the X-point. This transition is marked by the emergence of a magnetic island – and hence a second reconnection site – as well as electron flow vortices moving along the current sheet. The reconnection electric field at the X-point is shown to exceed all lower guide-field cases for a brief period, indicating a strong burst in reconnection. By extending the simulation to three spatial dimensions it is shown that the locations of vortices along the current sheet (visualised by their Q-value) vary in the out-of-plane direction, producing tilted vortex tubes. The vortex tubes on opposite sides of the diffusion region are tilted in opposite directions, similarly to bifurcated current sheets in oblique tearing-mode reconnection. The tilt angles of vortex tubes were compared to a theoretical estimation and were found to be a good match. Particle velocity distribution functions for different guide-field runs, for 2.5D and 3D simulations, are analysed and compared.

Magnetic Reconnection in an X-point Collapse

Jan Graf **von der Pahlen** and D. Tsiklauri
UKSP Nugget: 41. Dec **2013**
http://www.uksolphys.org/uksp-nugget/41-magnetic-reconnection-in-an-x-point-collapse/
The research presented in this nugget [3] is an extension of the works of [1,2], where collisionless magnetic reconnection in a stressed X-point collapse was investigated using a 2.5D PIC code (i.e. a PIC code over a domain with two spatial dimensions and three particle velocity components). The same set-up was used in this simulation, also including ‘closed’ boundary conditions, where particles are reflected at the boundary and magnetic flux is conserved, fixing magnetic field lines. The alternative boundary conditions introduced here are ‘open’ i.e. allowing particles and magnetic flux to escape at the boundary. Further, a uniform out-of-plane magnetic field (guide-field), ranging from 0.1 to 1 the characteristic in-plane field strength (BP), was introduced.

Contrastive Representation Learning for Predicting Solar Flares from Extremely Imbalanced Multivariate Time Series Data

Onur **Vural**, Shah Muhammad Hamdi, Soukaina Filali Boubrahimi
ICMLA 2024 on September 7 **2024**
https://arxiv.org/pdf/2410.00312
Major solar flares are abrupt surges in the Sun's magnetic flux, presenting significant risks to technological infrastructure. In view of this, effectively predicting major flares from solar active region magnetic field data through machine learning methods becomes highly important in space weather research. Magnetic field data can be represented

in multivariate time series modality where the data displays an extreme class imbalance due to the rarity of major flare events. In time series classification-based flare prediction, the use of contrastive representation learning methods has been relatively limited. In this paper, we introduce CONTREX, a novel contrastive representation learning approach for multivariate time series data, addressing challenges of temporal dependencies and extreme class imbalance. Our method involves extracting dynamic features from the multivariate time series instances, deriving two extremes from positive and negative class feature vectors that provide maximum separation capability, and training a sequence representation embedding module with the original multivariate time series data guided by our novel contrastive reconstruction loss to generate embeddings aligned with the extreme points. These embeddings capture essential time series characteristics and enhance discriminative power. Our approach shows promising solar flare prediction results on the Space Weather Analytics for Solar Flares (SWAN-SF) multivariate time series benchmark dataset against baseline methods.

Solar Flare Prediction and Feature Selection using Light Gradient Boosting Machine Algorithm

Vysakh P. A., Prateek Mayank
Solar Phys. 298, Article number: 137 **2023**
https://arxiv.org/pdf/2310.19332.pdf
Solar flares are among the most severe space weather phenomena, and they have the capacity to generate radiation storms and radio disruptions on Earth. The accurate prediction of solar flare events remains a significant challenge, requiring continuous monitoring and identification of specific features that can aid in forecasting this phenomenon, particularly for different classes of solar flares. In this study, we aim to forecast C and M class solar flares utilising a machine-learning algorithm, namely the Light Gradient Boosting Machine. We have utilised a dataset spanning 9 years, obtained from the Space-weather Helioseismic and Magnetic Imager Active Region Patches (SHARP), with a temporal resolution of 1 hour. A total of 37 flare features were considered in our analysis, comprising of 25 active region parameters and 12 flare history features. To address the issue of class imbalance in solar flare data, we employed the Synthetic Minority Oversampling Technique (SMOTE). We used two labeling approaches in our study: a fixed 24-hour window label and a varying window that considers the changing nature of solar activity. Then, the developed machine learning algorithm was trained and tested using forecast verification metrics, with an emphasis on evaluating the true skill statistic (TSS). Furthermore, we implemented a feature selection algorithm to determine **the most significant features from the pool of 37 features that could distinguish between flaring and non-flaring active regions**. We found that utilising a limited set of useful features resulted in improved prediction performance. For the 24-hour prediction window, we achieved a TSS of 0.63 (0.69) and accuracy of 0.90 (0.97) for ≥C (≥M) class solar flares.

Solar Flare Detection Method using Rn-222 Radioactive Source

Jonathan **Walg**, Yaniv Zigel, Anatoly Rodnianski, Itzhak Orion
2020
https://arxiv.org/ftp/arxiv/papers/2002/2002.02787.pdf
arXiv:1902.10131
Solar neutrino detection is known to be a very challenging task, due to the minuscule absorption cross-section and mass of the neutrino. One research showed that relative large solar-flares affected the decay-rates of Mn-54 in December 2006. Since most the radiation emitted during a solar flare are blocked before reaching the earth surface, it should be assumed that such decay-rate changes could be due to neutrino flux increase from the sun, in which only neutrinos can penetrate the radionuclide. This study employs the Rn-222 radioactive source for the task of solar flare detection, based on the prediction that it will provide a stable gamma ray counting rate. In order to ascertain counting stability, three counting systems were constructed to track the count-rate changes. The signal processing approach was applied in the raw data analysis. The Rn-222 count-rate measurements showed several radiation counting dips, indicating that the radioactive nuclide can be affected by order of magnitude neutrino flux change from the sun. We conclude that using the cooled Radon source obtained the clearest responses, and therefore this is the preferable system for detecting neutrino emissions from a controlled source.

Pre-Flare Flows in the Corona

A.J. **Wallace** · L.K. Harra · L. van Driel-Gesztelyi · L.M. Green · S.A. Matthews
Solar Phys (**2010**) 267: 361–375
Solar flares take place in regions of strong magnetic fields and are generally accepted to be the result of a resistive instability leading to magnetic reconnection. When new

flux emerges into a pre-existing active region it can act as a flare and coronal mass ejection trigger. In this study we observed active region 10955 after the emergence of small-scale additional flux at the magnetic inversion line. We found that flaring began when additional positive flux levels exceeded 1.38 Ч 10^{20} Mx (maxwell), approximately 7 h after the initial flux emergence. We focussed on the pre-flare activity of one B-class flare that occurred on the following day. The earliest indication of activity was a rise in the non-thermal velocity one hour before the flare. 40 min before flaring began, brightenings and pre-flare flows were observed along two loop systems in the corona, involving the new flux and the preexisting active region loops. We discuss the possibility that reconnection between the new flux and pre-existing loops before the flare drives the flows by either generating slow mode magnetoacoustic waves or a pressure gradient between the newly reconnected loops. The subsequent B-class flare originated from fast reconnection of the same loop systems as the pre-flare flows.

Unveiling key factors in solar eruptions leading to the solar superstorm in 2024 May

NOAA active region (AR) 13664/8 produced the most intense geomagnetic effects since the Halloween event of 2003. The resulting extreme solar storm is thought to be the consequence of multiple interacting coronal mass ejections (CMEs). Notably, this AR exhibits exceptionally rapid magnetic flux emergence. The eruptions on which we focus all occurred along collisional polarity inversion lines (PILs) through collisional shearing during a three-day period of extraordinarily high flux emergence (∼1021 Mx h−1). Our key findings reveal how photospheric magnetic configurations in eruption sources influence solar superstorm formation and geomagnetic responses, and link exceptionally strong flux emergence to sequential homologous eruptions: (1) We identified the source regions of seven halo CMEs that were distributed primarily along two distinct PILs. This distribution suggests two groups of homologous CMEs. (2) The variations in the magnetic flux emergence rates in the source regions are correlated with the CME intensities. This might explain the two contrasting cases of complex ejecta that are observed at Earth. (3) Our calculations of the magnetic field gradients around the CME source regions show strong correlations with eruptions. This provides crucial insights into solar eruption mechanisms and enhances our prediction capabilities for future events.

Exploring Standing and Reflected Slow-mode Waves in Flaring Coronal Loops: A Parametric Study Using 2.5D MHD Modeling

Tongjiang **Wang**, Leon Ofman, Stephen J. Bradshaw

Solar Phys. **299**, 37 **2024**

https://arxiv.org/pdf/2403.02464.pdf

https://doi.org/10.1007/s11207-024-02285-z

Recent observations of reflected propagating and standing slow-mode waves in hot flaring coronal loops have spurred our investigation into their underlying excitation and damping mechanisms. To understand these processes, we conduct 2.5D magnetohydrodynamic (MHD) simulations using an arcade active region model that includes a hot and dense loop. Our simulations allow for in-depth parametric investigations complementing and expanding our previous 3D MHD modeling results. We excite these waves in two distinct models as motivated by observations from the SDO/AIA. Model 1 incorporates classical compressive viscosity coefficient, while Model 2 adopts a 10-times enhanced viscosity coefficient. We find that: (1) Our 2.5D MHD simulations reinforce previous conclusions derived from 1D and 3D MHD models that significantly enhanced viscosity is crucial for the rapid excitation of standing slow waves with damping times consistent with observations by Wang et al. (2015). (2) We uncover that nonlinearity in Model 1 delays the conversion of a reflected propagating wave into a standing wave. In contrast, Model 2 exhibits a much weak influence of nonlinearity. (3) Our results reveal that the transverse temperature structure holds more influence on wave behavior than the density structure. In Model 1, increased loop temperature contrast significantly enhances wave trapping within the structure, mitigating the impact of temperature-dependent viscous damping. Conversely, in Model 2, the impact of temperature structure on wave behavior weakens in comparison to the effect of viscosity. (4) Model 1 displays evident nonlinear coupling to the fast and kink magnetoacoustic waves and pronounced wave leakage into the corona. However, analyzing three observed wave events by SDO/AIA aligns with Model 2 predictions, providing further support for the substantial viscosity increase.

A Strong-flare Prediction Model Developed Using a Machine-learning Algorithm Based on the Video Data Sets of the Solar Magnetic Field of Active Regions

Jingjing **Wang**1,2, Bingxian Luo1,2,3, Siqing Liu1,2,3, and Yue Zhang4

2023 ApJS 269 54
https://iopscience.iop.org/article/10.3847/1538-4365/ad036d/pdf
It is well accepted that the physical properties obtained from the solar magnetic field observations of active regions (ARs) are related to solar eruptions. These properties consist of temporal features that might reflect the evolution process of ARs, and spatial features that might reflect the graphic properties of ARs. In this study, we generated video data sets with timescales of 1 day and image data sets of the SHARP radial magnetic field of the ARs from 2010 May to 2020 December. For the ARs that evolved from "quiet" to "active" and erupted the first strong flares in 4 days, we extract and investigate both the temporal and spatial features of ARs from videos, aiming to capture the evolution properties of their magnetic field structures during their transition process from "quiet" (non–strong flaring) to "active" (strong flaring). We then conduct a comparative analysis of the model performance by video input and single-image input, as well as of the effect of the model performance variation with the prediction window up to 3 days. We find that for those ARs that erupted the first strong flares in 4 days, the temporal features that reflect their evolution from "quiet" to "active" before the first strong flares can be recognized and extracted from the video data sets by our network. These features turn out to be important predictors that can effectively improve strong-flare prediction, especially by reducing the false alarms in a nearly 2 day prediction window.
Introduction

Enhanced three-minute oscillation above a sunspot during a solar flare
Ya **Wang**, Lyndsay Fletcher, Sargam Mulay, Haisheng Ji, Wenda Cao
ApJ **961** 231 **2023**
https://arxiv.org/pdf/2311.17223.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ad10a9/pdf
Three-minute oscillations are a common phenomenon in the solar chromosphere above a sunspot. Oscillations can be affected by the energy release process related to solar flares. In this paper, we report on an enhanced oscillation in flare event SOL**2012-07-05**T21:42 with a period of around three minutes, that occurred at the location of a flare ribbon at a sunspot umbra-penumbra boundary, and was observed both in chromo-spheric and coronal passbands. An analysis of this oscillation was carried out using simultaneous ground-based observations from the Goode Solar Telescope (GST) at the Big Bear Solar Observatory (BBSO) and space-based observations from the Solar Dynamics Observatory (SDO). A frequency shift was observed before and after the flare, with the running penumbral wave that was present with a period of about 200 s before the flare co-existing with a strengthened oscillation with a period of 180 s at the same locations after the flare. We also found a phase difference between different passbands, with the oscillation occurring from high-temperature to low-temperature passbands. Theoretically, the change in frequency is strongly dependent on the variation of the inclination of the magnetic field and the chromospheric temperature. Following an analysis of the properties of the region, we find the frequency change is caused by the slight decrease of the magnetic inclination angle to the local vertical. In addition, we suggest that the enhanced three-minute oscillation is related to the additional heating, maybe due to the downflow, during the EUV late phase of the flare.

Spectral Features of the Solar Transition Region and Chromospheric Lines at Flare Ribbons Observed with IRIS
L. F. **Wang**1,2, Y. Li3,4, Q. Li3,4, X. Cheng1,2, and M. D. Ding1,2
2023 ApJS 268 62
https://arxiv.org/pdf/2308.11275.pdf
https://iopscience.iop.org/article/10.3847/1538-4365/acf127/pdf
We report on the spectral features of the Si ivλ1402.77, C iiλ1334.53, and Mg iih or k lines, formed in the layers from the transition region to the chromosphere, in three two-ribbon flares (with X, M, and C class) observed with IRIS. All three lines show significant redshifts within the main flare ribbons, which mainly originate from the chromospheric condensation during the flares. The average redshift velocities of the Si iv line within the main ribbons are 56.6, 25.6, and 10.5 km s−1 for the X-, M-, and C-class flares, respectively, which show a decreasing tendency with the flare class. The C ii and Mg ii lines show a similar tendency but with smaller velocities compared to the Si iv line. Additionally, the Mg iih or k line shows a blue-wing enhancement in the three flares, in particular at the flare ribbon fronts, which is supposed to be caused by an upflow in the upper chromosphere due to the heating of the atmosphere. Moreover, the Mg iih or k line exhibits a central reversal at the flare ribbons but turns to pure emission shortly after 1–4 minutes. Correspondingly, the C ii line also shows a central reversal but in a smaller region. However, for the Si iv line, the central reversal is only found in the X-class flare. As usual, the central reversal of these lines can be caused by the opacity effect. This implies that, in addition to the optically thick lines (C ii and Mg ii lines), the Si iv line can become optically thick in a strong flare, which is likely related to the nonthermal electron beam heating. **2015 Dec 19, 2022 Jan 18, 2022 Mar 30**

Three-dimensional Turbulent Reconnection within Solar Flare Current Sheet
Yulei **Wang**, Xin Cheng, Mingde Ding, Zhaoyuan Liu, Jian Liu, Xiaojue Zhu

ApJL **954** L36 **2023**
https://arxiv.org/pdf/2308.10494.pdf
https://iopscience.iop.org/article/10.3847/2041-8213/acf19d/pdf
Solar flares can release coronal magnetic energy explosively and may impact the safety of near-earth space environments. Their structures and properties on macroscale have been interpreted successfully by the generally-accepted two-dimension standard model invoking magnetic reconnection theory as the key energy conversion mechanism. Nevertheless, some momentous dynamical features as discovered by recent high-resolution observations remain elusive. Here, we report a self-consistent high-resolution three-dimension magnetohydrodynamical simulation of turbulent magnetic reconnection within a flare current sheet. It is found that fragmented current patches of different scales are spontaneously generated with a well-developed turbulence spectrum at the current sheet, as well as at the flare loop-top region. The close coupling of tearing-mode and Kelvin-Helmholtz instabilities plays a critical role in developing turbulent reconnection and in forming dynamical structures with synthetic observables in good agreement with realistic observations. The sophisticated modeling makes a paradigm shift from the traditional to three-dimension turbulent reconnection model unifying flare dynamical structures of different scales.

Towards a live homogeneous database of solar active regions based on SOHO/MDI and SDO/HMI synoptic magnetograms. I. Automatic detection and calibration

Ruihui **Wang**, Jie Jiang, Yukun Luo
Astrophysical Journal Supplement Series **268** 55 **2023**
https://arxiv.org/pdf/2308.06914.pdf **File**
https://iopscience.iop.org/article/10.3847/1538-4365/acef1b/pdf **File**
Recent studies indicate that a small number of rogue solar active regions (ARs) may have a significant impact on the end-of-cycle polar field and the long-term behavior of solar activity. The impact of individual ARs can be qualified based on their magnetic field distribution. This motivates us to build a live homogeneous AR database in a series of papers. As the first of the series, we develop a method to automatically detect ARs from 1996 onwards based on SOHO/MDI and SDO/HMI synoptic magnetograms. The method shows its advantages in excluding decayed ARs and unipolar regions and being compatible with any available synoptic magnetograms. The identified AR flux and area are calibrated based on the co-temporal SDO/HMI and SOHO/MDI data. The homogeneity and reliability of the database are further verified by comparing it with other relevant databases. We find that ARs with weaker flux have a weaker cycle dependence. Stronger ARs show the weaker cycle 24 compared with cycle 23. Several basic parameters, namely, location, area, and flux of negative and positive polarities of identified ARs are provided in the paper. This paves the way for AR's new parameters quantifying the impact on the long-term behavior of solar activity to be presented in the subsequent paper of the series. The constantly updated database covering more than two full solar cycles will be beneficial for the understanding and prediction of the solar cycle. The database and the detection codes are accessible online.
The detection algorithm and full database of detected ARs are freely accessible at https://github.com/Wang-Ruihui/Alive-homogeneous-database-of-solar-active-regions

Change ratios of magnetic helicity and magnetic free energy during major solar flares

Quan **Wang**, Mei Zhang, Shangbin Yang, Xiao Yang, Xiaoshuai Zhu
RAA **2023**
https://arxiv.org/pdf/2308.05366.pdf **File**
Magnetic helicity is an important concept in solar physics, with a number of theoretical statements pointing out the important role of magnetic helicity in solar flares and coronal mass ejections (CMEs). Here we construct a sample of 47 solar flares, which contains **18 no-CME-associated confined flares and 29 CME-associated eruptive flares**. We calculate the change ratios of magnetic helicity and magnetic free energy before and after these 47 flares. Our calculations show that the change ratios of magnetic helicity and magnetic free energy show distinct different distributions in confined flares and eruptive flares. The median value of the change ratios of magnetic helicity in confined flares is −0.8%, while this number is −14.5% for eruptive flares. For the magnetic free energy, the median value of the change ratios is −4.3% for confined flares, whereas this number is −14.6% for eruptive flares. This statistical result, using observational data, is well consistent with the theoretical understandings that magnetic helicity is approximately conserved in the magnetic reconnection, as shown by confined flares, and the CMEs take away magnetic helicity from the corona, as shown by eruptive flares.
Table 1. Information and results of the **18 confined flare** events 2012-2017
Table 2. Information and results of the **29 eruptive flare** events 2011-2017

Sequential Remote Brightenings and Co-spatial Fast Downflows during Two Successive Flares

B. T. **Wang**, X. Cheng, C. Li, J. Chen, M. D. Ding
ApJ **953** 172 **2023**

https://arxiv.org/pdf/2306.15991.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ace319/pdf
Remote brightenings often appear at outskirts of source active regions of solar eruptive events, nevertheless, their origin remains to be ascertained. In this study, we report imaging and spectroscopic observations of sequential remote brightenings with a combination of Hα Imaging Spectrograph (HIS) onboard the Chinese Hα Solar Explorer (CHASE), which is the first space-based solar telescope of China, and the Solar Dynamics Observatory. It is found that, during two successive M-class flares occurring on **2022 August 17**, multiple ribbon-like brightenings appeared in sequence away from the flaring active region. Meanwhile, abundant cool filament materials moved downward to the sequential remote brightenings as visible at the Hα red wing with a line-of-sight speed up to 70 km s−1. The extrapolated three-dimensional magnetic field configuration shows that the sequential remote brightenings correspond to the footpoints of closed ambient field lines whose conjugate footpoints are rooted in the main flare site. We suggest that the sequential remote brightenings are most likely caused by the heating of interchange reconnection between the erupting flux rope and closed ambient field, during which the rope-hosting filament materials are transferred to the periphery of flaring active region along the closed ambient field rather than to the interplanetary space like in the scenario of the slow solar wind formation.

Efficient Electron Acceleration Driven by Flux Rope Evolution during Turbulent Reconnection

Z. **Wang**1,2, A. Vaivads2, H. S. Fu1,3, J. B. Cao1,3, and Y. Y. Liu1,3
2023 ApJ 946 39
https://iopscience.iop.org/article/10.3847/1538-4357/acbd3e/pdf
Magnetic flux ropes or magnetic islands are important structures responsible for electron acceleration and energy conversion during turbulent reconnection. However, the evolution of flux ropes and the corresponding electron acceleration process still remain open questions. In this paper, we present a comparative study of flux ropes observed by the Magnetospheric Multiscale mission in the outflow region during an example of turbulent reconnection in Earth's magnetotail. Interestingly, we find the farther the flux rope is away from the X-line, the bigger the size of the flux rope and the slower it moves. We estimate the power density converted at the observed flux ropes via the three fundamental electron acceleration mechanisms: Fermi, betatron, and parallel electric field. The dominant acceleration mechanism at all three flux ropes is the betatron mechanism. The flux rope that is closest to the X-line, having the smallest size and the fastest moving velocity, is the most efficient in accelerating electrons. Significant energy also returns from particles to fields around the flux ropes, which may facilitate the turbulence in the reconnection outflow region. **2020 August 3**

Precursor Identification for Strong Flares Based On Anomaly Detection Algorithm

Jingjing **Wang**, Bingxian Luo, and Siqing Liu
Front. Astron. Space Sci. 9:1037863. **2022**
doi: 10.3389/fspas.2022.1037863
https://www.frontiersin.org/articles/10.3389/fspas.2022.1037863/pdf
In this study, we assume that the magnetic configuration of active regions (ARs) in quiet periods has certain similarities and can be considered “normal” features. While there are some other magnetic features of active regions that are related to strong flares, they can be considered the precursor of strong flares and “anomaly” features. Our study aims to identify those “anomalies” and apply them in strong-flare forecasting. An unsupervised auto-encoder network has been used to understand and memorize these “normal” features, and then, based on the mean squared errors between the pictures of the ARs and the corresponding reconstructed pictures derived by the network, an anomaly detection algorithm has been adopted to identify the precursor for strong flares and develop a strong-flare classification model. The strong-flare classification model reaches an F1 score of 0.8139, an accuracy of 0.8954, a recall of 0.8785, and a precision of 0.7581. Moreover, for those correctly predicted strong-flare events (94 M-class flares and above), the model reaches an average first warning time of 45.24 h. The results indicate that the anomaly detection algorithm can be used in precursor identification for strong flares and help in both improving strong-flare prediction accuracy and enlarging the time in advance. Also, the obtained average maximum warning period for strong-flare prediction (nearly 2 days) will be useful for future applications for space-weather solar flare prediction. **15 Feb 2011. 22 Oct 2014**

Current-sheet Oscillations Caused by Kelvin-Helmholtz Instability at the Loop Top of Solar Flares

Yulei **Wang**, Xin Cheng, Zining Ren, Mingde Ding
ApJL **931** L32 **2022**
https://arxiv.org/pdf/2205.10361.pdf
https://iopscience.iop.org/article/10.3847/2041-8213/ac715a/pdf
Current sheets (CSs), long stretching structures of magnetic reconnection above solar flare loops, are usually observed to oscillate, their origins, however, are still puzzled at present. Based on a high-resolution 2.5-dimensional MHD simulation of magnetic reconnection, we explore the formation mechanism of the CS oscillations. We find that large-

amplitude transverse waves are excited by the Kelvin-Helmholtz instability (KHI) at the highly turbulent cusp-shaped region. The perturbations propagate upward along the CS with a phase speed close to local Alfvén speed thus resulting in the CS oscillations we observe. Though the perturbations damp after propagating for a long distance, the CS oscillations are still detectable. In terms of detected CS oscillations, with a combination of differential emission measure technique, we propose a new method for measuring the magnetic field strength of the CSs and its distribution in height. **2011-10-22**

Annihilation of Magnetic Islands at the Top of Solar Flare Loops

Yulei **Wang**, Xin Cheng, Mingde Ding, Quanming Lu
ApJ 923:227 **2021**
https://arxiv.org/pdf/2110.08526.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ac3142/pdf
The dynamics of magnetic reconnection in the solar current sheet (CS) is studied by high-resolution 2.5-dimensional MHD simulation. With the commence of magnetic reconnection, a number of magnetic islands are formed intermittently and move quickly upward and downward along the CS. When colliding with the semi-closed flux of flare loops, the downflow islands cause a second reconnection with a rate even comparable with that in the main CS. Though the time-integrated magnetic energy release is still dominated by the reconnection in main CS, the second reconnection can release substantial magnetic energy, annihilating the main islands and generating secondary islands with various scales at the flare loop top. The distribution function of the flux of the second islands is found to follow a power-law varying from $f(\psi)\sim\psi-1$ (small scale) to $\psi-2$ (large scale), which seems to be independent with background plasma β and if including thermal conduction. However, the spatial scale and the strength of the termination shocks driven by main reconnection outflows or islands decrease if β increases or thermal conduction is included. We suggest that the annihilation of magnetic islands at the flare loop top, which is not included in the standard flare model, plays a non-negligible role in releasing magnetic energy to heat flare plasma and accelerate particles.

Slow-Mode Magnetoacoustic Waves in Coronal Loops **Review**

Tongjiang **Wang**, Leon Ofman, Ding Yuan, Fabio Reale, Dmitrii Y. Kolotkov, Abhishek K. Srivastava
Space Science Reviews **2021**
https://arxiv.org/pdf/2102.11376.pdf
Rapidly decaying long-period oscillations often occur in hot coronal loops of active regions associated with small (or micro-) flares. This kind of wave activity was first discovered with the SOHO/SUMER spectrometer from Doppler velocity measurements of hot emission lines, thus also often called "SUMER" oscillations. They were mainly interpreted as global (or fundamental mode) standing slow magnetoacoustic waves. In addition, increasing evidence has suggested that the decaying harmonic type of pulsations detected in light curves of solar and stellar flares are likely caused by standing slow-mode waves. The study of slow magnetoacoustic waves in coronal loops has become a topic of particular interest in connection with coronal seismology. We review recent results from SDO/AIA and Hinode/XRT observations that have detected both standing and reflected intensity oscillations in hot flaring loops showing the physical properties (e.g., oscillation periods, decay times, and triggers) in accord with the SUMER oscillations. We also review recent advances in theory and numerical modeling of slow-mode waves focusing on the wave excitation and damping mechanisms. MHD simulations in 1D, 2D and 3D have been dedicated to understanding the physical conditions for the generation of a reflected propagating or a standing wave by impulsive heating. Various damping mechanisms and their analysis methods are summarized. Calculations based on linear theory suggest that the non-ideal MHD effects such as thermal conduction, compressive viscosity, and optically thin radiation may dominate in damping of slow-mode waves in coronal loops of different physical conditions. Finally, an overview is given of several important seismological applications such as determination of transport coefficients and heating function.

Naked emergence of an anti-Hale active region
I. Overall evolution and magnetic properties⋆

Jincheng **Wang**1,2,3, Xiaoli Yan1,3, Defang Kong1,3, Zhike Xue1,3, Liheng Yang1,3, Qiaoling Li1,4, Yan Zhang1,4 and Hao Li5,6

https://doi.org/10.1051/0004-6361/202140685
Aims. In order to understand the emergence of the active region, we investigate the emerging process and magnetic properties of a naked anti-Hale active region during the period between **August 24 to 25, 2018**.
Methods. Using the data from Helioseismic and Magnetic Imager on board the Soar Dynamic Observatory and the New Vacuum Solar Telescope, we calculated different evolving parameters (such as pole separation, tilt angle) and magnetic parameters (such as vertical electric current, force-free parameter, relative magnetic helicity) during the emergence of the active region. With these calculated parameters and some reasonable assumptions, we use two different methods to estimate the twist of the active region.

Results. The magnetic flux and pole separation continue increasing while the tilt angle exhibits a decreasing pattern during the emergence of the active region. The increase of the pole separation is mainly contributed as a result of the enhancement in the longitude direction. A power-law relationship between pole separation and total flux is found during the emergence of the active region. On the other hand, it is found that both the positive and negative electric currents increased equivalently and the average flux-weighted force-free parameter $\tilde{\alpha}$ remains almost consistently positive, on the order of ∼10−8 m−1. The relative magnetic helicity is mainly contributed by the shear term, while the relative magnetic helicity injection flux of the shear term changes its sign at the latter stage of the emergence. The twist number of the whole active region remains on the order of 10−1 turns during the emergence of the active region. Conclusions. We find that the magnetic flux tube with low twist also could emerge into the solar atmosphere.

Erupting Magnetic Flux Rope Affects Running Penumbral Waves

Wensi **Wang**, Rui Liu
A&A **2021**
https://arxiv.org/pdf/2101.04915.pdf
Context. It is well known that solar flares have broad impacts on the low atmosphere, but it is largely unknown how they affect sunspot waves and oscillations. It is also under debate as to whether the flare-induced photospheric changes are due to the momentum conservation with coronal mass ejections or due to magnetic reconnection. Aims. To shed light on the so-called "back reaction" of solar eruptions, we investigated how running penumbral waves (RPWs) at one foot of an erupting magnetic flux rope (MFR) responds to the rope buildup and subsequent erosion. Results. During the rope-buildup stage, the western foot of the rope, which is completely enclosed by a hooked ribbon, expands rapidly and consequently overlaps a sunspot penumbra. This converts the original penumbral field into the rope field, which is associated with a transient increase in electric currents flowing through the ribbon-swept penumbral region. During the rope-erosion stage, the rope foot shrinks as the eastern section of the hooked ribbon slowly sweeps the same penumbral region, where the rope field is converted into flare loops. This conversion induces mixed effects on the photospheric field inclination but heats up the low atmosphere at the footpoints of these flare loops to transition-region temperatures, therefore resulting in the post-eruption RPWs with an enhanced contrast in the 1600A passband and an extended bandwidth to low frequencies at 3-5 mHz, compared with the pre-eruption RPWs that peak at 6 mHz. Conclusions. This observation clearly demonstrates that it is the magnetic reconnection in the corona that impacts the low atmosphere and leads to the changing behaviors of RPWs, which, in turn, offer a new window to diagnose flare reconnections. **2015 November 4**

High-resolution He I 10830 Å Narrowband Imaging for an M-class Flare. III. EUV Late Phase

Ya **Wang**1,2, Haisheng Ji1,3, Alexander Warmuth4, Ying Li1, and Wenda Cao5
2020 ApJ 905 126
https://doi.org/10.3847/1538-4357/abc47a
In this paper, we report the EUV late phase for the M1.8 class flare on **2012 July 5** in the active region (AR) 11515. The late phase is shown by the prominent appearance of EUV emission at 131 Å of two additional flare loop systems (flare arcades 2 and 3, as named in this paper) other than the main flare loop (flare arcade 1), as observed by the Atmospheric Imaging Assembly (AIA) on board the Solar Dynamic Observatory (SDO). Three sets of flare arcades connect four flare ribbons, which forms an asymmetric quadrupole magnetic field configuration. While the emission from flare arcade 2, linking the pair of secondary flare ribbons, and arcade 3, linking one of the main flare ribbons and one of the secondary flare ribbons, conjointly contributes to the EUV late phase, their heating mechanisms are quite different. While the brightening of flare arcade 2 is the result of disturbance created by the eruption of EUV hot channels to the overlying coronal magnetic field, the heating of flare arcade 3 was closely associated with two rapid contractions of the overlying filament threads during the partial eruption of the filament. The contractions are discernible in He i 10830 Å images and have signatures in the EUV wavelengths of AIA. The two rapid contractions are the result of a sudden drop in magnetic pressure after the eruption of two hot channels. Clear evidence suggests that magnetic reconnection may occur between the contracting filament threads and the low-lying magnetic field.

Solar Flare Predictive Features Derived from Polarity Inversion Line Masks in Active Regions Using an Unsupervised Machine Learning Algorithm

Jingjing **Wang**, Yuhang Zhang, Shea A. Hess Webber, Siqing Liu, Xuejie Meng, and Tieyan Wang
2020 ApJ 892 140
https://doi.org/10.3847/1538-4357/ab7b6c
sci-hub.tw/10.3847/1538-4357/ab7b6c
The properties of the polarity inversion line (PIL) in solar active regions (ARs) are strongly correlated to flare occurrences. The PIL mask, enclosing the PIL areas, has shown significant potential for improving machine-learning-based flare prediction models. In this study, an unsupervised machine-learning algorithm, Kernel Principle Component Analysis (KPCA), is adopted to directly derive features from the PIL mask and difference PIL mask, and use those features to classify ARs into two categories—non-strong flaring ARs and strong-flaring (M-class and above flares) ARs—for time-in-advance from one hour to 72 hr at a 1 hr cadence. The two best features are selected from the KPCA results to develop random-forest classifiers for predicting flares, and the models are then evaluated and compared to similar models based on the R value and difference R value. The results show that the features derived from the PIL masks by KPCA are effective in predicting flare occurrence, with overall better Fisher ranking scores and similar predictive statistics as the R value characteristics. **2017 September 6**

Predicting solar flares with machine learning: investigating solar cycle dependence

Xiantong **Wang**, Yang Chen, Gabor Toth, Ward B. Manchester, Tamas I. Gombosi, Alfred O. Hero, Zhenbang Jiao, Hu Sun, Meng Jin, Yang Liu
2020 *ApJ* **895** 3
https://arxiv.org/pdf/1912.00502.pdf
https://doi.org/10.3847/1538-4357/ab89ac
A deep learning network, Long-Short Term Memory (LSTM) network, is used in this work to predict whether the maximum flare class an active region (AR) will produce in the next 24 hours is class Γ. We considered Γ are ≥M, ≥C and any flare class. The essence of using LSTM, which is a recurrent neural network, is its capability to capture temporal information of the data samples. The input features are time sequences of 20 magnetic parameters from SHARPs - Space-weather HMI Active Region Patches. We analyzed active regions from June 2010 to Dec 2018, using the Geostationary Operational Environmental Satellite (GOES) X-ray flare catalogs and label the data samples with identified ARs in the GOES X-ray flare catalogs. Our results (i) shows consistent skill scores with recently published results using LSTMs and better than the previous work using single time input (eg. DeFN) (ii) The skill scores from the model show essential differences when different years of data was chosen for training and testing.

Further Evidence for Looplike Fine Structure inside "Unipolar" Active Region Plages

Y.-M. **Wang**, I. Ugarte-Urra, and J. W. Reep
2019 ApJ 885 34
sci-hub.se/10.3847/1538-4357/ab45f6
Earlier studies using extreme-ultraviolet images and line-of-sight magnetograms from the Solar Dynamics Observatory (SDO) have suggested that active region (AR) plages and strong network concentrations often have small, looplike features embedded within them, even though no minority-polarity flux is visible in the corresponding magnetograms. Because of the unexpected nature of these findings, we have searched the SDO database for examples of inverted-Y structures rooted inside "unipolar" plages, with such jetlike structures being interpreted as evidence for magnetic reconnection between small bipoles and the dominant-polarity field. Several illustrative cases are presented from the period of 2013–2015, all of which are associated with transient outflows from AR "moss." The triangular or dome-shaped bases have horizontal dimensions of ~2–4 Mm, corresponding to ~1–3 granular diameters. We also note that the spongy-textured Fe ix 17.1 nm moss is not confined to plages, but may extend into regions where the photospheric field is relatively weak or even has mixed polarity. We again find a tendency for bright coronal loops seen in the 17.1, 19.3, and 21.1 nm passbands to show looplike fine structure and compact brightenings at their footpoints. These observations provide further confirmation that present-day magnetograms are significantly underrepresenting the amount of minority-polarity flux inside AR plages and again suggest that footpoint reconnection and small-scale flux cancellation may play a major role in coronal heating, both inside and outside ARs. **2013 April 30, 2013 May 4-5, 2014 September 14, 2014 December 1, 2014 December 13, 2014 December 15, 2015 April 18, 2015 May 5, 2015 October 23, 2015 November 5, 2015 December 19.**

Parameters Derived from the SDO/HMI Vector Magnetic Field Data: Potential to Improve Machine-learning-based Solar Flare Prediction Models

Jingjing **Wang**1, Siqing Liu1,2, Xianzhi Ao1, Yuhang Zhang3, Tieyan Wang4, and Yang Liu5

2019 ApJ 884 175
sci-hub.se/10.3847/1538-4357/ab441b
It is well established that solar flares and coronal mass ejections (CMEs) are powered by the free magnetic energy stored in volumetric electric currents in the corona, predominantly in active regions (ARs). Much effort has been made to search for eruption-related signatures from magnetic field observed mostly in the photosphere; and the signatures are further employed for predicting flares and CMEs. The parameters in the Space-weather HMI Active Region Patches (SHARP) data from the Solar Dynamics Observatory/HMI observation of vector magnetic field are designed and generated for this purpose. In this paper, we report research done on modification of these SHARP parameters with an attempt to improve flare prediction. The newly modified parameters are weighed heavily by magnetic polarity inversion lines (PIL) with high magnetic gradient, as suggested by Schrijver, by multiplying the parameters with a PIL mask. We demonstrate that the number of the parameters that can well discriminate erupted and nonerupted ARs increases significantly by a factor of two, in comparison with the original parameters. This improvement suggests that the high-gradient PILs are tightly related with solar eruption that agrees with previous studies. This also provides new data that possess potential to improve the machine-learning-based solar flare prediction models. **2011 February 15**

Determination of transport coefficients by coronal seismology of flare-induced slow-mode waves: Numerical parametric study of 1D loop model

Tongjiang **Wang**, Leon Ofman
ApJ **886** 2 **2019**
https://arxiv.org/pdf/1909.10910.pdf
sci-hub.se/10.3847/1538-4357/ab478f
Recent studies of a flaring loop oscillation event on **2013 December 28** observed by the Atmospheric Imaging Assembly (AIA) of the Solar Dynamics Observatory (SDO) have revealed the suppression of thermal conduction and significant enhancement of compressive viscosity in hot (∼10 MK) plasma. In this study we aim at developing a new coronal seismology method for determining the transport coefficients based on a parametric study of wave properties using a 1D nonlinear MHD loop model in combination with the linear theory. The simulations suggest a two-step scheme: we first determine the effective thermal conduction coefficient from the observed phase shift between temperature and density perturbations as this physical parameter is insensitive to the unknown viscosity; then from the loop model with the obtained thermal conduction coefficient, we determine the effective viscosity coefficient from the observed decay time using the parametric modeling. With this new seismology technique we are able to quantify the suppression of thermal conductivity by a factor of about 3 and the enhancement of viscosity coefficient by a factor of 10 in the studied flaring loop. Using the loop model with these refined transport coefficients, we study the excitation of slow magnetoacoustic waves by launching a flow pulse from one footpoint. The simulation can self-consistently produce the fundamental standing wave on a timescale in agreement with the observation.

Roles of photospheric motions and flux emergence in the major solar eruption on 2017 September 6

Rui **Wang**, Ying D. Liu, J. Todd Hoeksema, I.V. Zimovets, Yang Liu
ApJ **2018**
https://arxiv.org/pdf/1810.13092.pdf
We study the magnetic field evolution in the active region (AR) 12673 that produced the largest solar flare in the past decade on **2017 September 6**. Fast flux emergence is one of the most prominent features of this AR. We calculate the magnetic helicity from photospheric tangential flows that shear and braid field lines (shear-helicity), and from normal flows that advect twisted magnetic flux into the corona (emergence-helicity), respectively. Our results show that the emergence-helicity accumulated in the corona is −1.6×1043 Mx2 before the major eruption, while the shear-helicity accumulated in the corona is −6×1043 Mx2, which contributes about 79\% of the total helicity. The shear-helicity flux is dominant throughout the overall investigated emergence phase. Our results imply that the emerged fields initially contain relatively low helicity. Much more helicity is built up by shearing and converging flows acting on preexisted and emerging flux. Shearing motions are getting stronger with the flux emergence, and especially on both sides of the polarity inversion line of the core field region. The evolution of the vertical currents shows that most of the intense currents do not appear initially with the emergence of the flux, which implies that most of the emerging flux is probably not strongly current-carrying. The helical magnetic fields (flux rope) in the core field region are probably formed by long-term photospheric motions. The shearing and converging motions are continuously generated driven by the flux emergence. AR 12673 is a representative as photospheric motions contribute most of the nonpotentiality in the AR with vigorous flux emergence.

High-resolution He i 10830 Å Narrowband Imaging for an M-class Flare. II. Multiple Hot Channels: Their Origin and Destination

Ya **Wang**1,2, Yingna Su1,3, Jinhua Shen4, Xu Yang5, Wenda Cao5, and Haisheng Ji1,3
2018 ApJ 859 148 DOI 10.3847/1538-4357/aac0f7

In this paper, we report our second-part result for the M1.8 class flare on **2012 July 5**, with an emphasis on the initiation process for the flare-associated filament eruption. The data set consists of high-resolution narrowband images in He i 10830 Å and broadband images in TiO 7057 Å taken at Big Bear Solar Observatory with the 1.6 m aperture Goode Solar Telescope. EUV images in different passbands observed by the Atmospheric Imaging Assembly on board the Solar Dynamics Observatory are used to distinguish hot plasma from cool plasma structures during the flare process. High-resolution 10830 Å images clearly show that, below the horizontal fibrils, which correspond to the filament's spine in full-disk Hα images, a sheared arch filament system (AFS) lies across the penumbra and surrounding satellite sunspots, between which continuous shearing motion is observed. Before the eruption, three microflares occurred successively and were followed by the appearance of three EUV hot channels. Two hot channels erupted, producing two flaring sites and two major peaks in GOES soft X-ray light curves; however, one hot channel's eruption failed. The 10830 Å imaging enables us to trace the first two hot channels to their very early stage, which is signified by the rising of the AFS after the first two precursors. Continuous flux emergence and localized flare-associated cancellation are observed under the AFS. In addition, EUV ejections were observed during the formation of the EUV hot channels. These observations support the fact that the hot channels are the result of magnetic reconnections during precursors.

Effect of transport coefficients on excitation of flare-induced standing slow-mode waves in coronal loops

Tongjiang **Wang**, Leon Ofman, Xudong Sun, Sami K Solanki, Joseph M Davila

ApJ **2018**

https://arxiv.org/pdf/1805.03282.pdf

Standing slow-mode waves have been recently observed in flaring loops by the Atmospheric Imaging Assembly (AIA) of the Solar Dynamics Observatory (SDO). By means of the coronal seismology technique transport coefficients in hot (~10 MK) plasma were determined by Wang et al.(2015, Paper I), revealing that thermal conductivity is nearly suppressed and compressive viscosity is enhanced by more than an order of magnitude. In this study we use 1D nonlinear MHD simulations to validate the predicted results from the linear theory and investigate the standing slow-mode wave excitation mechanism. We first explore the wave trigger based on the magnetic field extrapolation and flare emission features. Using a flow pulse driven at one footpoint we simulate the wave excitation in two types of loop models: model 1 with the classical transport coefficients and model 2 with the seismology-determined transport coefficients. We find that model 2 can form the standing wave pattern (within about one period) from initial propagating disturbances much faster than model 1, in better agreement with the observations. Simulations of the harmonic waves and the Fourier decomposition analysis show that the scaling law between damping time (τ) and wave period (P) follows $\tau \propto P2$ in model 2, while $\tau \propto P$ in model 1. This indicates that the largely enhanced viscosity efficiently increases the dissipation of higher harmonic components, favoring the quick formation of the fundamental standing mode. Our study suggests that observational constraints on the transport coefficients are important in understanding both, the wave excitation and damping mechanisms. **2013 December 28**

Unambiguous Evidence of Coronal Implosions During Solar Eruptions and Flares

Juntao **Wang**, P. J. A. Simoes, L. Fletcher

ApJ **859** 25 **2018**

https://arxiv.org/pdf/1804.02354.pdf

http://sci-hub.tw/http://iopscience.iop.org/0004-637X/859/1/25/

In the implosion conjecture, coronal loops contract as the result of magnetic energy release in solar eruptions and flares. However, after almost two decades, observations of this phenomenon are still rare, and most of previous reports are plagued by projection effects so that loop contraction could be either true implosion or just a change in loop inclination. In this paper, to demonstrate the reality of loop contractions in the global coronal dynamics, we present four events with the continuously contracting loops in an almost edge-on geometry from the perspective of SDO/AIA, which are free from the ambiguity caused by the projection effects, also supplemented by contemporary observations from STEREO for examination. In the wider context of observations, simulations and theories, we argue that the implosion conjecture is valid in interpreting these events. Furthermore, distinct properties of the events allow us to identify two physical categories of implosion. One type demonstrates a rapid contraction at the beginning of the flare impulsive phase, as magnetic free energy is removed rapidly by a filament eruption. The other type, which has no visible eruption, shows a continuous loop shrinkage during the entire flare impulsive phase which we suggest manifests the ongoing conversion of magnetic free energy in a coronal volume. Corresponding scenarios are described, which can provide reasonable explanations for the observations. We also point out that implosions may be suppressed in cases when a heavily-mass-loaded filament is involved, possibly serving as an alternative account for their observational rarity. **2011-09-14, 2014-02-17, 2016-04-08, 2016-11-22**

Evolution of Photospheric Flow and Magnetic Fields Associated with The 2015 June 22 M6.5 Flare

Jiasheng **Wang**, Chang Liu, Na deng, Haimin Wang

2018 ApJ 853 143
https://arxiv.org/pdf/1801.03486.pdf
http://sci-hub.tw/http://iopscience.iop.org/0004-637X/853/2/143/
The evolution of photospheric flow and magnetic fields before and after flares can provide important information regarding the flare triggering and back reaction processes. However, such studies on the flow field are rare due to the paucity of high-resolution observations covering the entire flaring period. Here we study the structural evolution of penumbra and shear flows associated with the **2015 June 22** M6.5 flare in NOAA AR 12371, using high-resolution imaging observation in the TiO band taken by the 1.6~m Goode Solar Telescope at Big Bear Solar Observatory, with the aid of the differential affine velocity estimator method for flow tracking. The accompanied photospheric vector magnetic field changes are also analyzed using data from the Helioseismic and Magnetic Imager. As a result, we found, for a penumbral segment in the negative field adjacent to the magnetic polarity inversion line (PIL), an enhancement of penumbral flows (up to an unusually high value of \sm2~\kms) and extension of penumbral fibrils after the first peak of the flare hard X-ray (HXR) emission. We also found an area at the PIL, which is co-spatial with a precursor brightening kernel, exhibits a gradual increase of shear flow velocity (up to \sm0.9~\kms) after the flare. The enhancing penumbral and shear flow regions are also accompanied by an increase of horizontal field and decrease of magnetic inclination angle(measured from the solar surface). These results are discussed in the context of the theory of back reaction of coronal restructuring on the photosphere as a result of flare energy release.

Observations of Reconnection Flows in a Flare on the Solar Disk

Magnetic reconnection is a well-accepted part of the theory of solar eruptive events, though the evidence is still circumstantial. Intrinsic to the reconnection picture of a solar eruptive event, particularly in the standard model for two-ribbon flares ("CSHKP" model), are an advective flow of magnetized plasma into the reconnection region, expansion of field above the reconnection region as a flux rope erupts, retraction of heated post-reconnection loops, and downflows of cooling plasma along those loops. We report on a unique set of SDO/AIA imaging and Hinode/EIS spectroscopic observations of the disk flare SOL**2016-03-23**T03:54 in which all four flows are present simultaneously. This includes spectroscopic evidence for a plasma upflow in association with large-scale expanding closed inflow field. The reconnection inflows are symmetric, and consistent with fast reconnection, and the post-reconnection loops show a clear cooling and deceleration as they retract. Observations of coronal reconnection flows are still rare, and most events are observed at the solar limb, obscured by complex foregrounds, making their relationship to the flare ribbons, cusp field and arcades formed in the lower atmosphere difficult to interpret. The disk location and favorable perspective of this event have removed these ambiguities giving a clear picture of the reconnection dynamics.

On Critical Height of Torus Instability in Two-Ribbon Solar Flares

Dong **Wang**, Rui Liu, Yuming Wang, Kai Liu, Jun Chen, Jiajia Liu, Zhenjun Zhou, Min Zhang
ApJL **2017**
https://arxiv.org/pdf/1706.03169.pdf
We studied the background field for 60 two-ribbon flares of M-and-above classes during 2011--2015. These flares are categorized into two groups, i.e., \emph{eruptive} and \emph{confined} flares, based on whether a flare is associated with a coronal mass ejection or not. The background field of source active regions is approximated by a potential field extrapolated from the Bz component of vector magnetograms provided by the Helioseismic and Magnetic Imager. We calculated the decay index n of the background field above the flaring polarity inversion line, and defined a critical height hcrit corresponding to the theoretical threshold (ncrit=1.5) of the torus instability. We found that hcrit is approximately half of the distance between the centroids of opposite polarities in active regions, and that the distribution of hcrit is bimodal: it is significantly higher for confined flares than for eruptive ones. The decay index increases monotonously with increasing height for 86\% (84\%) of the eruptive (confined) flares but displays a saddle-like profile for the rest 14\% (16\%), which are found exclusively in active regions of multipolar field configuration. Moreover, n at the saddle bottom is significantly smaller in confined flares than that in eruptive ones. These results highlight the critical role of background field in regulating the eruptive behavior of two-ribbon flares. **2012-03-14, 2014-02-04, 2014-10-22**

http://www.nature.com/articles/s41550-017-0085
Solar flares are generally believed to be powered by free magnetic energy stored in the corona, but the build up of coronal energy alone may be insufficient for the imminent flare occurrence. The flare onset mechanism is a critical but less understood problem, insights into which could be gained from small-scale energy releases known as precursors, which are observed as small pre-flare brightenings in various wavelengths, and also from certain small-scale magnetic configurations such as the opposite polarity fluxes, where magnetic orientation of small bipoles is opposite to that of the ambient main polarities. However, high-resolution observations of flare precursors together with the associated photospheric magnetic field dynamics are lacking. Here we study precursors of a flare using unprecedented spatiotemporal resolution of the 1.6 m New Solar Telescope, complemented by novel microwave data. Two episodes of precursor brightenings are initiated at a small-scale magnetic channel (a form of opposite polarity fluxes) with multiple polarity inversions and enhanced magnetic fluxes and currents, lying near the footpoints of sheared magnetic loops. The low-atmospheric origin of these precursor emissions is corroborated by microwave spectra. We propose that the emerging magnetic channel field interacts with the sheared arcades to cause precursor brightenings at the main flare core region. These high-resolution results provide evidence of low-atmospheric small-scale energy release and possible relationship to the onset of the main flare. **22 June 2015**

High resolution He I 10830 Å narrow-band imaging of an M-class flare. I - analysis of sunspot dynamics during flaring

Ya **Wang**, Yingna Su, Zhenxiang Hong, Zhicheng Zeng, Kaifan Ji, Philip R. Goode, Wenda Cao, Haisheng Ji
ApJ 833 250 **2016**
https://arxiv.org/pdf/1610.09227v1.pdf
In this paper, we report our first-step results of high resolution He\,\textsc{i} 10830 \AA\ narrow-band imaging (bandpass: 0.5 {\AA}) of an M1.8 class two-ribbon flare on **July 5, 2012**. The flare was observed with the 1.6 meter aperture New Solar Telescope at Big Bear Solar Observatory. For this unique data set, sunspot dynamics during flaring were analyzed for the first time. By directly imaging the upper chromosphere, running penumbral waves are clearly seen as an outward extension of umbral flashes, both take the form of absorption in the 10830 \AA\ narrow-band images. From a space-time image made of a slit cutting across a flare ribbon and the sunspot, we find that the dark lanes for umbral flashes and penumbral waves are obviously broadened after the flare. The most prominent feature is the sudden appearance of an oscillating absorption strip inside the ribbon when it sweeps into the sunspot's penumbral and umbral regions. During each oscillation, outwardly propagating umbral flashes and subsequent penumbral waves rush out into the inwardly sweeping ribbon, followed by a returning of the absorption strip with similar speed. We tentatively explain the phenomena as the result of a sudden increase in the density of ortho-Helium atoms in the area of the sunspot being excited by the flare's EUV illumination. This explanation is based on the observation that 10830 \AA\ absorption around the sunspot area gets enhanced during the flare. Nevertheless, questions are still open and we need further well-devised observations to investigate the behavior of sunspot dynamics during flares.

Arcade Implosion Caused by a Filament Eruption in a Flare

Juntao **Wang**, P. J. A. Simoes, L. Fletcher, J. K. Thalmann, H. S. Hudson, I. G. Hannah
ApJ 833 221 **2016**
https://arxiv.org/pdf/1610.05931v1.pdf **File**
Coronal implosions - the convergence motion of plasmas and entrained magnetic field in the corona due to a reduction in magnetic pressure - can help to locate and track sites of magnetic energy release or redistribution during solar flares and eruptions. We report here on the analysis of a well-observed implosion in the form of an arcade contraction associated with a filament eruption, during the C3.5 flare SOL**2013-06-19**T07:29. A sequence of events including magnetic flux-rope instability and distortion, followed by filament eruption and arcade implosion, lead us to conclude that the implosion arises from the transfer of magnetic energy from beneath the arcade as part of the global magnetic instability, rather than due to local magnetic energy dissipation in the flare. The observed net contraction of the imploding loops, which is found also in nonlinear force-free field extrapolations, reflects a permanent reduction of magnetic energy underneath the arcade. This event shows that, in addition to resulting in expansion or eruption of overlying field, flux-rope instability can also simultaneously implode unopened field due to magnetic energy transfer. It demonstrates the "partial opening of the field" scenario, which is one of the ways in 3D to produce a magnetic eruption without violating the Aly-Sturrock hypothesis. In the framework of this observation we also propose a unification of three main concepts for active region magnetic evolution, namely the metastable eruption model, the implosion conjecture, and the standard "CSHKP" flare model.

Waves in Solar Coronal Loops **Review**

Wang, Tongjiang
Wiley Book **2016**
http://onlinelibrary.wiley.com/doi/10.1002/9781119055006.ch23/summary
The corona is visible in the optical band only during a total solar eclipse or with a coronagraph. Coronal loops are believed to be plasma-filled closed magnetic flux anchored in the photosphere. Based on the temperature regime, they are generally classified into cool, warm, and hot loops. The magnetized coronal structures support propagation of various types of magnetohydrodynamics (MHD) waves. This chapter reviews the recent progress made in studies based on observations of four types of wave phenomena mainly occurring in coronal loops of active regions, including: flare-excited slow-mode waves; impulsively excited kink-mode waves; propagating slow magnetoacoustic waves; and ubiquitous propagating kink (Alfvénic) waves. This review not only comprehensively discusses these waves and coronal seismology but also topics that are newly emerging or hotly debated in order to provide the reader with useful guidance on further studies.

THE MECHANISMS OF ELECTRON ACCELERATION DURING MULTIPLE X LINE MAGNETIC RECONNECTION WITH A GUIDE FIELD
Huanyu **Wang**1,2, Quanming Lu1,2, Can Huang1,2, and Shui Wang
2016 ApJ 821 84
The interactions between magnetic islands are considered to play an important role in electron acceleration during magnetic reconnection. In this paper, two-dimensional particle-in-cell simulations are performed to study electron acceleration during multiple X line reconnection with a guide field. Because the electrons remain almost magnetized, we can analyze the contributions of the parallel electric field, Fermi, and betatron mechanisms to electron acceleration during the evolution of magnetic reconnection through comparison with a guide-center theory. The results show that with the magnetic reconnection proceeding, two magnetic islands are formed in the simulation domain. Next, the electrons are accelerated by both the parallel electric field in the vicinity of the X lines and the Fermi mechanism due to the contraction of the two magnetic islands. Then, the two magnetic islands begin to merge into one, and, in such a process, the electrons can be accelerated by both the parallel electric field and betatron mechanisms. During the betatron acceleration, the electrons are locally accelerated in the regions where the magnetic field is piled up by the high-speed flow from the X line. At last, when the coalescence of the two islands into one big island finishes, the electrons can be further accelerated by the Fermi mechanism because of the contraction of the big island. With the increase of the guide field, the contributions of the Fermi and betatron mechanisms to electron acceleration become less and less important. When the guide field is sufficiently large, the contributions of the Fermi and betatron mechanisms are almost negligible.

Evidence of thermal conduction suppression in hot coronal loops: Supplementary results
Tongjiang **Wang**, Leon Ofman, Xudong Sun, Elena Provornikova, Joseph M. Davila
Proceedings of IAUS 320, **2015**
http://arxiv.org/pdf/1510.02750v1.pdf
Slow magnetoacoustic waves were first detected in hot (>6 MK) flare loops by the SOHO/SUMER spectrometer as Doppler shift oscillations in Fe XIX and Fe XXI lines. Recently, such longitudinal waves have been found by SDO/AIA in the 94 and 131 \AA\ channels. Wang et al. (2015) reported the first AIA event revealing signatures in agreement with a fundamental standing slow-mode wave, and found quantitative evidence for thermal conduction suppression from the temperature and density perturbations in the hot loop plasma of $\gtrsim 9$ MK. The present study extends the work of Wang et al. (2015) by using an alternative approach. We determine the polytropic index directly based on the polytropic assumption instead of invoking the linear approximation. The same results are obtained as in the linear approximation, indicating that the nonlinearity effect is negligible. We find that the flare loop cools slower (by a factor of 2-4) than expected from the classical Spitzer conductive cooling, approximately consistent with the result of conduction suppression obtained from the wave analysis. The modified Spitzer cooling timescales based on the nonlocal conduction approximation are consistent with the observed, suggesting that nonlocal conduction may account for the observed conduction suppression in this event. In addition, the conduction suppression mechanism predicts that larger flares may tend to be hotter than expected by the EM-T relation derived by Shibata & Yokoyama (2002).

Evidence of thermal conduction suppression in a solar flaring loop by coronal seismology of slow-mode waves
Tongjiang **Wang**, Leon Ofman, Xudong Sun, Elena Provornikova, Joseph M. Davila
ApJL **811** L13 **2015**
http://arxiv.org/pdf/1509.00920v1.pdf
Analysis of a longitudinal wave event observed by the Atmospheric Imaging Assembly (AIA) onboard the Solar Dynamics Observatory (SDO) is presented. A time sequence of 131 A images reveals that a C-class flare occurred at one footpoint of a large loop and triggered an intensity disturbance (enhancement) propagating along it. The spatial

features and temporal evolution suggest that a fundamental standing slow-mode wave could be set up quickly after meeting of two initial disturbances from the opposite footpoints. The oscillations have a period of ~12 min and a decay time of ~9 min. The measured phase speed of 500±50 km/s matches the sound speed in the heated loop of ~10 MK, confirming that the observed waves are of slow mode. We derive the time-dependent temperature and electron density wave signals from six AIA extreme-ultraviolet (EUV) channels, and find that they are nearly in phase.The measured polytropic index from the temperature and density perturbations is 1.64±0.08 close to the adiabatic index of 5/3 for an ideal monatomic gas. The interpretation based on a 1D linear MHD model suggests that the thermal conductivity is suppressed by at least a factor of 3 in the hot flare loop at 9 MK and above. The viscosity coefficient is determined by coronal seismology from the observed wave when only considering the compressive viscosity dissipation. We find that to interpret the rapid wave damping, the classical compressive viscosity coefficient needs to be enhanced by a factor of 15 as the upper limit. **2013 December 28**

Thermodynamic Spectrum of Solar Flares Based on SDO/EVE Observations: Techniques and First Results

Yuming **Wang**, Zhenjun Zhou, Jie Zhang, Kai Liu, Rui Liu, Chenglong Shen, Phillip C. Chamberlin **2015**

http://arxiv.org/pdf/1507.08895v1.pdf

SDO/EVE provide rich information of the thermodynamic processes of solar activities, particularly of solar flares. Here, we develop a method to construct thermodynamic spectrum (TDS) charts based on the EVE spectral lines. Reading from the charts, we are able to easily recognize if there is a late phase following a main phase of a flare, and able to learn the begin, peak and end times of the flare as well as the drift of the temperature, i.e., the cooling rate, of the heated plasma during the flare. Through four M-class flares of different types, we illustrate which thermodynamic information can be revealed from the TDS charts. Further, we investigate the TDS charts of all the flares greater than M5.0, and some interesting results are achieved. First, there are two distinct drift patterns, called Type I and Type II. For Type I flares, the enhanced emission drifts from high to low temperture, whereas for Type II flares, the drift is somewhat reversed, suggesting a more violent and durable heating during Type II flares than Type I flares. Second, for late-phase flares, the peak intensity ratio of the late phase to the main phase read from the TDS chart is roughly correlated with the flare class identified by GOES SXR, and the flares with a stronger late phase are all confined. We believe that the re-deposition of the energy carried by a flux rope, that unsuccessfully erupts out, into thermal emissions is responsible for the strong late phase found in a confined flare. These results provide us new clues to advance our understanding of the thermodynamic processes of solar flares and associated solar eruptions, e.g., coronal mass ejections.

Structure and Evolution of Magnetic Fields Associated with Solar Eruptions (Invited Review)

Haimin **Wang**, Chang Liu

Research in Astronomy and Astrophysics, 15, 145 **2015**

http://arxiv.org/pdf/1412.8676v1.pdf **File**

This paper reviews the studies of solar photospheric magnetic field evolution in active regions and its relationship to solar flares. It is divided into two topics, the magnetic structure and evolution leading to solar eruptions and the rapid changes of photospheric magnetic field associated with eruptions. For the first topic, we describe the magnetic complexity, new flux emergence, flux cancellation, shear motions, sunspot rotation, and magnetic helicity injection, which may all contribute to the storage and buildup of energy and triggering of solar eruptions. For the second topic, we concentrate on the observations of rapid and irreversible changes of photospheric magnetic field associated with flares, and the implication on the restructuring of three-dimensional magnetic field. In particular, we emphasize the recent advances in observations of photospheric magnetic field, as state-of-the-art observing facilities (such as Hinode and Solar Dynamic Observatory) become available. The linkage between observations and theories and future prospectives in this research area are also discussed. **1989 March 10, 6 June 2000, 9 Apr 2001,2001 September 24, 24-26 Oct 2001, 28 and 29 Oct 2003, 2003 November 2., 2003 November 29, 5-8 N0v 2004, 2006 December 6, 2006 December 13, 12-16 Feb 2011, 2011 February 13., 2011 February 15, 2011 July 2, 2012 March 7**

Sudden Photospheric Motion and Sunspot Rotation Associated with the X2.2 Flare on 2011 February 15

Shuo **Wang**, Chang Liu, Na Deng, Haimin Wang
E-print, Jan **2014**; **2014** ApJ 782 L31
http://arxiv.org/pdf/1401.7957v1.pdf

The Helioseismic and Magnetic Imager provides 45 s cadence intensity images and 720 s cadence vector magnetograms. These unprecedented high-cadence and high-resolution data give us a unique opportunity to study the change of photospheric flows and sunspot rotations associated with flares. By using the differential affine velocity estimator method and the Fourier local correlation tracking method separately, we calculate velocity and vorticity of photospheric flows in the flaring NOAA AR 11158, and investigate their temporal evolution around the X2.2 flare on 2011 February 15. It is found that the shear flow around the flaring magnetic polarity inversion line exhibits a sudden decrease, and both of the two main sunspots undergo a sudden change in rotational motion during the impulsive phase of the flare. These results are discussed in the context of the Lorentz-force change that was proposed by Hudson et al. (2008) and Fisher et al. (2012). This mechanism can explain the connections between the rapid and irreversible photospheric vector magnetic field change and the observed short-term motions associated with the flare. In particular, the torque provided by the horizontal Lorentz force change agrees with what is required for the measured angular acceleration.

Three-ribbon Solar Flares: What Do They Imply for the 3D Magnetic Field Structure?

Haimin **Wang**, Chang Liu
HMI Science Nuggets, #21, **2014**
http://hmi.stanford.edu/hminuggets/?p=851

Solar flares are often seen with two chromospheric ribbons, which lie in opposite magnetic polarities and run parallel to the magnetic polarity inversion line (PIL), evidencing the standard flare geometry. With high-resolution observations, flares with a closed circular-like ribbon have also been revealed (Ref. 1 and references therein). The associated surface magnetic field configuration usually consists of a parasitic region encompassed by the opposite-polarity field, forming a circular PIL. Besides the circular ribbon, an inner and an outer (remote) ribbons are usually found. Some flares also exhibit surge-like eruptions from the area of the circular ribbon. In interpreting these events, the fan-spine magnetic topology is involved, where the dome-shaped fan portrays the closed separatrix surface, and the inner and outer spine field lines in different connectivity domains pass through a coronal null point.

Study of Two Successive Three-Ribbon Solar Flares on 2012 July 6

Haimin **Wang**, Chang Liu, Na Deng, Zhicheng Zeng, Yan Xu, Ju Jing and Wenda Cao
E-print, Dec **2013**; **2014** ApJ 781 L23
http://arxiv.org/pdf/1312.6649v1.pdf

This Letter reports two rarely observed three-ribbon flares (M1.9 and C9.2) on **2012 July 6** in NOAA AR 11515, which we found with Halpha observations of 0.1" resolution from the New Solar Telescope and CaII H images from Hinode. The flaring site is characterized with an intriguing "fish-bone-like" morphology evidenced by both Halpha images and a nonlinear force-free field (NLFFF) extrapolation, where two semi-parallel rows of low-lying, sheared loops connect an elongated, parasitic negative field with the sandwiching positive fields. The NLFFF model also shows that the two rows of loops are asymmetric in height and have opposite twists, and are enveloped by large-scale field lines including open fields. The two flares occurred in succession in half an hour and are located at the two ends of the flaring region. The three ribbons of each flare run parallel to the PIL, with the outer two lying in the positive field and the central one in the negative field. Both flares show surge-like flows in Halpha apparently toward the remote region, while the C9.2 flare is also accompanied by EUV jets possibly along the open field lines. Interestingly, the 12-25 keV hard X-ray sources of the C9.2 flare first line up with the central ribbon then shift to concentrate on the top of the higher branch of loops. These results are discussed in favor of reconnection along the coronal null-line producing the three flare ribbons and the associated ejections.

On the Strength of the Hemispheric Rule and the Origin of Active-region Helicity

Y.-M. **Wang**
2013 ApJ 775 L46

Vector magnetograph and morphological observations have shown that the solar magnetic field tends to have negative (positive) helicity in the northern (southern) hemisphere, although only ~60%-70% of active regions appear to obey this "hemispheric rule." In contrast, at least ~80% of quiescent filaments and filament channels that form during the decay of active regions follow the rule. We attribute this discrepancy to the difficulty in determining the helicity sign of newly emerged active regions, which are dominated by their current-free component; as the transverse field is canceled at the polarity inversion lines, however, the axial component becomes dominant there, allowing a more reliable determination of the original active-region chirality. We thus deduce that the hemispheric rule is far stronger than generally assumed, and cannot be explained by stochastic processes. Earlier studies have shown that the twist associated with the axial tilt of active regions is too small to account for the observed helicity; here, both tilt and twist are induced by the Coriolis force acting on the diverging flow in the emerging flux tube. However, in addition to this east-west expansion about the apex of the loop, each of its legs must expand continually in cross section during its rise through the convection zone, thereby acquiring a further twist through the Coriolis force. Since this transverse pressure effect is not limited by drag or tension forces, the final twist depends mainly on the rise time, and may be large enough to explain the observed active-region helicity.

THREE-DIMENSIONAL MAGNETOHYDRODYNAMIC MODELING OF PROPAGATING DISTURBANCES IN FAN-LIKE CORONAL LOOPS
Tongjiang **Wang**1,2, Leon Ofman1,2,3, and Joseph M. Davila
2013 ApJ 775 L23
Quasi-periodic propagating intensity disturbances (PDs) have been observed in large coronal loops in EUV images over a decade, and are widely accepted to be slow magnetosonic waves. However, spectroscopic observations from Hinode/EIS revealed their association with persistent coronal upflows, making this interpretation debatable. Motivated by the scenario that the coronal upflows could be the cumulative result of numerous individual flow pulses generated by sporadic heating events (nanoflares) at the loop base, we construct a velocity driver with repetitive tiny pulses, whose energy frequency distribution follows the flare power-law scaling. We then perform three-dimensional MHD modeling of an idealized bipolar active region by applying this broadband velocity driver at the footpoints of large coronal loops which appear open in the computational domain. Our model successfully reproduces the PDs with similar features as the observed, and shows that any upflow pulses inevitably excite slow magnetosonic wave disturbances propagating along the loop. We find that the generated PDs are dominated by the wave signature as their propagation speeds are consistent with the wave speed in the presence of flows, and the injected flows rapidly decelerate with height. Our simulation results suggest that the observed PDs and associated persistent upflows may be produced by small-scale impulsive heating events (nanoflares) at the loop base in the corona, and that the flows and waves may both contribute to the PDs at lower heights.

STUDY OF RAPID FORMATION OF A δ SUNSPOT ASSOCIATED WITH THE 2012 JULY 2 C7.4 FLARE USING HIGH-RESOLUTION OBSERVATIONS OF THE NEW SOLAR TELESCOPE
Haimin **Wang**1, Chang Liu1, Shuo Wang1, Na Deng1, Yan Xu1, Ju Jing1, and Wenda Cao
2013 ApJ 774 L24
Rapid, irreversible changes of magnetic topology and sunspot structure associated with flares have been systematically observed in recent years. The most striking features include the increase of the horizontal field at the polarity inversion line (PIL) and the co-spatial penumbral darkening. A likely explanation of the above phenomenon is the back reaction to the coronal restructuring after eruptions: a coronal mass ejection carries the upward momentum while the downward momentum compresses the field lines near the PIL. Previous studies could only use low-resolution (above 1") magnetograms and white-light images. Therefore, the changes are mostly observed for X-class flares. Taking advantage of the 0."1 spatial resolution and 15 s temporal cadence of the New Solar Telescope at the Big Bear Solar Observatory, we report in detail the rapid formation of sunspot penumbra at the PIL associated with the C7.4 flare on **2012 July 2**. It is unambiguously shown that the solar granulation pattern evolves to an alternating dark and bright fibril structure, the typical pattern of penumbra. Interestingly, the appearance of such a penumbra creates a new δ sunspot. The penumbral formation is also accompanied by the enhancement of the horizontal field observed using vector magnetograms from the Helioseismic and Magnetic Imager. We explain our observations as being due to the eruption of a flux rope following magnetic cancellation at the PIL. Subsequently, the re-closed arcade fields are pushed down toward the surface to form the new penumbra. NLFFF extrapolation clearly shows both the flux rope close to the surface and the overlying fields.

Study of Rapid Formation of a Delta Sunspot Associated with the 2012 July 2 C7.4 Flare Using High-resolution Observations of New Solar Telescope
Haimin **Wang**, Chang Liu, Shuo Wang, Na Deng, Yan Xu, Ju Jing and Wenda Cao
E-print, Aug **2013**, ApJL

Rapid, irreversible changes of magnetic topology and sunspot structure associated with flares have been systematically observed in recent years. The most striking features include the increase of horizontal field at the polarity inversion line (PIL) and the co-spatial penumbral darkening. A likely explanation of the above phenomenon is the back reaction to the coronal restructuring after eruptions: a coronal mass ejection carries the upward momentum while the downward momentum compresses the field lines near the PIL. Previous studies could only use low resolution (above 1") magnetograms and white-light images. Therefore, the changes are mostly observed for X-class flares. Taking advantage of the 0.1" spatial resolution and 15s temporal cadence of the New Solar Telescope at Big Bear Solar Observatory, we report in detail the rapid formation of sunspot penumbra at the PIL associated with the C7.4 flare on **2012 July 2**. It is unambiguously shown that the solar granulation pattern evolves to alternating dark and bright fibril structure, the typical pattern of penumbra. Interestingly, the appearance of such a penumbra creates a new delta sunspot. The penumbral formation is also accompanied by the enhancement of horizontal field observed using vector magnetograms from the Helioseismic and Magnetic Imager. We explain our observations as due to the eruption of a flux rope following magnetic cancellation at the PIL. Subsequently the re-closed arcade fields are pushed down towards the surface to form the new penumbra. NLFFF extrapolation clearly shows both the flux rope close to the surface and the overlying fields.

CIRCULAR RIBBON FLARES AND HOMOLOGOUS JETS

Haimin **Wang** and Chang Liu

2012 ApJ 760 101

Solar flare emissions in the chromosphere often appear as elongated ribbons on both sides of the magnetic polarity inversion line (PIL), which has been regarded as evidence of a typical configuration of magnetic reconnection. However, flares having a circular ribbon have rarely been reported, although it is expected in the fan-spine magnetic topology involving reconnection at a three-dimensional (3D) coronal null point. We present five circular ribbon flares with associated surges, using high-resolution and high-cadence Hα blue wing observations obtained from the recently digitized films of Big Bear Solar Observatory. In all the events, a central parasitic magnetic field is encompassed by the opposite polarity, forming a circular PIL traced by filament material. Consequently, a flare kernel at the center is surrounded by a circular flare ribbon. The four homologous jet-related flares on **1991 March 17 and 18** are of particular interest, as (1) the circular ribbons brighten sequentially, with cospatial surges, rather than simultaneously, (2) the central flare kernels show an intriguing "round-trip" motion and become elongated, and (3) remote brightenings occur at a region with the same magnetic polarity as the central parasitic field and are co-temporal with a separate phase of flare emissions. In another flare on **1991 February 25**, the circular flare emission and surge activity occur successively, and the event could be associated with magnetic flux cancellation across the circular PIL. We discuss the implications of these observations combining circular flare ribbons, homologous jets, and remote brightenings for understanding the dynamics of 3D magnetic restructuring.

THE RELATIONSHIP BETWEEN THE SUDDEN CHANGE OF THE LORENTZ FORCE AND THE MAGNITUDE OF ASSOCIATED FLARES

Shuo **Wang**, Chang Liu, and Haimin Wang

2012 ApJ 757 L5

The rapid and irreversible change of photospheric magnetic fields associated with flares has been confirmed by many recent studies. These studies showed that the photospheric magnetic fields respond to coronal field restructuring and turn to a more horizontal state near the magnetic polarity inversion line (PIL) after eruptions. Recent theoretical work has shown that the change in the Lorentz force associated with a magnetic eruption will lead to such a field configuration at the photosphere. The Helioseismic Magnetic Imager has been providing unprecedented full-disk vector magnetograms covering the rising phase of the solar cycle 24. In this study, we analyze 18 flares in four active regions, with GOES X-ray class ranging from C4.7 to X5.4. We find that there are permanent and rapid changes of magnetic field around the flaring PIL, the most notable of which is the increase of the transverse magnetic field. The changes of fields integrated over the area and the derived change of Lorentz force both show a strong correlation with flare magnitude. It is the first time that such magnetic field changes have been observed even for C-class flares. Furthermore, for seven events with associated coronal mass ejections (CMEs), we use an estimate of the impulse provided by the Lorentz force, plus the observed CME velocity, to estimate the CME mass. We find that if the timescale of the back reaction is short, i.e., in the order of 10 s, the derived values of CME mass (~1015 g) generally agree with those reported in literature.

RAPID TRANSITION OF UNCOMBED PENUMBRAE TO FACULAE DURING LARGE FLARES

Haimin **Wang**1, Na Deng1,2 and Chang Liu

2012 ApJ 748 76

In the past two decades, the complex nature of sunspots has been disclosed with high-resolution observations. One of the most important findings is the "uncombed" penumbral structure, where a more horizontal magnetic component

carrying most of Evershed flows is embedded in a more vertical magnetic background. The penumbral bright grains are locations of hot upflows and dark fibrils are locations of horizontal flows that are guided by a nearly horizontal magnetic field. On the other hand, it was found that flares may change the topology of sunspots in δ configuration: the structure at the flaring polarity inversion line becomes darkened while sections of peripheral penumbrae may disappear quickly and permanently associated with flares. The high spatial and temporal resolution observations obtained with the Hinode/Solar Optical Telescope provide an excellent opportunity to study the evolution of penumbral fine structures associated with major flares. Taking advantage of two near-limb events, we found that in sections of peripheral penumbrae swept by flare ribbons the dark fibrils completely disappear, while the bright grains evolve into faculae that are signatures of vertical magnetic flux tubes. The corresponding magnetic fluxes measured in the decaying penumbrae show stepwise changes temporally correlated with the flares. These observations suggest that the horizontal magnetic field component of the penumbra could be straightened upward (i.e., turning from horizontal to vertical) due to magnetic field restructuring associated with flares, which results in the transition of penumbrae to faculae.

RESPONSE OF THE PHOTOSPHERIC MAGNETIC FIELD TO THE X2.2 FLARE ON 2011 FEBRUARY 15

Shuo **Wang**1, Chang Liu1, Rui Liu1, Na Deng1, Yang Liu2 and Haimin Wang
2012 ApJ 745 L17

It is well known that the long-term evolution of the photospheric magnetic field plays an important role in building up free energy to power solar eruptions. Observations, despite being controversial, have also revealed a rapid and permanent variation of the photospheric magnetic field in response to the coronal magnetic field restructuring during the eruption. The Helioseismic and Magnetic Imager instrument (HMI) on board the newly launched Solar Dynamics Observatory produces seeing-free full-disk vector magnetograms at consistently high resolution and high cadence, which finally makes possible an unambiguous and comprehensive study of this important back-reaction process. In this study, we present a near disk-center, GOES-class X2.2 flare, which occurred in NOAA AR 11158 on **2011 February 15**. Using the magnetic field measurements made by HMI, we obtained the first solid evidence of a rapid (in about 30 minutes) and irreversible enhancement in the horizontal magnetic field at the flaring magnetic polarity inversion line (PIL) by a magnitude of ~30%. It is also shown that the photospheric field becomes more sheared and more inclined. This field evolution is unequivocally associated with the flare occurrence in this sigmoidal active region, with the enhancement area located in between the two chromospheric flare ribbons and the initial conjugate hard X-ray footpoints. These results strongly corroborate our previous conjecture that the photospheric magnetic field near the PIL must become more horizontal after eruptions, which could be related to the newly formed low-lying fields resulting from the tether-cutting reconnection.

Slow-Mode Oscillations of Hot Loops Excited at Flaring Footpoints

Tongjiang **Wang**, Wei Liu, Leon Ofman, Joseph M. Davila
(Submitted on 16 Jun **2017**)
5th Hinode Meeting: Exploring the Active Sun, ASP Conference Series, Vol. 456, eds. by L. Golub, I. De Moortel, and T. Shimizu, 127, **2012**
https://arxiv.org/pdf/1706.05427.pdf

The analysis of a hot loop oscillation event using SOHO/SUMER, GOES/SXI, and RHESSI observations is presented. Damped Doppler shift oscillations were detected in the Fe XIX line by SUMER, and interpreted as a fundamental standing slow mode. The evolution of soft X-ray emission from GOES/SXI and hard X-ray sources from RHESSI suggests that the oscillations of a large loop are triggered by a small flare, which may be produced by interaction (local reconnection) of this large loop with a small loop at its footpoint. This study provides clear evidence supporting our early conjecture that the slow-mode standing waves in hot coronal loops are excited by impulsive heating (small or microflares) at the loop's footpoint. **2003 April 24**

Evidence of Two-Stage Magnetic Reconnection in the 2005 January 15 X2.6 Flare

Pu **Wang**1, Yixuan Li2, Mingde Ding1, Haisheng Ji3;4, Haimin Wang
BBSO Preprint #1474, **2011**; New Astronomy

We analyze in detail the X2.6 flare that occurred on **2005 January 15** in the NOAA AR 10720 using multiwavelength observations. There are several interesting properties of the flare that reveal possible two-stage magnetic reconnection similar to that in the physical picture of tether-cutting, where the magnetic fields of two separate loop systems reconnect at the flare core region, and subsequently a large flux rope forms, erupts, and breaks open the overlying arcade fields. The observed manifestations include: (1) remote Hα brightenings appear minutes before the main phase of the flare; (2) separation of the flare ribbons has a slow and a fast phase, and the flare hard X-ray emission appears in the later fast phase; (3) rapid transverse field enhancement near the magnetic polarity inversion line (PIL) is found to be associated with the flare. We conclude that the flare occurrence fits the tether-cutting reconnection picture in a special way, in which there are three flare ribbons outlining the sigmoid configuration. We also discuss this event in the context of what

was predicted by Hudson, Fisher, & Welsch (2008), where the Lorentz force near the flaring PIL drops after the flare and consequently the magnetic field lines there turn to be more horizontal as we observed.

OBSERVATIONAL EVIDENCE OF BACK REACTION ON THE SOLAR SURFACE ASSOCIATED WITH CORONAL MAGNETIC RESTRUCTURING IN SOLAR ERUPTIONS
Haimin **Wang** and Chang Liu
Astrophysical Journal Letters, 716:L195–L199, **2010** June
Most models of solar eruptions assume that coronal field lines are anchored in the dense photosphere and thus the photospheric magnetic fields would not have rapid, irreversible changes associated with eruptions resulted from the coronal magnetic reconnection. Motivated by the recent work of Hudson et al. on quantitatively evaluating the back reaction due to energy release from the coronal fields, in this Letter we synthesize our previous studies and present analysis of new events about flare-related changes of photospheric magnetic fields. For the 11 X-class flares where vector magnetograms are available, we always find an increase of transverse field at the polarity inversion line (PIL) although only four events had measurements with 1 minute temporal resolution. We also discuss 18 events with 1 minute cadence line-of-sight magnetogram observation, which all show prominent changes of magnetic flux contained in the flaring δ spot region. Except in one case, the observed limbward flux increases while diskward flux decreases rapidly and irreversibly after flares. This observational evidence provides support, either directly or indirectly, for the theory and prediction of Hudson et al. that the photospheric magnetic fields must respond to coronal field restructuring and turn to a more horizontal state near the PIL after eruptions.

FOOTPOINT MOTIONS AS EVIDENCE FOR PATCHY RECONNECTIONS IN AN M9.1 SOLAR FLARE
Lin **Wang**
Astrophysical Journal, 694:247–256, **2009** March
http://www.iop.org/EJ/article/-alert=43190/0004-637X/694/1/247/apj_694_1_247.pdf
We present an investigation on the UV footpoint motions of an M9.1 two-ribbon solar flare that occurred on **2004 July 22**, employing the *TRACE* 1700 Å images and a magnetogram observed by *SOHO*/MDI. In the beginning, we found that the UV footpoints spread a two-dimensional distribution in, especially, the negative magnetic region, rather than a quasi-one-dimensional distribution as expected. Based on an assumption, we extract the information of the footpoints and link them into trajectories. From the results, we find some unexpected motion patterns and features, such as bidirectional elongations of footpoints, large angles between the footpoint trajectories, a "merging" pattern of the motion, and an apparent prevalence of motions along the iso-Gauss contours over those along the gradient of the magnetic field. We suggest that the quasi-three-dimensional CSHKP model with a uniform arcade may be inapplicable to the flare, in spite of the two-ribbon appearance. Instead, the **"patchy reconnection"** concept presented by Klimchuk in 1997 may be appropriate.Only a fraction of the magnetic field participates in the energetic reconnection. The elongations may offer crucial restrictions on the excitation of the reconnections. The large angles and the "merging" process may imply a chaotic geometry of the reconnection subsystems, rather than a symmetrical one. The prevalence may offer an important clue in solar flare studies.

MAGNETIC CHANGES IN THE COURSE OF THE X7.1 SOLAR FLARE ON 2005 JANUARY 20
Jingxiu **Wang** et al **2009** ApJ 690 862-874, **File**
http://www.iop.org/EJ/abstract/0004-637X/690/1/862
Rapid magnetic changes in the course of the X7.1 solar flare on **2005 January 20** at the photosphere in the host active region (AR), NOAA AR 10720, are diagnosed. The database for this study consists of Huairou vector magnetograms, Transition Region and Coronal Explorer (TRACE) white light and UV/EUV images, RHESSI hard X-ray, and Solar and Heliospheric Observatory EUV observations. For such an event that is close to but not on the solar west limb (N12 W58), the projection effects in the observed vector magnetograms are untangled by combining an intuitive geometric analysis and a transformation of the magnetograms into the heliographic coordination system. The magnetic changes in the horizontal magnetic fields are emphasized. We find definitive evidence of weakening in the horizontal magnetic fields in a few isolated patches in the outskirts of this δ-sunspot group and strengthening in the horizontal fields (HFs) in an extended area centralized at the magnetic neutral line between major sunspots of opposite polarities. The rapid magnetic changes take place at the level of 100-300 G, several factors of ten of the noise level. The identified HF changes are consistent with the darkening of inner penumbrae and weakening of outer penumbrae in this δ-sunspot group. The enhanced HFs spatially coincide with the TRACE 1550 Å rope-like structures lying low above the magnetic neutral line. Unexpectedly, during the flare, the lower lying rope-like structures remain in place, though they exhibit episodic disturbance and brightening, while the outer EUV loops are impulsively expanding. The rapid magnetic changes manifest an impulsive input of free magnetic energy in the photosphere, resulting from an impulsive growth of

a new emerging flux region (EFR) along the magnetic neutral line. The facts of the increasing core fields in magnetic nonpotentiality, the continued disturbance of the inner rope-like structures, and the breakout of the outer loops during the major flare cannot be interpreted by any single flare model. However, the nature of magnetohydrodynamical catastrophe is clearly implied for the flare triggering.

Study of White-Light Flares Observed by Hinode

Haimin **Wang**
BBSO Preprint, #1373, **2008**
http://solar.njit.edu/preprints/wang1373.pdf
White-light flares are considered as the most energetic flaring events that are observable in optical broad-band continuum of solar spectrum. They have not been commonly observed. Observations of white-light flares with sub-arcsecond resolution have been very rare. The continuous high resolution observations of Hinode provide an unique opportunity to systematically study the white-light flares with a spatial resolution around 0.2 arcsec.We surveyed all the flares above GOES magnitude C5.0 since the launch of Hinode in 2006 October, 13 of them were covered by Hinode G-band observations.We analyzed the peak contrast and equivalent area (calculated via integrated excess emission contrast) of these flares as a function of GOES X-ray flux, and found that the cut-off visibility is likely around M1 flares under the observing limit of Hinode. Many other observational and physical factors should affect the visibility of white-light flares; as the observing conditions are improved, smaller flares are likely to have detectable white-light emissions. We are cautious that this limit visibility is an overestimate, as G-band observations contains emissions from upper atmosphere. Among 13 events analyzed, only the M8.7 flare of **2007 June 4** had near-simultaneous observations in both G-band and blue continuum. The blue continuum had a peak contrast of 94% vs. 175% in G-band for this event. The equivalent area in blue continuum is an order of magnitude lower than that in G-band. Very recently, Jess et al. studied a C2.0 flare with a peak contrast of 300% in blue continuum. Comparing to the events presented in this Letter, that event is probably a unusual white-light flare: a very small kernel with a large contrast that can be detected in high resolution observations.

STUDY OF MAGNETIC CHANNEL STRUCTURE IN ACTIVE REGION 10930

Haimin **Wang**,1, 2 Ju Jing,1, 2 Changyi Tan,1, 2 Thomas Wiegelmann,3 and Masahito Kubo4
Astrophysical Journal, 687:658Y667, **2008**
http://www.journals.uchicago.edu/doi/abs/10.1086/592082
The concept of ‘‘magnetic channel’’ was first introduced by Zirin & Wang. They were defined as a series of oppositely directed vertical-field inversions separated by extremely narrow elongated transverse fields. In this paper, we utilized unprecedented filtergraph and spectropolarimetry observations from Hinode, and studied the evolution and physical properties of channel structure of AR 10930 in detail.We found the following: (1) Channels are associated with new flux emergence in the middle of existing penumbra connecting the _ sunspot. (2) The width of each channel is in the order of 100 or less. (3) The line-of-sight magnetic gradient is highest in the channel, 2.4Y4.9 G km_1. (4) The fields are highly sheared and inclined with a median shear angle around 64_ and inclination angle around 25_. (5) Using nonlinear force-free field (NLFF) extrapolation, we derive a near surface current system carrying electric current in the order of 5 ; 1011 A. (6) The X3.4 flare on 2006 December 13 occurred during the period that the channels rapidly formed, but a few hours before the maximum phase of channel structure development. Based on the observational evidence, we propose that the channels are formed during the emergence of a sequence of magnetic bipoles that are squeezed in the compact penumbra of the _ sunspot and they are highly nonpotential. Formation of channels might be a precursor of major flares.

A STATISTICAL STUDY OF SOLAR ACTIVE REGIONS THAT PRODUCE EXTREMELY FAST CORONAL MASS EJECTIONS

Yuming **Wang**1, 2 and Jie Zhang
The Astrophysical Journal, 680:1516-1522, **2008**
http://www.journals.uchicago.edu/doi/pdf/10.1086/587619
We present statistical results on the properties of the solar source regions that produced the 57 fastest (_1500 km s_1) front-side coronal mass ejections (CMEs) from 1996 June to 2007 January. The properties of these fast-CMEY producing regions, 35 in total, are compared with those of all 1143 active regions (ARs) in the period studied. An automated method, based on SOHO MDI magnetic synoptic charts, is used to select and characterize the ARs. For

each, a set of parameters is derived that includes the areas (positive, negative, and total, denoted A_P, A_N, and A_T, respectively), the magnetic fluxes (positive, negative, and total, F_P, F_N, and F_T), the average magnetic field strength (B_{avg}), a quasi elongation (e) characterizing the overall shape of the AR, the number and length of polarity inversion lines (PILs, or neutral lines, N_{PIL} and L_{PIL}, respectively), and the average and maximum magnetic gradient on the PILs (GOP_{avg} and GOP_{max}). Our statistical analysis shows a general trend between the scales of an AR and the likelihood of its producing a fast CME; that is, the larger the geometric size (A_T), the larger the magnetic flux (F_T), the stronger the magnetic field (B_{avg}), and the more complex the magnetic configuration (N_{PIL} and L_{PIL}), the greater the possibility of producing a fast CME. When all the ARs are sorted into three evenly sized groups with low, intermediate, and high values of these parameters, we find that for all the parameters, more than 60% of extremely fast CMEs are from the high-value group. The two PIL parameters are the best indicators of fast-CME production, with more than 80% coming from the high-value group.

SUCCESSIVE FLARING DURING THE 2005 SEPTEMBER 13 ERUPTION

Haimin **Wang**, Chang Liu, Ju Jing, and Vasyl Yurchyshyn

The Astrophysical Journal, 671:973Y977, **2007** December 10; File

We report a detailed analysis of successive flaring during the X1.5 event in theNOAAAR 0808 on 2005 September 13.We identify a filament lying at the southeast boundary of the active region as the physical linkage between the two flares in close succession. It is noticeable that the filament erupted_13 minutes after the initial flare onset at_19:22UT near the central magnetic polarity inversion line (PIL). During this time period, the filament only showed a slow rising; meanwhile, a spatially associated large magnetic loop with one leg connecting to the initial flaring site began to brighten in the TRACE 195 8 channel. After _19:35 UT, the filament abruptly erupted together with the bright TRACE loop. Besides the moving ribbons at the first flaring site, the filament eruption caused a secondary flare identified with another set of moving ribbons. This event thus provides a clear evidence for the successive flaring where the initial flare destabilizes the nearby flux loop system, leading to the filament eruption with the second flare. We also identify the initial flare core by finding rapid, irreversible enhancements of the photospheric transverse magnetic fields at a section of the PIL.

A COMPARATIVE STUDY BETWEEN ERUPTIVE X-CLASS FLARES ASSOCIATED WITH CORONAL MASS EJECTIONS AND CONFINED X-CLASS FLARES

Yuming **Wang**1,2 and Jie Zhang

Astrophysical Journal, 665:1428Y1438, **2007** August; **File**

We examine the two kinds of major energetic phenomena that occur in the solar atmosphere: eruptive and confined events. The former describes flares with associated coronal mass ejections (CMEs), while the latter denotes flares without associated CMEs.We find that about 90% of X-class flares are eruptive, but the remaining 10% are confined. To probe why the largest energy releases could be either eruptive or confined, we investigate four X-class events from each of the two types. Both sets of events are selected to have very similar intensities (X1.0 to X3.6) and duration (rise time under 13 minutes and decay time over 9 minutes) in soft X-ray observations, to reduce any bias due to flare size on CME occurrence. We find that the occurrence of eruption (or confinement) is sensitive to the displacement of the location of the energy release, defined as the distance between the flare site and the flux-weighted magnetic center of the source active region. The displacement is 6Y17Mmfor confined events but as large as 22Y37Mmfor eruptive events. This means that confined events occur closer to the magnetic center, while the eruptive events tend to occur close to the edge of active regions.We use the potential field source-surface model to infer the coronal magnetic field above the source active regions and calculate the flux ratio of low (<1.1 R_) to high (_1.1 R_) corona.We find that the confined events have a lower ratio (<5.7) than the eruptive events (>7.1). These results imply that a stronger overlying arcade field may prevent energy releases in the low corona from being eruptive, resulting in flares, but without CMEs. **Table.**

Solar Trans-equatorial Activity

Jingxiu **Wang** · Yuzong Zhang · Guiping Zhou · Louise K. Harra · David R.Williams · Yunchun Jiang

Solar Phys (**2007**) 244: 75–94

We have found that solar flares in NOAA active region (AR) 10696 were often associated with large-scale trans-equatorial activities. These trans-equatorial activities appeared to be very common and manifest themselves through *i*) the formation and eruption of trans-equatorial loops (TELs), *ii*) the formation and eruption of trans-equatorial filaments (TEFs), and *iii*) the trans-equatorial brightening (TEB) in the chromosphere. It is determined that the TEF was formed following episodic plasma ejecta from flares occurring in the AR. The TEF eruption was associated with a trans-equatorial flare. All flares in the AR that were accompanied by trans-equatorial activities were associated with halo coronal mass ejections (CMEs). It was noticed that one or several major flares in the AR were followed by an increase of brightness and nonpotentiality of a TEL. These coupled events had a lifetime of more than 12 hours. In addition their associated halo CMEs always had a positive acceleration, indicating prolonged magnetic reconnections in the outer corona at high altitudes.

Flarelike brightenings of active region loops observed with SUMER

T. J. **Wang**, D. E. Innes, S. K. Solanki, W. Curdt

Proc. of 11th European Solar Physics Meeting, **2005**
http://arxiv.org/pdf/1510.00337v1.pdf
Coronal loops on the east limb of the Sun were observed by SUMER on SOHO for several days. Small flare-like brightenings are detected very frequently in the hot flare line Fe~{\small XIX}. We find that the relatively intense events are in good coincidence with the transient brightenings seen by Yohkoh/SXT. A statistical analysis shows that these brightenings have durations of 5-84 min and extensions along the slit of 2-67 Mm. The integrated energy observed in Fe~{\small XIX} for each event is in the range of 3×1018−5×1023 ergs, and the estimated thermal energy ranges from 1026−1029 ergs. Application of the statistical method proposed by Parnell \& Jupp (2000) yields a value of 1.5 to 1.8 for the index of a power law relation between the frequency of the events and the radiated energy in Fe~{\small XIX}, and a value of 1.7 to 1.8 for the index of the frequency distribution of the thermal energy in the energy range >1027 ergs. We examine the possibility that these small brightenings give a big contribution to heating of the active region corona. **16−20 September 2000, 25−30 September 2000**

Initial features of an X-class flare observed with SUMER and TRACE

T. J. **Wang**, S. K. Solanki, D. E. Innes, W. Curdt
SOLMAG 2002. Proc. the Magnetic Coupling of the Solar Atmosphere Euroconference and IAU Colloquium 188, Ed. H. Sawaya-Lacoste. ESA SP-505. Noordwijk, Netherlands: ESA Publications Division, ISBN 92-9092-815-8, **2002**, p. 607 - 610 **2018**
https://arxiv.org/pdf/1805.10418.pdf
A class X1.5 flare started on the solar limb at 00:43 UT on **21 April 2002**, which was associated with a CME observed at 01:27 UT by LASCO C2. The coordinated analyses of this flare include TRACE 195 {\AA} images and SUMER spectra in lines of Fe XXI, Fe XII, and C II. We find that: 1) The flare began with a jet seen by TRACE, which was detected by SUMER in the C II line as a strong brightening with blue shifts up to 170 km s[Math Processing Error]. At that time only weak emission was detected in Fe XII and Fe XXI. 2) Subsequently, a weak looplike brightening started south of the jet, moving outwards with an average speed of about 150 km s[Math Processing Error]. The SUMER spectra responded this moving loop as separatingly brightenings, visible only in the Fe XXI line. The southwards moving component contains red- and blue-shifted emission features and has an apparent speed of [Math Processing Error]120 km s[Math Processing Error]. The absence of signatures in Fe XII and C II lines indicates that the moving weak loop seen by TRACE corresponds to the emission from very hot plasma, in a blend line in the 195 {\AA} bandpass due to Fe XXIV formed at T > 10 MK. 3) The trigger mechanism of the flare and associated CME can be interpreted in the same way as that proposed by Wang et al. (2002) for an event with similar initial features.

A Comparative Study between Eruptive X-Class Flares Associated with Coronal Mass Ejections and Confined X-Class Flares

Yuming **Wang**1,2 and Jie Zhang1
2007 ApJ 665 1428
https://iopscience.iop.org/article/10.1086/519765/pdf
We examine the two kinds of major energetic phenomena that occur in the solar atmosphere: eruptive and confined events. The former describes flares with associated coronal mass ejections (CMEs), while the latter denotes flares without associated CMEs. We find that about 90% of X-class flares are eruptive, but the remaining 10% are confined. To probe why the largest energy releases could be either eruptive or confined, we investigate four X-class events from each of the two types. Both sets of events are selected to have very similar intensities (X1.0 to X3.6) and duration (rise time under 13 minutes and decay time over 9 minutes) in soft X-ray observations, to reduce any bias due to flare size on CME occurrence. We find that the occurrence of eruption (or confinement) is sensitive to the displacement of the location of the energy release, defined as the distance between the flare site and the flux-weighted magnetic center of the source active region. The displacement is 6-17 Mm for confined events but as large as 22-37 Mm for eruptive events. This means that confined events occur closer to the magnetic center, while the eruptive events tend to occur close to the edge of active regions. We use the potential field source-surface model to infer the coronal magnetic field above the source active regions and calculate the flux ratio of low (<1.1 R⊙) to high (≥1.1 R⊙) corona. We find that the confined events have a lower ratio (<5.7) than the eruptive events (>7.1). These results imply that a stronger overlying arcade field may prevent energy releases in the low corona from being eruptive, resulting in flares, but without CMEs. **1998 May 2, 2000 Mar 2, 2000 Jun 6, 2000 Sep 30, 2000 Nov 24, 2001 Apr 2, 2001 Jun 23, 2003 Jun 9, 2004 Feb 26, 2004 Jul 15, 2004 Jul 16, 2004 Jul 17, 2004 Oct 30**
TABLE 1 Confined X-Class Flares from 1996 to 2004 and Selected Eruptive Flares

COMPARISON OF THE 1998 APRIL 29 M6.8 AND 1998 NOVEMBER 5 M8.4 FLARES

HAIMIN **WANG**, PHILIP R. GOODE, CARSTEN DENKER, GUO YANG, VASYL YURCHISHIN. NARIAKI NITTA, JOSEPH B. GURMAN, CHRIS ST. CYR, AND ALEXANDER G. KOSOVICHEV
ASTROPHYSICAL JOURNAL, 536:971И981, **2000, File**
We combined, and analyzed in detail, the Ha and magnetograph data from Big Bear Solar Observatory

(BBSO), full-disk magnetograms from the Michelson Doppler Imager (MDI) on board Solar and Heliospheric Observatory (SOHO), coronagraph data from the Large Angle Spectrometric Coronagraph (LASCO) of SOHO, Fe XII 195 data from the Extreme ultraviolet Imaging Telescope (EIT) of SOHO, A_ and Yohkoh soft X-ray telescope (SXT) data of the M6.8 Care of 1998 April 29 in National Oceanic and Atmospheric Administration (NOAA) region 8375 and the M8.4 Care of 1998 November 5 in NOAA region 8384. These two Cares have remarkable similarities :
1. Partial halo coronal mass ejections (CMEs) were observed for both events. For the 1998 April 29 event, even though the Care occurred in the southeast of the disk center, the ejected material moved predominantly across the equator, and the central part of the CME occurred in the northeast limb. The direction in which the cusp points in the postCare SXT images determines the dominant direction of the CMEs.
2. Coronal dimming was clearly observed in EIT Fe XII 195 for both but was not observed in A_ Yohkoh SXT for either event. Dimming started 2 hr before the onset of the Cares, indicating large-scale coronal restructuring before both Cares.
3. No global or local photospheric magnetic Peld change was detected from either event ; in particular, no magnetic Peld change was found in the dimming areas.
4. Both events lasted several hours and, thus, could be classiPed as long duration events (LDEs). However, they are di†erent in the following important aspects. For the 1998 April 29 event, the Care and the CME are associated with an erupting Plament in which the two initial ribbons were well connected and then gradually separated. SXT preCare images show the classical S-shape sheared conPguration (sigmoid structure). For the 1998 November 5 event, two initial ribbons were well separated, and the SXT preCare image shows the interaction of at least two loops. In addition, no Plament eruption was observed. We conclude that even though these two events resulted in similar coronal consequences, they are due to two distinct physical processes : eruption of sheared loops and interaction of two loops.

Thermal-nonthermal energy partition in solar flares derived from X-ray, EUV, and bolometric observations

Alexander **Warmuth**, Gottfried Mann
A&A 644, A172 **2020**
https://arxiv.org/pdf/2011.04442.pdf
https://doi.org/10.1051/0004-6361/202039529
https://www.aanda.org/articles/aa/pdf/2020/12/aa39529-20.pdf
In solar flares, energy is released impulsively and is partly converted into thermal energy of hot plasmas and kinetic energy of accelerated nonthermal particles. Despite numerous efforts, no consensus on quantifying this energy balance has yet been reached. We aim to understand the reasons for the contradicting results on energy partition obtained by various recent studies. We considered five recent studies that address the thermal-nonthermal energy partition in solar flares. Their results are reviewed, and their methods are compared and discussed in detail. The main uncertainties in deriving the energy partition are identified as (a) the derivation of the differential emission measure (DEM) distribution and (b) the role of the conductive energy loss for the thermal component, as well as (c) the determination of the low-energy cutoff for the injected electrons. The bolometric radiated energy, as a proxy for the total energy released in the flare, is a useful independent constraint on both thermal and nonthermal energetics. In most of the cases, the derived energetics are consistent with this constraint. There are indications that the thermal-nonthermal energy partition changes with flare strength: in weak flares, there appears to be a deficit of energetic electrons, while the injected nonthermal energy is sufficient to account for the thermal component in strong flares. This behavior is identified as the main cause of the dissimilar results in the studies we considered. The changing partition has two important consequences: (a) an additional direct (i.e. non-beam) heating mechanism has to be present, and (b) considering that the bolometric emission originates mainly from deeper atmospheric layers, conduction or waves are required as additional energy transport mechanisms.

The STIX Aspect System (SAS): The Optical Aspect System of the Spectrometer/Telescope for Imaging X-Rays (STIX) on Solar Orbiter

The Spectrometer/Telescope for Imaging X-rays (STIX) is a remote sensing instrument on Solar Orbiter that observes the hard X-ray bremsstrahlung emission of solar flares. This paper describes the STIX Aspect System (SAS), a subunit that measures the pointing of STIX relative to the Sun with a precision of ±4″±4″, which is required to accurately localize the reconstructed X-ray images on the Sun. The operating principle of the SAS is based on an optical lens that images the Sun onto a plate that is perforated by small apertures arranged in a cross-shaped configuration of four radial arms. The light passing through the apertures of each arm is detected by a photodiode. Variations of spacecraft pointing and of distance from the Sun cause the solar image to move over different apertures, leading to a modulation of the

measured lightcurves. These signals are used by ground analysis to calculate the locations of the solar limb, and hence the pointing of the telescope.

Constraints on energy release in solar flares from RHESSI and GOES X-ray observations II. Energetics and energy partition

A. **Warmuth** and G. Mann

A&A 588, A116 **(2016)** **10.1051/0004-6361/201527475**

Aims. We derive constraints on energy release, transport and conversion processes in solar flares based on a detailed characterization of the physical parameters of both the thermal plasma and the accelerated nonthermal electrons based on X-ray observations. In particular, we address the questions of whether the energy required to heat the thermal plasma can be supplied by nonthermal particles, and how the energetics derived from X-rays compare to the total bolometric radiated energy.
Methods. Time series of spectral fits and images for 24 flares ranging from GOES class C3.4 to X17.2 were obtained using RHESSI hard X-ray observations. This has been supplemented by GOES soft X-ray fluxes. In our companion Paper I, we have used this data set to obtain the basic physical parameters for the thermal plasma (using the isothermal approximation) and the injected energetic electrons (assuming the thick-target model). Here, we used this data set to derive the flare energetics, including thermal energy, radiative and conductive energy loss, gravitational and flow energy of the plasma, and kinetic energy of the injected electrons. We studied how the thermal energies compare to the energy in nonthermal electrons, and how the various energetics and energy partition depend on flare importance.
Results. All flare energetics show a good to excellent correlation with the peak GOES flux. The gravitational energy of the evaporated plasma and the kinetic energy of plasma flows can be neglected in the discussion of flare energetics. The radiative energy losses are comparable to the maximum thermal energy, while the conductive losses are considerably higher than the maximum thermal energy, especially in weaker flares. The total heating requirement of the hot plasma amounts to ≈50% of the total bolometric energy loss, with the conductive losses as a major contribution. The nonthermal energy input by energetic electrons is not sufficient to account for the total heating requirements of the hot plasma or for the bolometric losses, in particular in weak flares.
Conclusions. Our results support the standard model of solar flares, with the following modifications. (1) Heating the hot thermal plasma and supplying the bolometric radiated energy requires an additional non-beam heating mechanism. (2) Strong conductive losses are a necessary additional energy transport process that transfers the energy released in the corona to the lower (and denser) atmospheric layers, where the bulk of the released energy is efficiently radiated away at longer wavelengths (EUV, UV, and white light) by cooler material.

Constraints on energy release in solar flares from RHESSI and GOES X-ray observations I. Physical parameters and scalings

A. **Warmuth** and G. Mann

A&A 588, A115 **(2016)**

http://www.aanda.org/articles/aa/pdf/2016/04/aa27474-15.pdf

Aims. We constrain energy release and particle acceleration processes in solar flares by means of comprehensively characterizing the physical parameters of both the thermal plasma and the accelerated nonthermal particles using X-ray data. Our aim is to bridge the gap between detailed case studies and large statistical studies.
Methods. We obtained time series of spectral fits and images for 24 flares ranging from GOES class C3.4 to X17.2 using RHESSI hard X-ray observations. These data were used to derive basic physical parameters for the thermal plasma (using the isothermal approximation) and the injected nonthermal electrons (assuming the thick-target model). For the thermal component, this was supplemented by GOES soft X-ray data. We derived the ranges and distributions of the various parameters, the scaling with flare importance, and the relation between thermal parameters derived from RHESSI and GOES. Finally, we investigated the relation between thermal and nonthermal parameters.
Results. Temperature and emission measure of the thermal plasma are strongly correlated with the peak GOES X-ray flux. Higher emission measures result both from a larger source volume and a higher density, with the latter effect being more important. RHESSI consistently gives higher temperatures and lower emission measures than GOES does, which is a signature of a multithermal plasma. The discrepancy between RHESSI and GOES is particularly pronounced in the early flare phase, when the thermal X-ray sources tend to be large and located higher in the corona. The energy input rate by nonthermal electrons is correlated with temperature and with the increase rate of emission measure and thermal energy.
Conclusions. The derived relations between RHESSI- and GOES-derived thermal parameters and the relation between thermal parameters and energy input by nonthermal electrons are consistent with a two-component model of the thermal flare plasma. Both RHESSI and GOES observe a cooler plasma component (≈10−25 MK) that is generated by chromospheric evaporation caused by a nonthermal electron beam. In addition, a hotter component (≥25 MK) is only detected by RHESSI; this component is more consistent with direct in situ heating of coronal plasma. With the exception of the early impulsive phase, RHESSI observes a combination of the evaporated and the directly heated component.

Table 1. Overview of the 24 analyzed flares.

Thermal and nonthermal hard X-ray source sizes in solar flares obtained from RHESSI observations
II. Scaling relations and temporal evolution

A. **Warmuth** and G. Mann

A&A 552, A87 **(2013)**
http://www.aanda.org/articles/aa/pdf/2016/04/aa27475-15.pdf

Context. A thorough understanding of solar flares requires determining the physical parameters of both the hot thermal plasma and the accelerated nonthermal electrons. This can be provided by hard X-ray (HXR) observations. In addition to HXR spectroscopy, imaging is needed to measure the geometric HXR source sizes. These parameters may vary as a function of flare size, importance, and time.
Aims. We determine the scaling relations of the geometric source parameters of both thermal and nonthermal HXR sources with respect to length scale and flare importance, and we characterize their temporal evolution. This is required for further studies involving parameters such as thermal energies, plasma densities, and current densities.
Methods. In a previous paper, we obtained time series of the geometric HXR source sizes (thermal and nonthermal) for 24 flares from GOES class C3.4 to X17.2 using the RHESSI instrument. Here, we investigate how themal volumes, nonthermal footpoint areas, and footpoint separations depend on the flare length scale and GOES importance. In addition,we study the time evolution of these geometric parameters. Table: 2002-2003.
Results. The increase in the thermal source volume with length scale is slightly below a Euclidian scaling, but not too far from it. The thermal source volume is correlated with GOES class, which contrasts with what was found for RHESSI microflares. The nonthermal footpoint areas, on the other hand, are not well-correlated with either length scale or GOES class. With regard to temporal evolution, the RHESSI thermal source volumes tend to show a more complex behavior than the simple growth-decline pattern typical of flares observed in EUV. In most events, the thermal volume shows a rapid initial rise to a peak in the early impulsive phase. This peak is correlated with the initial downward motion of the coronal source, and is consistent with the notion of initially contracting magnetic field lines.
Conclusions. The behavior of the geometric parameters of thermal and nonthermal HXR sources is generally consistent with the standard model of eruptive solar flares: a quasi-Euclidian scaling of volume with length scale, an initially decreasing thermal volume due to field line shrinking, followed by an increase in both volume and footpoint separation with time as the arcade of reconnected flare loops grows. However, the thermal volume is not the dominant factor in determining thermal energy, as well as thermal SXR and HXR flux. Electron density and/or temperature seem to be more important parameters in this respect. **2002 Apr. 10**

Thermal and nonthermal hard X-ray source sizes in solar flares obtained from RHESSI observations
I. Observations and evaluation of methods

A. **Warmuth** and G. Mann

A&A 552, A86 (**2013**)

Context. In solar flares, a large amount of thermal and nonthermal energy is released impulsively in the form of heated plasma and accelerated particles. These processes can be studied via hard X-ray (HXR) diagnostics. In addition to spectroscopic observations, a thorough understanding of the thermal and nonthermal particle populations requires the knowledge of the HXR source sizes.
Aims. We derive the geometric source parameters of both thermal coronal sources and the nonthermal HXR footpoints in solar flares. We compare and evaluate four different methods for obtaining source sizes, and then derive the most reliable source sizes, as well as the systematic uncertainties.
Methods. We obtained time series of HXR images for 24 flares from GOES class C3.4 to X17.2 using the RHESSI instrument. The four imaging techniques employed are CLEAN, Pixon, visibility forward fit, and MEM_NJIT. From this data set, we derived the geometric parameters of the thermal HXR sources and the nonthermal footpoints. Using the different imaging techniques allowed us to quantify systematic measurement uncertainties.
Results. We find that the different methods give consistent results on HXR source sizes. The correlations are very good for the thermal sources, and somewhat lower for the footpoints. The MEM_NJIT algorithm gives systematically smaller sizes than the other methods, possibly a result of over-resolution. Thermal source volumes are in the range of 2 × 1025−1.2 × 1028 cm3 (with a median relative uncertainty of 30%), and nonthermal footpoint areas in the range of 2 × 1016−6 × 1017 cm2 (median relative uncertainty: 40%). The thermal volumes of our sample are in the same range as those derived for microflares, which would imply that source size is not an important parameter for flare energetics.
Conclusions. Using different imaging algorithms for determining HXR source sizes offers the advantage that uncertainties can be better quantified thus making the derived parameters more reliable. Combined with geometric parameters that were derived as time series in a larger number of flares, this will allow the study of the scaling relations and the temporal evolution of thermal and nonthermal HXR sources.

RAPID CHANGES OF ELECTRON ACCELERATION CHARACTERISTICS AT THE END OF THE IMPULSIVE PHASE OF AN X-CLASS SOLAR FLARE

Alexander **Warmuth**1, Gordon D. Holman2, Brian R. Dennis2, Gottfried Mann1, Henry Aurass1, and Ryan O. Milligan2

Astrophysical Journal, 699:917–922, **2009, File**

http://www.iop.org/EJ/toc/-alert=43190/0004-637X/699/1

obtained with *RHESSI*. This flare exhibits HXR pulses during the impulsive phase, with a particularly pronounced peak at the end of the impulsive phase. This peak is associated with HXR emission up to high energies (>300 keV) but does not show any Neupert effect (i.e., no simultaneous rise in soft X-rays). Fitting the spatially integrated photon spectra with a Maxwellian plus a nonthermal thick-target component reveals that the data are consistent with a high low-energy cutoff (≈ 100 keV) of the energetic electrons during the late peak. The high lowenergy cutoff straightforwardly explains the lack of a Neupert effect—while highly energetic electrons are produced efficiently, there is a lack of low-energy electrons that usually contain the bulk of the total energy. Hence, the energy input into the chromosphere remains too small to trigger chromospheric evaporation. This observation shows that the characteristics of electron acceleration can change dramatically and rapidly at the end of the impulsive phase of solar flares. This could be evidence for physically distinct acceleration processes acting in the same event, or alternatively for a sudden shift in the characteristic parameters of the accelerator. Using radio observations and comparing HXR images with magnetograms, we conclude that changes in the strength and the topology of the magnetic field in which the accelerator is working are responsible for the profound changes in the injected electron spectrum.

Modelling shock drift acceleration of electrons at the reconnection outflow termination shock in solar flares - Observational constraints and parametric study:

A. **Warmuth**, G. Mann and H. Aurass

A&A 494 (**2009**) 677-691

http://www.aanda.org/10.1051/0004-6361:200810101

Context. The acceleration of electrons to nonthermal energies in solar flares is one of the main unsolved questions in solar physics. One possibility for producing these energetic electrons is acceleration at the reconnection outflow termination shock (TS).

Aims. By comparing theoretical results with observations of nonthermal electrons, we determine whether shock drift acceleration (SDA) at the TS is a viable electron acceleration mechanism.

Methods. We used radio observations to constrain the characteristics of the TS, and hard X-ray observations provided by *RHESSI*, *INTEGRAL*, and *HXRS* to obtain the characteristics of the injected electrons. Invoking relativistic shock-drift acceleration at the TS, we calculated electron flux spectra, which are then compared with the corresponding observational results from *RHESSI*. A parametric study of the model allows us to answer the question under which conditions the TS is a viable electron accelerator.

Results. SDA at the TS is able to reproduce the required fluxes and kinetic power of nonthermal electrons in solar flares as long as there is significant heating of the outflow jet and a sufficiently large shock area. A prediction of the model is that the flux and power of injected electrons is higher than the values that are usually given by fitting observed spectra, since the low-energy cutoff is generally below 10 keV. The synthetic spectra are consistent with the observed spectral indices up to ≈100 keV. Beyond that, they soften too quickly. Possibly this is because we have not yet considered various additional effects, such as multiple reflections at the shock or some form of preacceleration. The observed relation between electron flux and spectral index is reproduced by the model, as well as the temporal evolution of the energetic electrons. We conclude that SDA at the TS is a viable electron acceleration mechanism that deserves further study.

Constraining Electron Acceleration at a Standing Shock with HXR and Radio Observations

Warmuth, A.; Mann, G.; Aurass, H.

Central European Astrophysical Bulletin (CEAB), **2007**CEAB...31..135W

The acceleration of electrons to non-thermal energies in solar flares is one of the main unsolved questions in solar physics. One possibility for the production of these energetic electrons is acceleration at the reconnection outflow termination shock (TS). We use radio observations to constrain the characteristics of the TS, and hard X-ray and γ-ray observations provided by RHESSI and INTEGRAL to obtain the characteristics of the injected differential electron flux. Invoking relativistic shock-drift acceleration at the TS, we calculate differential electron fluxes, which are then compared with the observations. This approach allows us to answer the question if, and under which conditions, the TS is a viable electron accelerator.

Data-driven model of the solar corona above an active region

J. **Warnecke** and H. Peter

A&A 623, L12 (**2019**)
https://www.aanda.org/articles/aa/pdf/2019/04/aa35385-19.pdf
Aims. We aim to reproduce the structure of the corona above a solar active region as seen in the extreme ultraviolet (EUV) using a three-dimensional magnetohydrodynamic (3D MHD) model.
Methods. The 3D MHD data-driven model solves the induction equation and the mass, momentum, and energy balance. To drive the system, we feed the observed evolution of the magnetic field in the photosphere of the active region AR 12139 into the bottom boundary. This creates a hot corona above the cool photosphere in a self-consistent way. We synthesize the coronal EUV emission from the densities and temperatures in the model and compare this to the actual coronal observations.
Results. We are able to reproduce the overall appearance and key features of the corona in this active region on a qualitative level. The model shows long loops, fan loops, compact loops, and diffuse emission forming at the same locations and at similar times as in the observation. Furthermore, the low-intensity contrast of the model loops in EUV matches the observations.
Conclusions. In our model the energy input into the corona is similar as in the scenarios of fieldline-braiding or flux-tube tectonics, that is, energy is transported to the corona through the driving of the vertical magnetic field by horizontal photospheric motions. The success of our model shows the central role that this process plays for the structure, dynamics, and heating of the corona. **16 August 2014**

Spectroscopic Observations of Current Sheet Formation and Evolution

Harry P. **Warren**, David H. Brooks, Ignacio Ugarte-Urra, Jeffrey W. Reep, Nicholas A. Crump, George A. Doschek
2018 *ApJ* **854** 122
https://arxiv.org/pdf/1711.10826.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/aaa9b8/pdf
We report on the structure and evolution of a current sheet that formed in the wake of an eruptive X8.3 flare observed at the west limb of the Sun on **September 10, 2017**. Using observations from the EUV Imaging Spectrometer (EIS) on Hinode and the Atmospheric Imaging Assembly (AIA) on the Solar Dynamics Observatory (SDO), we find that plasma in the current sheet reaches temperatures of about 20 MK and that the range of temperatures is relatively narrow. The highest temperatures occur at the base of the current sheet, in the region near the top of the post-flare loop arcade. The broadest high temperature line profiles, in contrast, occur at the largest observed heights. Further, line broadening is strong very early in the flare and diminishes over time. The current sheet can be observed in the AIA 211 and 171 channels, which have a considerable contribution from thermal bremsstrahlung at flare temperatures. Comparisons of the emission measure in these channels with other EIS wavelengths and AIA channels dominated by Fe line emission indicate a coronal composition and suggest that the current sheet is formed by the heating of plasma already in the corona. Taken together, these observations suggest that some flare heating occurs in the current sheet while additional energy is released as newly reconnected field lines relax and become more dipolar.
Hinode/ EIS Nugget March 2018 http://solarb.mssl.ucl.ac.uk/SolarB/nuggets/nugget_2018mar.jsp

Transition Region and Chromospheric Signatures of Impulsive Heating Events. I. Observations

Harry P. **Warren**, Jeffrey W. Reep, Nicholas A. Crump, Paulo J. A. Simoes
ApJ 829 35 **2016**
http://arxiv.org/pdf/1606.09045v1.pdf
We exploit the high spatial resolution and high cadence of the Interface Region Imaging Spectrograph (IRIS) to investigate the response of the transition region and chromosphere to energy deposition during a small flare. Simultaneous observations from RHESSI provide constraints on the energetic electrons precipitating into the flare footpoints while observations of XRT, AIA, and EIS allow us to measure the temperatures and emission measures from the resulting flare loops. We find clear evidence for heating over an extended period on the spatial scale of a single IRIS pixel. During the impulsive phase of this event the intensities in each pixel for the Si IV 1402.770, C II 1334.535, Mg II 2796.354 and O I 1355.598 emission lines are characterized by numerous, small-scale bursts typically lasting 60s or less. Red shifts are observed in Si IV, C II, and Mg II during the impulsive phase. Mg II shows red-shifts during the bursts and stationary emission at other times. The Si IV and C II profiles, in contrast, are observed to be red-shifted at all times during the impulsive phase. These persistent red-shifts are a challenge for one-dimensional hydrodynamic models, which predict only short-duration downflows in response to impulsive heating. We conjecture that energy is being released on many small-scale filaments with a power-law distribution of heating rates. 2014-11-19

Abundances in Solar Flares

OBSERVATIONS OF THERMAL FLARE PLASMA WITH THE EUV VARIABILITY EXPERIMENT
Harry P. **Warren**1, John T. Mariska2, and George A. Doschek
2013 ApJ 770 116
One of the defining characteristics of a solar flare is the impulsive formation of very high temperature plasma. The properties of the thermal emission are not well understood, however, and the analysis of solar flare observations is often predicated on the assumption that the flare plasma is isothermal. The EUV Variability Experiment (EVE) on the Solar Dynamics Observatory provides spectrally resolved observations of emission lines that span a wide range of temperatures (e.g., Fe XV-Fe XXIV) and allow for thermal flare plasma to be studied in detail. In this paper we describe a method for computing the differential emission measure distribution in a flare using EVE observations and apply it to several representative events. We find that in all phases of the flare the differential emission measure distribution is broad. Comparisons of EVE spectra with calculations based on parameters derived from the Geostationary Operational Environmental Satellites soft X-ray fluxes indicate that the isothermal approximation is generally a poor representation of the thermal structure of a flare.

A SYSTEMATIC SURVEY OF HIGH-TEMPERATURE EMISSION IN SOLAR ACTIVE REGIONS
Harry P. **Warren**1, Amy R. Winebarger2, and David H. Brooks
2012 ApJ 759 141
The recent analysis of observations taken with the EUV Imaging Spectrometer and X-Ray Telescope instruments on Hinode suggests that well-constrained measurements of the temperature distribution in solar active regions can finally be made. Such measurements are critical for constraining theories of coronal heating. Past analysis, however, has suffered from limited sample sizes and large uncertainties at temperatures between 5 and 10 MK. Here we present a systematic study of the differential emission measure distribution in 15 active region cores. We focus on measurements in the "inter-moss" region, that is, the region between the loop footpoints, where the observations are easier to interpret. To reduce the uncertainties at the highest temperatures we present a new method for isolating the Fe XVIII emission in the AIA/SDO 94 Å channel. The resulting differential emission measure distributions confirm our previous analysis showing that the temperature distribution in an active region core is often strongly peaked near 4 MK. We characterize the properties of the emission distribution as a function of the total unsigned magnetic flux. We find that the amount of high-temperature emission in the active region core is correlated with the total unsigned magnetic flux, while the emission at lower temperatures, in contrast, is inversely related. These results provide compelling evidence that high-temperature active region emission is often close to equilibrium, although weaker active regions may be dominated by evolving million degree loops in the core.

OBSERVATIONS OF RECONNECTING FLARE LOOPS WITH THE ATMOSPHERIC IMAGING ASSEMBLY
Harry P. **Warren**, Casey M. O'Brien1 and Neil R. Sheeley, Jr.
2011 ApJ 742 92
Perhaps the most compelling evidence for the role of magnetic reconnection in solar flares comes from the supra-arcade downflows that have been observed above many post-flare loop arcades. These downflows are thought to be related to highly non-potential field lines that have reconnected and are propagating away from the current sheet. We present new observations of supra-arcade downflows taken with the Atmospheric Imaging Assembly (AIA) on the Solar Dynamics Observatory (SDO). The morphology and dynamics of the downflows observed with AIA provide new evidence for the role of magnetic reconnection in solar flares. With these new observations we are able to measure downflows originating at larger heights than in previous studies. We find, however, that the initial velocities measured here (~144 km s–1) are well below the Alfvén speed expected in the lower corona, and consistent with previous results. We also find no evidence that the downflows brighten with time, as would be expected from chromospheric evaporation. These observations suggest that simple two-dimensional models cannot explain the detailed observations of solar flares.

THE TEMPERATURE DEPENDENCE OF SOLAR ACTIVE REGION OUTFLOWS
Harry P. **Warren**, Ignacio Ugarte-Urra1, Peter R. Young1, and Guillermo Stenborg2
Astrophysical Journal, 727:58 (5pp), **2011** January
Spectroscopic observations with the EUV Imaging Spectrometer (EIS) on *Hinode* have revealed large areas of high-speed outflows at the periphery of many solar active regions. These outflows are of interest because they may connect to the heliosphere and contribute to the solar wind. In this paper, we use slit rasters from EIS in combination

with narrowband slot imaging to study the temperature dependence and morphology of an outflow region and show that it is more complicated than previously thought. Outflows are observed primarily in emission lines from Fe xi to Fe xv. Observations at lower temperatures (Si vii), in contrast, show bright fan-like structures that are dominated by inflows. These data also indicate that the morphology of the outflows and the fans is different, outflows are observed in regions where there is no emission in Si vii. This suggests that the fans, which are often associated with outflows in studies involving imaging data, are not directly related to the active region outflows.

EVIDENCE FOR STEADY HEATING: OBSERVATIONS OF AN ACTIVE REGION CORE WITH HINODE AND TRACE

Harry P. Warren1, Amy R. Winebarger2 and David H. Brooks1,3
2010 ApJ 711 228-238
The timescale for energy release is an important parameter for constraining the coronal heating mechanism. Observations of "warm" coronal loops (~1 MK) have indicated that the heating is impulsive and that coronal plasma is far from equilibrium. In contrast, observations at higher temperatures (~3 MK) have generally been consistent with steady heating models. Previous observations, however, have not been able to exclude the possibility that the high temperature loops are actually composed of many small-scale threads that are in various stages of heating and cooling and only appear to be in equilibrium. With new observations from the EUV Imaging Spectrometer and X-ray Telescope (XRT) on *Hinode* we have the ability to investigate the properties of high temperature coronal plasma in extraordinary detail. We examine the emission in the core of an active region and find three independent lines of evidence for steady heating. We find that the emission observed in XRT is generally steady for hours, with a fluctuation level of approximately 15% in an individual pixel. Short-lived impulsive heating events are observed, but they appear to be unrelated to the steady emission that dominates the active region. Furthermore, we find no evidence for warm emission that is spatially correlated with the hot emission, as would be expected if the high temperature loops are the result of impulsive heating. Finally, we also find that intensities in the "moss," the footpoints of high temperature loops, are consistent with steady heating models provided that we account for the local expansion of the loop from the base of the transition region to the corona. In combination, these results provide strong evidence that the heating in the core of an active region is effectively steady, that is, the time between heating events is short relative to the relevant radiative and conductive cooling times.

Observation and Modeling of Coronal "Moss" With the EUV Imaging Spectrometer on *Hinode*

Emission Line Intensity Ratios of Fe xxvi/ xxv/ xxiv in Solar Flares Observed by Hinotori

Tetsuya **Watanabe**1
2024 ApJ 965 41
https://iopscience.iop.org/article/10.3847/1538-4357/ad298c/pdf
High-resolution spectra observed by the Solar X-ray spectrometer on board the Hinotori mission are revisited. Flat crystals slightly offset to the satellite spin axis produce automatic spectral scans for emission lines emerging from highly charged iron ions in solar flares every half-spin time period. All the downlinked data of the mission are converted to FITS format and major flare spectral data are revived as IDL save files in ISAS/DARTS. Based on these data sets, single-temperature fits are performed for the emission line complex of highly charged iron ions in the wavelength range of 1.75–1.95 Å and compared with theoretical predictions. Synthetic spectra with single electron temperatures estimated from j/w line-intensity ratios fit fairly well for Fe xxiv and Fe xxiii lines in the wavelength range of 1.85–1.88 Å, while intensity ratios of Fe xxv lines (x, y, z) and the inner-shell excitation line of Fe xxiv (q) to the Fe xxv resonance line (w) have systematic excesses. Empirical relations for the observed line ratios are derived. Ion fractions of Fe+25/Fe+24 estimated by intensity ratios of Lyα/w in the temperature range of log Te=7.25–7.45 are consistent with values in ionization equilibrium, and the remaining excesses of the Fe xxv line ratios may suggest problems with the atomic parameters or atomic modeling. **1981 October 7**

White-light Emission and Chromospheric Response by an X1.8-class Flare on 2012 October 23

Kyoko **Watanabe**1 and Shinsuke Imada2
2020 ApJ 891 88
sci-hub.si/10.3847/1538-4357/ab711b
On **2012 October 23**, a strong white-light emission, associated with an X1.8-class flare, was observed by the Solar Optical Telescope on board the Hinode satellite. White-light kernels were clearly observed along the Ca ii H

ribbons. RHESSI also observed hard X-ray emissions that were almost located on the white-light kernels. The total energy of the white-light emission was and the total energy of the accelerated electrons was almost of the same order when we used 40 keV as the lower energy cutoff. The white-light emission appears to have originated from nonthermal electrons in these energies. Moreover, the EUV imaging spectrometer on board the Hinode satellite performed a raster scan over this flaring active region and the flare occurred during the scan. Over the white-light kernels, we observed redshifts of a few tens of km s−1 in Fe xii. It appears that these EUV responses originated from some accelerated electrons due to the solar flare and they are considered to be the source of the white-light emission. In fact, the electron density of the white-light kernels was less than , which is sufficiently low for nonthermal electrons to penetrate into the photosphere.

Characteristics that Produce White-Light Enhancements in Solar Flares Observed by Hinode/SOT

Kyoko **Watanabe**, Jun Kitagawa, Satoshi Masuda
ApJ **850** 204 **2017**
https://arxiv.org/pdf/1710.09531.pdf

To understand the conditions that produce white-light (WL) enhancements in solar flares, a statistical analysis of visible continuum data as observed by Hinode/Solar Optical Telescope (SOT) was performed. In this study, approximately 100 flare events from M- and X-class flares were selected. The time period during which the data were recorded spans from January 2011 to February 2016. Of these events, approximately half are classified as white-light flares (WLFs), whereas the remaining events do not show any enhancements of the visible continuum (non-WLF; NWL). In order to determine the existence of WL emission, running difference images of not only the Hinode/SOT WL (G-band, blue, green, and red filter) data but also the Solar Dynamics Observatory/Helioseismic and Magnetic Imager continuum data are used. A comparison between these two groups of WL data in terms of duration, temperature, emission measure of GOES soft X-rays, distance between EUV flare ribbons, strength of hard X-rays, and photospheric magnetic field strength was undertaken. In this statistical study, WLF events are characterized by a shorter time-scale and shorter ribbon distance compared with NWL events. From the scatter plots of the duration of soft X-rays and the energy of non-thermal electrons, a clear distinction between WLF and NWL events can be made. It is found that the precipitation of large amounts of accelerated electrons within a short time period plays a key role in generating WL enhancements. Finally, it was demonstrated that the coronal magnetic field strength in the flare region is one of the most important factors that allow the individual identification of WLF events from NWL events. **2015 March 11, 2012 July 12**
Table 1. WLF event list and physical parameters from GOES & SDO data. (2011-2015)

Emission Height and Temperature Distribution of White-Light Emission Observed by Hinode/SOT from the 2012 January 27 X-class Solar Flare

Kyoko **Watanabe**, Toshifumi Shimizu, Satoshi Masuda, Kiyoshi Ichimoto, and Masanori Ohno
E-print, Oct **2013**; ApJ, 776, 123 (**2013**)

White-light emissions were observed from an X1.7 class solar flare on **2012 January 27**, using three continuum bands (red, green, and blue) of the Solar Optical Telescope on board the Hinode satellite. This event occurred near the solar limb, and so differences in the locations of the various emissions are consistent with differences in heights above the photosphere of the various emission sources. Under this interpretation, our observations are consistent with the white-light emissions occurring at the lowest levels of where the Ca II H emission occurs. Moreover, the centers of the source regions of the red, green, and blue wavelengths of the white-light emissions are significantly displaced from each other, suggesting that those respective emissions are emanating from progressively lower heights in the solar atmosphere. The temperature distribution was also calculated from the white-light data, and we found the lower-layer emission to have a higher temperature. This indicates that high-energy particles penetrated down to near the photosphere, and deposited heat into the ambient lower layers of the atmosphere.

Production of High-Temperature Plasmas During the Early Phases of a C9.7 Flare. II. Bi-directional Flows Suggestive of Reconnection in a Pre-flare Brightening Region

T. **Watanabe**, H. Hara, A. C. Sterling, L. K. Harra
Solar Physics, November **2012**, Volume 281, Issue 1, pp 87-99

The **6 June 2007** 16:55 UT flare was well observed with high time-cadence sparse raster scans by the EUV Imaging Spectrometer (EIS) on board the Hinode spacecraft. The observation covers an active region area of 240 arcsec × 240 arcsec with the 1 arcsec slit in about 160 seconds.
We describe here spectral properties of a “pre-flare brightening” to this flare, which started about nine minutes prior to flare-ribbon onset. This flare brightening looks like two small loops apparently having a cusp-shape structure about 40 – 50 arcsec west of the main flaring loops, which show dynamic behavior in velocity during the early phases of the flare: The He ii line at 256.32 Å shows the existence of a bi-directional flow along the Sun–Earth line of sight of about −70 and +100 km s−1. On the other hand, the Fe xvi line at 262.98 Å formed at higher coronal temperatures shows only a slight increase in intensity at the location of these loops, and the Fe xxiii line at 263.76 Å barely appears. Electron

density at the site derived from the intensity ratios of the Fe xiv line pair at 264.78 Å and 274.20 Å is lower than the average of 109.3 cm−3 in other parts of the active-region outskirts. Combining a time series of STEREO-A/B SECCHI-EUVI 171 Å images, we conclude that the pre-flare-brightening region may be heated via magnetic reconnection taking place as a result of loop–loop interaction**.**

Hinode Flare Catalogue

K. **Watanabe**, S. Masuda and T. Segawa
Solar Phys. Volume 279, Number 1, 317-322 **2012; File**
We describe a catalogue of solar flares observed by the three instruments (SOT, XRT, EIS) onboard the Hinode satellite. From the launch of the Hinode satellite in September 2006 until late 2011, about 5000 solar flares (larger than A-class in the GOES classification) occurred during the five-year period of Hinode observations, and more than half of them were captured by the Hinode telescopes. Observation information for RHESSI and Nobeyama Radioheliograph are also included in the catalogue. This catalogue is distributed to users through the Internet. It will be useful and helpful for scientists in surveying flares to be analyzed, facilitate access to Hinode data, and help advance data analysis activities among the world solar community**.** **http://st4a.stelab.nagoya-u.ac.jp/hinode_flare/**

ELLERMAN BOMBS AT HIGH RESOLUTION. I. MORPHOLOGICAL EVIDENCE FOR PHOTOSPHERIC RECONNECTION

Hiroko **Watanabe**1, Gregal Vissers2, Reizaburo Kitai1, Luc Rouppe van der Voort2 and Robert J. Rutten
2011 ApJ 736 71
High-resolution imaging-spectroscopy movies of solar active region NOAA 10998 obtained with the Crisp Imaging Spectropolarimeter at the Swedish 1-m Solar Telescope show very bright, rapidly flickering, flame-like features that appear intermittently in the wings of the Balmer Hα line in a region with moat flows and likely some flux emergence. They show up at regular Hα blue-wing bright points that outline the magnetic network, but flare upward with much larger brightness and distinct "jet" morphology seen from aside in the limbward view of these movies. We classify these features as Ellerman bombs and present a morphological study of their appearance at the unprecedented spatial, temporal, and spectral resolution of these observations. The bombs appear along the magnetic network with footpoint extents up to 900 km. They show apparent travel away from the spot along the pre-existing network at speeds of about 1 km s–1. The bombs flare repetitively with much rapid variation at timescales of seconds only, in the form of upward jet-shaped brightness features. These reach heights of 600-1200 km and tend to show blueshifts; some show bi-directional Doppler signature and some seem accompanied with an Hα surge. They are not seen in the core of Hα due to shielding by overlying chromospheric fibrils. The network where they originate has normal properties. The morphology of these jets strongly supports deep-seated photospheric reconnection of emergent or moat-driven magnetic flux with pre-existing strong vertical network fields as the mechanism underlying the Ellerman bomb phenomenon.

PRODUCTION OF HIGH-TEMPERATURE PLASMAS DURING THE EARLY PHASES OF A C9.7 FLARE

Tetsuya **Watanabe** 1,2, Hirohisa Hara 1,2, Alphonse C. Sterling 3,4 and Louise K. Harra 5
2010 ApJ 719 213
Explosive chromospheric evaporation is predicted from some current solar flare models. In this paper, we analyze a flare with high time cadence raster scans with the EUV Imaging Spectrometer (EIS) on board the Hinode spacecraft. This observation covers an area of 240" × 240", with the 1" slit in about 160 s. The early phases of a C9.7 flare that occurred on **2007 June 6** were well observed. The purpose of our analysis is to study for the first time the spatially resolved spectra of high-temperature plasma, especially from Fe XXIII and Fe XXIV, allowing us to explore the explosive chromospheric evaporation scenario further. Sections of raster images obtained between 17:20:09 and 17:20:29 (UT) show a few bright patches of emission from Fe XXIII/Fe XXIV lines at the footpoints of the flaring loops; these footpoints were not clearly seen in the images taken earlier, between 17:17:30 and 17:17:49 (UT). Fe XXIII spectra at these footpoints show dominating blueshifted components of –(300 to 400) km s–1, while Fe XV/XIV lines are nearly stationary; Fe XII lines and/or lower temperature lines show slightly redshifted features, and Fe VIII and Si VII to He II lines show ~+50 km s–1 redshifted components. The density of the 1.5-2 MK plasma at these footpoints is estimated to be 3 × 1010 cm–3 by the Fe XIII/XIV line pairs around the maximum of the flare. High-temperature loops connecting the footpoints appear in the Fe XXIII/XXIV images taken over 17:22:49-17:23:08 (UT) which is near the flare peak. Line profiles of these high-temperature lines at this flare peak time show only slowly moving components. The concurrent cooler Fe XVII line at 254.8 Å is relatively weak, indicating the predominance of high-temperature plasma (>107 K) in these loops. The characteristics observed during the early phases of this flare are consistent with the scenario of explosive chromospheric evaporation.

G-BAND AND HARD X-RAY EMISSIONS OF THE 2006 DECEMBER 14 FLARE OBSERVED BY *HINODE*/SOT AND *RHESSI*

Kyoko **Watanabe**1, S¨am Krucker2, Hugh Hudson2, Toshifumi Shimizu1, Satoshi Masuda3, and Kiyoshi Ichimoto4

Astrophysical Journal, 715:651–655, **2010** May; **File**

We report on *G*-band emission observed by the Solar Optical Telescope on board the *Hinode* satellite in association with the X1.5-class flare on **2006 December 14**. The *G*-band enhancements originate from the footpoints of flaring coronal magnetic loops, coinciding with nonthermal hard X-ray bremsstrahlung sources observed by the *Reuven Ramaty High Energy Solar Spectroscopic Imager*. At the available 2 minute cadence, the *G*-band and hard X-ray intensities are furthermore well correlated in time. Assuming that the *G*-band enhancements are continuum emission from a blackbody, we derived the total radiative losses of the white-light flare (white-light power). If the *G*-band enhancements additionally have a contribution from lines, the derived values are overestimates. We compare the white-light power with the power in hard X-ray producing electrons using the thick-target assumption. Independent of the cutoff energy of the accelerated electron spectrum, the white-light power and the power of accelerated electrons are roughly proportional. Using the observed upper limit of ~30 keV for the cutoff energy, the hard X-ray producing electrons provide at least a factor of 2 more power than needed to produce the white-light emission. For electrons above 40 keV, the powers roughly match for all four of the time intervals available during the impulsive phase. Hence, the flare-accelerated electrons contain enough energy to produce the white-light flare emissions. The observed correlation in time, space, and power strongly suggests that electron acceleration and white-light production in solar flares are closely related. However, the results also call attention to the inconsistency in apparent source heights of the hard X-ray (chromosphere) and white-light (upper photosphere) sources.

25 Years of Self-organized Criticality: Concepts and Controversies **Review**

Nicholas W. **Watkins**, Gunnar Pruessner, Sandra C. Chapman, Norma B. Crosby, Henrik J. Jensen

Space Science Reviews **2015**

Introduced by the late Per Bak and his colleagues, self-organized criticality (SOC) has been one of the most stimulating concepts to come out of statistical mechanics and condensed matter theory in the last few decades, and has played a significant role in the development of complexity science. SOC, and more generally fractals and power laws, have attracted much comment, ranging from the very positive to the polemical. The other papers (Aschwanden et al. in Space Sci. Rev., 2014, this issue; McAteer et al. in Space Sci. Rev., 2015, this issue; Sharma et al. in Space Sci. Rev. 2015, in preparation) in this special issue showcase the considerable body of observations in solar, magnetospheric and fusion plasma inspired by the SOC idea, and expose the fertile role the new paradigm has played in approaches to modeling and understanding multiscale plasma instabilities. This very broad impact, and the necessary process of adapting a scientific hypothesis to the conditions of a given physical system, has meant that SOC as studied in these fields has sometimes differed significantly from the definition originally given by its creators. In Bak's own field of theoretical physics there are significant observational and theoretical open questions, even 25 years on (Pruessner 2012). One aim of the present review is to address the dichotomy between the great reception SOC has received in some areas, and its shortcomings, as they became manifest in the controversies it triggered. Our article tries to clear up what we think are misunderstandings of SOC in fields more remote from its origins in statistical mechanics, condensed matter and dynamical systems by revisiting Bak, Tang and Wiesenfeld's original papers.

Observation of a Flare and Filament Eruption in Lyman-αα on 8 September 2011 by the PRoject for OnBoard Autonomy/Large Yield Radiometer (PROBA2/LYRA)

L. **Wauters**, M. Dominique, R. Milligan, I. E. Dammasch, M. Kretzschmar & J. Machol

Solar Physics volume 297, Article number: 36 (**2022**)

https://link.springer.com/content/pdf/10.1007/s11207-022-01963-0.pdf

The Large Yield Radiometer (LYRA) instrument onboard the PRoject for OnBoard Autonomy (PROBA2) observes the solar irradiance in four channels in the UV–EUV. One of these channels is centered around the hydrogen line at 121.6 nm. The solar Lyman-αα emission line is an optically thick line mostly formed in the chromosphere. Although it is one of the strongest lines of the solar spectrum, only a limited number of instruments provided observations of solar flares in Lyman-αα, and those observations differ significantly in shape, durations, and amplitude. We focus on an event that happened on **8 September 2011** (SOL2011-09-08T15:46). This event, an M6.7 flare, was associated with a filament eruption that happened during the decaying phase of the flare. Most of the irradiance fluctuations observed in the Lyman-αα time series are synchronized with nonthermal emission fluctuations, as is predicted by flare models. However, there is a late-phase peak in Lyman-αα observations that rather correlates with the timing of the filament eruption. We demonstrate that the eruption of the filament is at the origin of this peak.

Understanding Problem Forecasts of ISEST Campaign Flare-CME Events

David **Webb**, Nariaki Nitta

Solar Physics October **2017**, 292:142

The goal of the International Study of Earth-affecting Solar Transients (ISEST) project as part of the Variability of the Sun and Its Terrestrial Impact (VarSITI) program is to understand the origin, evolution, and propagation of solar transients through the space between the Sun and Earth, and to improve our prediction capability for space weather. A goal of ISEST Working Group 4 (Campaign Events) is to study a set of well-observed Sun-to-Earth events to develop an understanding of why some events are successfully forecast (textbook cases), whereas others become problem or failed forecasts. In this article we study six cases during the rise of Solar Cycle 24 that highlight forecasting problems. Likely source coronal mass ejections (CMEs) were identified in all six cases, but the related solar surface activity ranged from uncertain or weak to X-class flares. The geoeffects ranged from none to severe as in the two Sun–Earth events in 2015 that caused severe storms. These events were chosen to illustrate some key problems in understanding the chain from cause to geoeffect. **6 Jan. 2012, 7 – 9 Mar. 2012, 12 – 14 July 2012, 23 – 24 July 2012, 4 – 8 Oct. 2012, 15 – 17 Mar. 2013, 1 June 2013, 7 – 9 Jan. 2014, 10 – 13 Sep. 2014, 15 – 17 Mar. 2015, 21 – 24 June 2015**

Episodic energy release during the main- and post-impulsive phase of a solar flare

Yuqian **Wei**, Bin Chen, Sijie Yu, Haimin Wang, Yixian Zhang, Lindsay Glesener

ApJ **964** 174 **2024**

https://arxiv.org/pdf/2403.00985.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/ad2e8f/pdf

When and where the magnetic field energy is released and converted in eruptive solar flares remains an outstanding topic in solar physics. To shed light on this question, here we report multi-wavelength observations of a C9.4-class eruptive limb flare that occurred on **2017 August 20**. The flare, accompanied by a magnetic flux rope eruption and a white light coronal mass ejection, features three post-impulsive X-ray and microwave bursts immediately following its main impulsive phase. For each burst, both microwave and X-ray imaging suggest that the non-thermal electrons are located in the above-the-loop-top region. Interestingly, contrary to many other flares, the peak flux of the three post-impulsive microwave and X-ray bursts shows an increase for later bursts. Spectral analysis reveals that the sources have a hardening spectral index, suggesting a more efficient electron acceleration into the later post-impulsive bursts. We observe a positive correlation between the acceleration of the magnetic flux rope and the non-thermal energy release during the post-impulsive bursts in the same event. Intriguingly, different from some other eruptive events, this correlation does not hold for the main impulse phase of this event, which we interpret as energy release due to the tether-cutting reconnection before the primary flux rope acceleration occurs. In addition, using footpoint brightenings at conjugate flare ribbons, a weakening reconnection guide field is inferred, which may also contribute to the hardening of the non-thermal electrons during the post-impulsive phase. **2017 August 20**

The Photospheric Imprints of Coronal Electric Currents

Brian T. **Welsch**

ApJ **2022**

https://arxiv.org/pdf/2211.01911.pdf

Flares and coronal mass ejections are powered by magnetic energy stored in coronal electric currents. Here, we explore the nature of coronal currents in observed and model active region (ARs) by studying manifestations of these currents in photospheric vector magnetograms. We employ Gauss's separation method, recently introduced to the solar physics literature, to partition the photospheric field into three distinct components, each arising from a separate source: (i) currents passing through the photosphere, (ii) currents flowing below it, and (iii) currents flowing above it. We refer to component (iii) as the photospheric imprint of coronal currents. In both AR 10930 and AR 11158, photospheric imprints exhibit large-scale, spatially coherent structures along these regions' central, sheared polarity inversion lines (PILs) that are consistent with coronal currents flowing horizontally above these PILs, similar to recent findings in AR 12673 by Schuck et al. (2022). We find similar photospheric imprints in a simple model of a non-potential AR with known currents. We find that flare-associated changes in photospheric imprints in AR 11158 accord with earlier reports that near-PIL fields become more horizontal, consistent with the "implosion" scenario. We hypothesize that this evolution effectively shortens, in an overall sense, current-carrying coronal fields, leading to decreased inductive energy (DIE) in the coronal field. We further hypothesize that, in the hours prior to flares, parts of the coronal field slowly expand, in a process we deem coronal inflation (CI) -- essentially, the inverse of the implosion process. Both of these hypotheses are testable with non-potential coronal field extrapolations. **2006/12/12, 2011/02/15**

SWAP Observations of Post-flare Giant Arches in the Long-Duration 14 October 2014 Solar Eruption

Matthew J. **West** and Daniel B. Seaton

ApJL **2015**
http://arxiv.org/pdf/1502.00801v1.pdf
On **14 October 2014** the Sun Watcher with Active Pixels and Image Processing (SWAP) EUV solar telescope on-board the Project for On-Board Autonomy 2 (PROBA2) spacecraft observed an eruption that led to the formation of perhaps the largest post-eruptive loop system seen in the solar corona in solar cycle 24. The initial eruption occurred at about 18:30 UT on 14 October, behind the East Solar limb, and was observed as a a coronal mass ejection and an M2.2 solar flare. In the 48 hours following the eruption, the associated post-eruptive loops grew to a height of approximately 400000 km (>0.5 solar-radii) at rates between 2-6 km/s. We conclude from our observations of this event that ordinary post-eruptive loops and so-called post-flare giant arches are fundamentally the same and are formed by the same magnetic reconnection mechanism.

Photospheric response to a flare

Michael S. **Wheatland**, Donald B. Melrose, Alpha Mastrano
ApJ **864** 159 **2018**
https://arxiv.org/pdf/1808.03097.pdf
http://sci-hub.tw/http://iopscience.iop.org/article/10.3847/1538-4357/aad8ae/meta
Flares produce sudden and permanent changes in the horizontal photospheric magnetic field. In particular flares generally produce increased magnetic shear in the photospheric field along the neutral line. Recent observations show also that flares can produce sudden photospheric motion. We present a model for the observed changes as the response of the photosphere to a large-amplitude shear Alfv\'{e}n wave propagating down from the corona on either side of the neutral line. The Alfv\'{e}nic front is assumed to impact the photosphere close to the neutral line first, and then successively further away with time, such that the line of impact coincides with the flare ribbon. The wave introduces magnetic shear and velocity shear. The magnetic shear introduced at the photosphere has the same sign on either side of the neutral line, while the velocity shear has the opposite sign. We discuss the possibility that this process is responsible for particle acceleration in flares. **22 June 2015**

Estimating Electric Current Densities in Solar Active Regions

M. S. **Wheatland**
Solar Phys. **2015**
Electric currents in solar active regions are thought to provide the energy released via magnetic reconnection in solar flares. Vertical electric current densities J z at the photosphere may be estimated from vector magnetogram data, subject to substantial uncertainties. The values provide boundary conditions for nonlinear force-free modelling of active region magnetic fields. A method is presented for estimating values of J z taking into account uncertainties in vector magnetogram field values, and minimisingJ2zacross the active region. The method is demonstrated using the boundary values of the field for a force-free twisted bipole, with the addition of noise at randomly chosen locations.

ANTI-PHASE SIGNATURE OF FLARE GENERATED TRANSVERSE LOOP OSCILLATIONS

R. S. **White**, E. Verwichte, and C. Foullon
2013 ApJ 774 104
Transverse loop oscillations observed by the Atmospheric Imaging Assembly instrument on the Solar Dynamics Observatory spacecraft are studied after an impulsive solar flare eruption on **2012 May 8**. We have found that a transversely oscillating coronal loop seen in the 171 Å bandpass oscillates in anti-phase with respect to adjacent larger loops seen in the 193 Å and 211 Å bandpasses. These unusual oscillations are analyzed to investigate the excitation mechanism responsible for their initial inwardly directed anti-phase behavior. The transverse oscillations are analyzed by constructing space-time diagrams from cuts made parallel to the projected loop displacements. The displacement time oscillation profiles are background subtracted and fitted with a damped cosine curve that includes a linear change in the period with time. The local magnetic topology of the active region is modeled using potential field source surface extrapolation. It reveals that the loops are anchored in different topological regions with foot point locations identified on either side of the EUV flare peak emission source. In this context, the oscillation characteristics indicate that the excitation mechanism is closely linked to the local magnetic field topology and the reconnection generated wave dynamics in the active region rather than following an external flare blast wave. We discuss how observations such as these may serve to identify reconnection processes in similar quadrupolar active regions.

First observation of a transverse vertical oscillation during the formation of a hot post-flare loop

R. S. **White**, E. Verwichte and C. Foullon

A&A 545, A129 (**2012**)
Aims. We report and analyse the first observation of a transverse oscillation in a hot coronal loop with the Atmospheric Imaging Assembly (AIA) on the Solar Dynamics Observatory (SDO), following a linked coronal-flare mass-ejection event on the **3 November 2010**. The oscillating coronal loop is observed off the east solar limb and exclusively in the 131 Å and 94 Å bandpasses, indicating a loop plasma of temperature in the range of 9–11 MK. Furthermore, the loop is not observed to cool into the other AIA channels, but just disappears from all bandpasses at the end of the oscillation.
Methods. A time series analysis of the loop oscillation is conducted by taking several cuts at different positions along the loop, estimating the transverse displacements over time for two strands in the loop and fitting those with a damped cosine curve. Intensity time variations, both along the loop and for a series of cut cross-sections, are investigated. Using a three-dimensional loop geometry obtained from a comparison of STEREO-B/EUVI and AIA images, we model different modes of transverse oscillations in the uniformly filled loop.
Results. Our time series analysis reveals a period of 302 ± 14 s (291 ± 9 s) and a damping time of 306 ± 43 s (487 ± 125 s) for the first (second) loop strand. A spatial phase shift along the loop of approximately 180° suggests that we observe a higher order harmonic. Intensity oscillations are consistent with an interpretation in terms of a vertically polarised mode. Our forward modelling suggests that the loop oscillates as either a second or third order harmonic of this mode.
Conclusions. This is the first observation of a transverse loop oscillation observed exclusively in the hot coronal lines. The loop oscillation is vertically polarised and is dominated by a higher order harmonic mode. We conclude that the excitation mechanism of this 5 min period oscillation is directly connected with the reconnection processes that form the post flare loop, which differs from the blast wave excitation mechanism often proposed as the cause of cooler transverse loop oscillations.

Solar Flare Sounding Rocket Campaign

A Statistical Study to Determine the Origin of Long-Duration Gamma-ray Flares

Lisa M. **Winter**, Valerie Bernstein, Nicola Omodei, Melissa Pesce-Rollins
ApJ **864** 39 **2018**
https://arxiv.org/pdf/1807.06001.pdf **File**
http://sci-hub.tw/10.3847/1538-4357/aad3c0
Two scenarios have been proposed to account for sustained ≥30\,MeV gamma-ray emission in solar flares: (1) prolonged particle acceleration/trapping involving large-scale magnetic loops at the flare site, and (2) precipitation of high-energy (> 300 MeV) protons accelerated at coronal/interplanetary shock waves. To determine which of these scenarios is more likely, we examine the associated soft X-ray flares, coronal mass ejections (CMEs), and solar energetic proton events (SEPs) for: (a) the long-duration gamma-ray flares (LDGRFs) observed by the Large Area Telescope (LAT) on \Fermi, and (b) delayed and/or spatially-extended high-energy gamma-ray flares observed by the Gamma-ray Spectrometer on the Solar Maximum Mission, the Gamma-1 telescope on the Gamma satellite, and the Energetic Gamma-Ray Experiment Telescope on the Compton Gamma-Ray Observatory. For the \Fermi data set of 11 LDGRFs with >100 MeV emission lasting for ≥∼2 hours, we search for associations and reverse associations between LDGRFs, X-ray flares, CMEs, and SEPs, i.e., beginning with the gamma-ray flares and also, in turn, with X-class soft X-ray flares, fast (≥ 1500 km s−1) and wide CMEs, and intense (peak flux ≥2.67×10−3 protons cm−2 s−1 sr−1, with peak to background ratio > 1.38) > 300 MeV SEPs at 1 A.U. While LDGRFs tend to be associated with bright X-class flares, we find that only 1/3 of the X-class flares during the time of \Fermi monitoring coincide with an LDGRF. However, nearly all fast, wide CMEs are associated with an LDGRF. These preliminary association analyses favor the proton precipitation scenario, although there is a prominent counter-example of a potentially magnetically well-connected solar eruption with > 100 MeV emission for ∼10 h for which the near-Earth > 300 MeV proton intensity did not rise above background. **2011.03.07, 2012.01.27, 2012.03.07,**

Using the Maximum X-ray Flux Ratio and X-ray Background to Predict Solar Flare Class

Lisa M. **Winter**, K. Balasubramaniam
JGR or Space Weather **2015**
http://arxiv.org/pdf/1504.00294v1.pdf

We present the discovery of a relationship between the maximum ratio of the flare flux (namely, 0.5-4 Ang to the 1-8 Ang flux) and non-flare background (namely, the 1-8 Ang background flux), which clearly separates flares into classes by peak flux level. We established this relationship based on an analysis of the Geostationary Operational Environmental Satellites (GOES) X-ray observations of ~ 50,000 X, M, C, and B flares derived from the NOAA/SWPC flares catalog. Employing a combination of machine learning techniques (K-nearest neighbors and nearest-centroid algorithms) we show a separation of the observed parameters for the different peak flaring energies. This analysis is validated by successfully predicting the flare classes for 100% of the X-class flares, 76% of the M-class flares, 80% of the C-class flares and 81% of the B-class flares for solar cycle 24, based on the training of the parametric extracts for solar flares in cycles 22-23. **Aug 09 2011**

Frequency Distribution of Acoustic Oscillation in the Solar Atmosphere During Flare Event

A. **Wiśniewska**1,2, E. Chmielewska3, K. Radziszewski3, M. Roth2, and J. Staiger2
2019 ApJ 886 32
https://doi.org/10.3847/1538-4357/ab487c
We present a study of multi-wavelength observations, of a C 2.3 solar flare in Active Region NOAA 12353, observed on **2015 May 23**, which reveal new properties of acoustic waves in the flaring region. The space-, and ground-based data measured by the HELioseismological Large Regions Interferometric Device, operating at the Vacuum Tower Telescope, the Atmospheric Imaging Assembly (AIA), and Helioseismic and Magnetic Imager on board the Solar Dynamic Observatory, were used in this paper. First, using power spectra of solar oscillations, we identified the dominant frequencies and their location at seven different atmospheric levels before and after the flare event. Second, based on AIA observations taken in six Extreme Ultraviolet filters, we derived Differential Emission Measure (DEM) profiles and DEM maps of the flare. Finally, we confirm the sigma shape of the magnetic field in the active area, directly related to the flare. Our results are as follows: the high-frequency waves ($\nu > 5$ mHz) in the photosphere, in both cases, before and after the flare, are generated at the footpoints of the chromospheric loop, while in the chromosphere (Hα line), before the event the power enhancement exhibits the maximum of flare emission, and after the eruption the enhancement by all frequencies is observed only in the post-flare loop area. Moreover, the power of oscillation in the pores surrounding the area before the flare has a random character, while after the flare oscillation power is concentrated in the pore, and weakened outside of. We conclude that accurate detection of high-frequency acoustic waves in active regions can lead to faster and easier prediction of high-energy events.

WHAT IS THE RELATIONSHIP BETWEEN PHOTOSPHERIC FLOW FIELDS AND SOLAR FLARES?

Astrophysical Journal, 705:821–843, **2009** November
We estimated photospheric velocities by separately applying the Fourier Local Correlation Tracking and Differential Affine Velocity Estimator methods to 2708 co-registered pairs of *SOHO*/MDI magnetograms, with nominal 96 minute cadence and ~2_ pixels, from 46 active regions (ARs) from 1996 to 1998 over the time interval τ_{45} when each AR was within 45◦ of disk center. For each magnetogram pair, we computed the reprojected, average estimated radial magnetic field, $\tilde{} B_R$; and each tracking method produced an independently estimated flow field, **u**. We then quantitatively characterized these magnetic and flow fields by computing several extensive and intensive properties of each; extensive properties scale with AR size, while intensive properties do not depend directly on AR size. Intensive flow properties included moments of speeds, horizontal divergences, and radial curls; extensive flow properties included sums of these properties over each AR, and a crude proxy for the ideal Poynting flux, $S_R = \_|\mathbf{u}| \tilde{} B_R$. Several quantities derived from $\tilde{} B_R$ were also computed, including: √, the total unsigned flux; R, a measure of the unsigned flux near strong-field polarity inversion lines; and $\_ \tilde{} B_R$. Next, using correlation and discriminant analysis, we investigated the associations between these properties and flares from the *GOES* flare catalog, when averaged over both τ_{45} and shorter time windows of 6 and 24 hr. Our AR sample included both flaring and flare-quiet ARs; the latter did not flare above *GOES* C1.0 level during τ_{45}. Among magnetic properties, we found R to be most strongly associated with flare flux. Among extensive flow properties, the proxy Poynting flux, S_R, was most strongly associated with flare flux, at a level comparable to that of R. All intensive flow properties studied were more poorly associated with flare flux than these extensive properties. Past flare activity was also associated with future flare occurrence. The largest coefficients of determination from correlations with flare flux that we performed are~ 0.25, implying no single variable that we considered can explain the majority of variability in average flare flux.

Estimating electric current densities in solar active regions

M.S. **Wheatland**
Solar Phys. Volume 290, Issue 4, pp 1147-1157 **2015**
http://arxiv.org/pdf/1503.02741v1.pdf
Electric currents in solar active regions are thought to provide the energy released via magnetic reconnection in solar flares. Vertical electric current densities Jz at the photosphere may be estimated from vector magnetogram data, subject to substantial uncertainties. The values provide boundary conditions for nonlinear force- free modelling of active region magnetic fields. A method is presented for estimating values of Jz taking into account uncertainties in vector magnetogram field values, and minimizing J2z across the active region. The method is demonstrated using the boundary values of the field for a force-free twisted bipole, with the addition of noise at randomly chosen locations.

The Energetics of a Flaring Solar Active Region and Observed Flare Statistics

M. S. **Wheatland**
The Astrophysical Journal, Vol. 679, No. 2: 1621-1628, **2008**.
http://www.journals.uchicago.edu/doi/abs/10.1086/587871
A stochastic model for the energy of a flaring solar active region is presented, generalizing and extending the approach of Wheatland and Glukhov. The probability distribution for the free energy of an active region is described by the solution to a master equation involving deterministic energy input and random jump transitions downward in energy (solar flares). It is shown how two observable distributions, the flare frequency-energy distribution and the flare waiting-time distribution, may be derived from the steady state solution to the master equation, for given choices for the energy input and for the rates of flare transitions. An efficient method of numerical solution of the steady state master equation is presented. Solutions appropriate for flaring, involving a constant rate of energy input and powerlaw distributed jump transition rates, are numerically investigated. The flarelike solutions exhibit power-law flare frequency-energy distributions below a high-energy rollover, set by the largest energy the active region is likely to have. The solutions also exhibit approximately exponential (i.e., Poisson) waiting-time distributions, despite the rate of flaring depending on the free energy of the system.

Including Flare Sympathy in a Model for Solar Flare Statistics

The Relationship Between Solar Radio and Hard X-ray Emission **A Review**

S. M. **White**1,5, A. O. Benz2, S. Christe3, F. F´arn´ık4, M. R. Kundu5, G. Mann6, Z. Ning7, J.-P. Raulin8, A. V. R. Silva-V´alio8, P. Saint-Hilaire9, N. Vilmer10, and A.Warmuth6
Space Sci. Rev., 159:225–261, **2011, File**
This **review** discusses the complementary relationship between radio and hard X-ray observations of the Sun using primarily results from the era of the *Reuven Ramaty High Energy Solar Spectroscopic Imager* satellite. A primary focus of joint radio and hard X-ray studies of solar flares uses observations of nonthermal gyrosynchrotron emission at radio wavelengths and bremsstrahlung hard X-rays to study the properties of electrons accelerated in the main flare site, since it is well established that these two emissions show very similar temporal behavior. A quantitative prescription is given for comparing the electron energy distributions derived separately from the two wavelength ranges: this is an important application with the potential for measuring the magnetic field strength in the flaring region, and reveals significant differences between the electrons in different energy ranges. Examples of the use of simultaneous data from the two wavelength ranges to derive physical conditions are then discussed, including the case of microflares, and the comparison of images at radio and hard X-ray wavelengths is presented. There have been puzzling results obtained from observations of solar flares at millimeter and submillimeter wavelengths, and the comparison of these results with corresponding hard X-ray data is presented. Finally, the review discusses the association of hard X-ray releases with radio emission at decimeter and meter wavelengths, which is dominated by plasma emission (at lower frequencies) and electron cyclotron maser emission (at higher frequencies), both coherent emission mechanisms that require small numbers of energetic electrons. These comparisons show broad general associations but detailed correspondence remains more elusive.

The Dependence of Solar Flare Magnitude on sunspot Area During Activity Cycle 24

Lucy **Will**1, Ellis A. Avallone2, and Xudong Sun

2022 Res. Notes AAS 6 37
We measure the sunspot areas of activity cycle 24 using ten years of continuum images from the Helioseismic and Magnetic Imager, and compare them with the peak flare soft X-ray flux from the Geostationary Operational Environmental Satellite. We find that the sunspot area in our sample is positively correlated with the magnitude of the largest flare they produce. Complex spot groups with βγδ magnetic classification tend to be larger and more likely to produce intense flares. Our findings are qualitatively consistent with previous studies.

Investigating the Efficacy of Topologically Derived Time-Series for Flare Forecasting. I. Dataset Preparation

Thomas **Williams**, Christopher B. Prior, David MacTaggart
ApJ **2024**
https://arxiv.org/pdf/2412.04335
The accurate forecasting of solar flares is considered a key goal within the solar physics and space weather communities. There is significant potential for flare prediction to be improved by incorporating topological fluxes of magnetogram datasets, without the need to invoke three-dimensional magnetic field extrapolations. Topological quantities such as magnetic helicity and magnetic winding have shown significant potential towards this aim, and provide spatio-temporal information about the complexity of active region magnetic fields. This study develops time-series that are derived from the spatial fluxes of helicity and winding that show significant potential for solar flare prediction. It is demonstrated that time-series signals, which correlate with flare onset times, also exhibit clear spatial correlations with eruptive activity; establishing a potential causal relationship. A significant database of helicity and winding fluxes and associated time series across 144 active regions is generated using SHARP data processed with the ARTop code that forms the basis of the time-series and spatial investigations conducted here. We find that a number of time-series in this dataset often exhibit extremal signals that occur 1-8 hours before a flare. This, publicly available, living dataset will allow users to incorporate these data into their own flare prediction algorithms.

Evidence from EIS for axial filament rotation before a large flare

Williams, D. R., Harra, L. K., Brooks, D. H., Imada, S., Hansteen, V. H.
E-print, Feb. 2009; PASJ (Vol. 61, No. 3, June **2009**
http://www.mssl.ucl.ac.uk/~drw/papers/antisymvel/v4_erupfil.pdf
In this article, we present observations made with the Extreme-ultraviolet Imaging Spectrometer (EIS) on-board the Hinode solar satellite, of an active region filament in the He II emission line at 256.32 ?. The host active region (AR 10930) produces an X-class flare during these observations. We measure Doppler shifts with apparent velocities of up to 20 km/s, which are antisymmetric about the filament length and occur several minutes before the flare?s impulsive phase. This is indicative of a rotation of the filament, which is in turn consistent with expansion of a twisted flux rope due to the MHD helical kink instability. This is the first time that such an observation has been possible in this transition-region line, and we note that the signature observed occurs before the first indications of pre-flare activity in the GOES solar soft X-ray flux, suggesting that the filament begins to destabilise in tandem with a reorganistation of the local magnetic field. We suggest that this expansion is triggered by the decrease of magnetic tension around, and/or total pressure above, the filament. **13 Dec 2006**

Magnetic reconnection in flux-tubes undergoing spinning footpoint motions

A. L. **Wilmot-Smith** and I. De Moortel
A&A 473 (**2007**) 615-623 (Section 'The Sun')

Identifying Observables That Can Differentiate Between Impulsive and Footpoint Heating: Time Lags and Intensity Ratios

Amy R. **Winebarger**1, Roberto Lionello2, Cooper Downs2, Zoran Mikić2, and Jon Linker2
2018 ApJ 865 111 DOi 10.3847/1538-4357/aad9fb
Observations of solar coronal loops have identified several common loop characteristics, including that loops appear to cool and have higher than expected densities. Two potential heating scenarios have been suggested to explain these observations. One scenario is that the loops are formed by many strands, each heated independently by a series of small-scale impulsive heating events, or nanoflares. Another hypothesis is that the heating is quasi-steady and highly stratified, i.e., "footpoint heating"; such heating can drive thermal nonequilibrium in some structures depending on the scale height and magnitude of the energy deposition, and the geometry of the structure. Studies of both types of heating have found that they can qualitatively reproduce the observed loop properties. The goal of this paper is to identify observables that can be used to differentiate between these two heating scenarios. To do this, we use a single loop geometry. For footpoint heating, we vary the heating magnitude and stratification, for impulsive heating, we vary the heating magnitude. We use one-dimensional hydrodynamic codes to calculate the resulting temperature and density evolution. We convolve the temperature and density with the response functions of four EUV channels of the

Atmospheric Imaging Assembly and one filter channel of Hinode's X-ray Telescope. We consider two principal diagnostics: the time lag between the appearance of the loop in two different channels, and the ratio of the peak intensities of the loop in the two channels. Based on this limited data set, we find (1) that footpoint heating can predict longer time lags than impulsive heating in some channel pairs, (2) that footpoint heating can predict zero or negative time lags in some channel pairs, (3) that the intensity ratio expected from impulsive heating is confined to a narrow range, while footpoint heating predicts a wider range of intensity ratios, and (4) that the range of temperatures expected in impulsive heating is broader than the range of temperatures expected in footpoint heating. This preliminary study identifies observables that may be useful in discriminating between heating models in future work.

DETECTING NANOFLARE HEATING EVENTS IN SUBARCSECOND INTER-MOSS LOOPS USING Hi-C

Amy R. **Winebarger**1, Robert W. Walsh2, Ronald Moore1, Bart De Pontieu3, Viggo Hansteen4, Jonathan Cirtain1, Leon Golub5, Ken Kobayashi6, Kelly Korreck5, Craig DeForest7, Mark Weber5, Alan Title3, and Sergey Kuzin

2013 ApJ 771 21

The High-resolution Coronal Imager (Hi-C) flew aboard a NASA sounding rocket on **2012 July 11** and captured roughly 345 s of high-spatial and temporal resolution images of the solar corona in a narrowband 193 Å channel. In this paper, we analyze a set of rapidly evolving loops that appear in an inter-moss region. We select six loops that both appear in and fade out of the Hi-C images during the short flight. From the Hi-C data, we determine the size and lifetimes of the loops and characterize whether these loops appear simultaneously along their length or first appear at one footpoint before appearing at the other. Using co-aligned, co-temporal data from multiple channels of the Atmospheric Imaging Assembly on the Solar Dynamics Observatory, we determine the temperature and density of the loops. We find the loops consist of cool (~105 K), dense (~1010 cm–3) plasma. Their required thermal energy and their observed evolution suggest they result from impulsive heating similar in magnitude to nanoflares. Comparisons with advanced numerical simulations indicate that such dense, cold and short-lived loops are a natural consequence of impulsive magnetic energy release by reconnection of braided magnetic field at low heights in the solar atmosphere.

USING A DIFFERENTIAL EMISSION MEASURE AND DENSITY MEASUREMENTS IN AN ACTIVE REGION CORE TO TEST A STEADY HEATING MODEL

Amy R. **Winebarger**1, Joan T. Schmelz2, Harry P. Warren3, Steve H. Saar4 and Vinay L. Kashyap

2011 ApJ 740 2

The frequency of heating events in the corona is an important constraint on the coronal heating mechanisms. Observations indicate that the intensities and velocities measured in active region cores are effectively steady, suggesting that heating events occur rapidly enough to keep high-temperature active region loops close to equilibrium. In this paper, we couple observations of active region (AR) 10955 made with the X-Ray Telescope and the EUV Imaging Spectrometer on board Hinode to test a simple steady heating model. First we calculate the differential emission measure (DEM) of the apex region of the loops in the active region core. We find the DEM to be broad and peaked around 3 MK. We then determine the densities in the corresponding footpoint regions. Using potential field extrapolations to approximate the loop lengths and the density-sensitive line ratios to infer the magnitude of the heating, we build a steady heating model for the active region core and find that we can match the general properties of the observed DEM for the temperature range of $6.3 < \log T < 6.7$. This model, for the first time, accounts for the base pressure, loop length, and distribution of apex temperatures of the core loops. We find that the density-sensitive spectral line intensities and the bulk of the hot emission in the active region core are consistent with steady heating. We also find, however, that the steady heating model cannot address the emission observed at lower temperatures. This emission may be due to foreground or background structures, or may indicate that the heating in the core is more complicated. Different heating scenarios must be tested to determine if they have the same level of agreement.

Using the maximum X-ray flux ratio and X-ray background to predict solar flare class

L. M. **Winter**, K. Balasubramaniam

Space Weather Volume 13, Issue 5 May **2015** Pages 286–297

http://arxiv.org/pdf/1504.00294v1.pdf

We present the discovery of a relationship between the maximum ratio of the flare flux (namely, 0.5–4 Å to the 1–8 Å flux) and nonflare background (namely, the 1–8 Å background flux), which clearly separates flares into classes by peak flux level. We established this relationship based on an analysis of the Geostationary Operational Environmental Satellites X-ray observations of ~ 50,000 X, M, C, and flares derived from the NOAA/Space Weather Prediction Center flares catalog. Employing a combination of machine learning techniques (K-nearest neighbors and nearest centroid algorithms) we show a separation of the observed parameters for the different peak flaring energies. This analysis is validated by successfully predicting the flare classes for 100% of the X-class flares, 76% of the M-class flares, 80% of the C-class flares, and 81% of the B-class flares for solar cycle 24, based on the training of the parametric extracts for solar flares in cycles 22–23.

SIMULATING THE EFFECTS OF INITIAL PITCH-ANGLE DISTRIBUTIONS ON SOLAR FLARES

Henry D. **Winter**1, Petrus Martens2 and Katharine K. Reeves

2011 ApJ 735 103

In this work, we model both the thermal and non-thermal components of solar flares. The model we use, HYLOOP, combines a hydrodynamic equation solver with a non-thermal particle tracking code to simulate the thermal and non-thermal dynamics and emission of solar flares. In order to test the effects of pitch-angle distribution on flare dynamics and emission, a series of flares is simulated with non-thermal electron beams injected at the loop apex. The pitch-angle distribution of each beam is described by a single parameter and allowed to vary from flare to flare. We use the results of these simulations to generate synthetic hard and soft X-ray emissions (HXR and SXR). The light curves of the flares in Hinode's X-ray Telescope passbands show a distinct signal that is highly dependent on pitch-angle distribution. The simulated HXR emission in the 3-6 keV bandpass shows the formation and evolution of emission sources that correspond well to the observations of pre-impulsive flares. This ability to test theoretical models of thermal and non-thermal flare dynamics directly with observations allows for the investigation of a wide range of physical processes governing the evolution of solar flares. We find that the initial pitch-angle distribution of non-thermal particle populations has a profound effect on loop top HXR and SXR emission and that apparent motion of HXR is a natural consequence of non-thermal particle evolution in a magnetic trap.

Long-period oscillations in the lower solar atmosphere prior to flare events

A. **Wiśniewska**1, M. B. Korsós2,3,5, I. Kontogiannis1, Sz. Soós3,5 and R. Erdélyi4,3,5

A&A, 686, A224 (**2024**)

https://www.aanda.org/articles/aa/pdf/2024/06/aa48606-23.pdf

Context. Multiple studies have identified a range of oscillation periods in active regions, from 3−5 min to long-period oscillations that last from tens of minutes to several hours. Recently, it was also suggested that these periods are connected with eruptive activity in the active regions. Thus, it is essential to understand the relation between oscillations in solar active regions and their solar eruption activity.

Aims. We investigate the long-period oscillations of NOAA 12353 prior to a series of C-class flares and correlate the findings with the 3- to 5-min oscillations that were previously studied in the same active region. The objective of this work is to elucidate the presence of various oscillations with long periods in the lower solar atmosphere both before and after the flare events.

Methods. To detect long-period oscillations, we assessed the emergence, shearing, and total magnetic helicity flux components from the photosphere to the top of the chromosphere. To analyze the magnetic helicity flux in the lower solar atmosphere, we used linear force-free field extrapolation to construct a model of the magnetic field structure of the active region. Subsequently, the location of long-period oscillations in the active region was probed by examining the spectral energy density of the measured intensity signal in the 1700 Å, 1600 Å, and 304 Å channels of the Atmospheric Imaging Assembly (AIA) of the Solar Dynamics Observatory (SDO). Significant oscillation periods were determined by means of a wavelet analysis.

Results. Based on the evolution of the three magnetic helicity flux components, 3- to 8-h periods were found both before and after the flare events, spanning from the photosphere to the chromosphere. These 3- to 8-h periods were also evident throughout the active region in the photosphere in the 1700 Å channel. Observations of AIA 1600 Å and 304 Å channels, which cover the chromosphere to the transition region, revealed oscillations of 3−8 h near the region in which the flare occurred. The spatial distribution of the measured long-period oscillations mirror the previously reported distribution of 3- to 5-min oscillations in NOAA 12353 that were seen both before and after the flares.

Conclusions. This case study suggest that the varying oscillation properties in a solar active region could be indicative of future flaring activity. **2015 May 21-23**

Frequency Distribution of Acoustic Oscillation in the Solar Atmosphere During Flare Event

A. **Wisniewska**, E. Chmielewska, K. Radziszewski, M. Roth, J. Staiger

2019 ApJ 886 32

https://doi.org/10.3847/1538-4357/ab487c

https://arxiv.org/ftp/arxiv/papers/2203/2203.02420.pdf

We present a study of multi-wavelength observations, of a C 2.3 solar flare in Active Region NOAA 12353, observed on **2015 May 23**, which reveal new properties of acoustic waves in the flaring region. The space-, and ground-based data measured by the HELioseismological Large Regions Interferometric Device, operating at the Vacuum Tower Telescope, the Atmospheric Imaging Assembly, and Helioseismic and Magnetic Imager on board the Solar Dynamic Observatory, were used in this paper. First, using power spectra of solar oscillations, we identified the dominant frequencies and their location at seven different atmospheric levels before and after the flare event. Second, based on AIA observations taken in six Extreme Ultraviolet filters, we derived Differential Emission Measure (DEM) profiles and DEM maps of the flare. Finally, we confirm the {\sigma}-classification of the magnetic field in the active area, directly related to the flare. Our results are as follows: the high-frequency waves ({\nu}>5 mHz) in the photosphere, in

both cases, before and after the flare, are generated at the foot-points of the chromospheric loop, while in the chromosphere (H{\alpha} line), before the event the power enhancement exhibits for maximum of flare emission, and after the eruption the enhancement by all frequencies is observed only in the post flare loop area. Moreover, the power of oscillation in the pores surrounding area before the flare has a random character, while after the flare oscillation's power is concentrated in the pore, and weakened outside of. We conclude that the accurate detection of high-frequency acoustic waves in the active regions can lead to faster and easier prediction of high-energy events.

3D Numerical Simulation of Kink-driven Rayleigh–Taylor Instability Leading to Fast Magnetic Reconnection

Pakorn **Wongwaitayakornkul**1, Hui Li2, and Paul M. Bellan1
2020 ApJL 895 L7
https://doi.org/10.3847/2041-8213/ab8e35
Fast magnetic reconnection involving non-MHD microscale physics is believed to underlie both solar eruptions and laboratory plasma current disruptions. While there is extensive research on both the MHD macroscale physics and the non-MHD microscale physics, the process by which large-scale MHD couples to the microscale physics is not well understood. An MHD instability cascade from a kink to a secondary Rayleigh–Taylor instability in the Caltech astrophysical jet laboratory experiment provides new insights into this coupling and motivates a 3D numerical simulation of this transition from large to small scale. A critical finding from the simulation is that the axial magnetic field inside the current-carrying dense plasma must exceed the field outside. In addition, the simulation verifies a theoretical prediction and experimental observation that, depending on the strength of the effective gravity produced by the primary kink instability, the secondary instability can be Rayleigh–Taylor or mini-kink. Finally, it is shown that the kink-driven Rayleigh–Taylor instability generates a localized electric field sufficiently strong to accelerate electrons to very high energy.

Unsupervised Machine Learning for the Identification of Preflare Spectroscopic Signatures

Magnus M. **Woods**1,2, Alberto Sainz Dalda1,2,3, and Bart De Pontieu2,4,5
2021 ApJ 922 137
https://iopscience.iop.org/article/10.3847/1538-4357/ac2667/pdf
https://doi.org/10.3847/1538-4357/ac2667
The study of the preflare environment is of great importance to understanding what drives solar flares. k-means clustering, an unsupervised machine-learning technique, has the ability to cluster large data set in a way that would be impractical or impossible for a human to do. In this paper we present a study using k-means clustering to identify possible preflare signatures in spectroscopic observations of the Mg ii h and k spectral lines made by NASA's Interface Region Imaging Spectrometer. Our analysis finds that spectral profiles showing single-peak Mg ii h and k and single-peaked emission in the Mg ii UV triplet lines are associated with preflare activity up to 40 minutes prior to flaring. Subsequent inversions of these spectral profiles reveal increased temperature and electron density in the chromosphere, which suggest that significant heating events in the chromosphere may be associated with precursor signals to flares.

Serial Flaring in an Active Region: Exploring Why Only One Flare Is Eruptive

Magnus M. **Woods**1,2,3,4, Satoshi Inoue2, Louise K. Harra1, Sarah A. Matthews1, and Kanya Kusano2
2020 ApJ **890** 84
https://iopscience.iop.org/article/10.3847/1538-4357/ab6bc8/pdf
Over a four hour period between **2014 June 12–13** a series of three flares were observed within AR 12087. This sequence of flares started with a non-eruptive M-class flare, followed by a non-eruptive C-class flare, and finally ended with a second C-class flare that had an associated filament eruption. In this paper we combine spectroscopic analysis of Interface Region Imaging Spectrometer observations of the Si iv line during the three flares along with a series of nonlinear force-free field (NLFFF) extrapolations in order to investigate the conditions that lead the final flare to be eruptive. From this analysis it is found to be unlikely that the eruption was triggered by either kink instability or by tether-cutting reconnection, allowing the flux rope to rise into a region where it would be susceptible to the torus instability. The NLFFF modeling does, however, suggest that the overlying magnetic field has a fan-spine topology, raising the possibility that breakout reconnection occurring during the first two flares weakened the overlying field, allowing the flux rope to erupt in the subsequent third flare.

Observations and Modelling of the Pre-Flare Period of the 29 March 2014 X1 Flare

M. M. **Woods**, L. K. Harra, S. A.Matthews, D. H. Mackay, S. Dacie, D. M. Long
Solar Phys. 292:38 **2017**
https://arxiv.org/pdf/1701.06457v1.pdf
On the **29 March 2014** NOAA active region (AR) 12017 produced an X1 flare which was simultaneously observed by an unprecedented number of observatories. We have investigated the pre-flare period of this flare from 14:00 UT until 19:00 UT using joint observations made by the Interface Region Imaging Spectrometer (IRIS) and the Hinode Extreme

Ultraviolet Imaging Spectrometer (EIS). Spectral lines providing coverage of the solar atmosphere from chromosphere to the corona were analysed to investigate pre-flare activity within the AR. The results of the investigation have revealed evidence of strongly blue-shifted plasma flows, with velocities up to 200 km/s, being observed 40 minutes prior to flaring. These flows are located along the filament present in the active region and are both spatially discrete and transient. In order to constrain the possible explanations for this activity, we undertake non-potential magnetic field modelling of the active region. This modelling indicates the existence of a weakly twisted flux rope along the polarity inversion line in the region where a filament and the strong pre-flare flows are observed. We then discuss how these observations relate to the current models of flare triggering. We conclude that the most likely drivers of the observed activity are internal reconnection in the flux rope, early onset of the flare reconnection, or tether cutting reconnection along the filament.

New Solar Irradiance Measurements from the Miniature X-Ray Solar Spectrometer CubeSat

Thomas N. **Woods**, Amir Caspi, Phillip C. Chamberlin, Andrew Jones, Richard Kohnert, James Paul Mason, Christopher S. Moore, Scott Palo, Colden Rouleau, Stanley C. Solomon, Janet Machol, Rodney Viereck

ApJL **2016**

https://arxiv.org/pdf/1610.01936v1.pdf

The goal of the Miniature X-ray Solar Spectrometer (MinXSS) CubeSat is to explore the energy distribution of soft X-ray (SXR) emissions from the quiescent Sun, active regions, and during solar flares, and to model the impact on Earth's ionosphere and thermosphere. The energy emitted in the SXR range (0.1 to 10 keV) can vary by more than a factor of 100, yet we have limited spectral measurements in the SXRs to accurately quantify the spectral dependence of this variability. The MinXSS primary science instrument is an Amptek, Inc. X123 X-ray spectrometer that has an energy range of 0.5-30 keV with a nominal 0.15 keV energy resolution. Two flight models have been built. The first, MinXSS-1, has been making science observations since 2016 June 9, and has observed numerous flares, including 40 C-class and 7 M-class flares. These SXR spectral measurements have advantages over broadband SXR observations, such as providing the capability to derive multiple-temperature components and elemental abundances of coronal plasma, improved irradiance accuracy, and higher resolution spectral irradiance as input to planetary ionosphere simulations. MinXSS spectra obtained during the **M5.0 flare on 2016 July 23** highlight these advantages, and indicate how the elemental abundance changes from primarily coronal to more photospheric during the flare. MinXSS-1 observations are compared to the Geostationary Operational Environmental Satellite (GOES) X-Ray Sensor (XRS) measurements of SXR irradiance and estimated corona temperature. Additionally, a suggested improvement to the calibration of the GOES XRS data is presented.

New Solar Extreme-ultraviolet Irradiance Observations during Flares

Woods, Thomas N.; Hock, Rachel; Eparvier, Frank; Jones, Andrew R.; Chamberlin, Phillip C.; Klimchuk, James A.; Didkovsky, Leonid; Judge, Darrell; Mariska, John; Warren, Harry; Schrijver, Carolus J.; Webb, David F.; Bailey, Scott; Tobiska, W. Kent

Astrophysical Journal, Volume 739, Issue 2, article id. 59, 13 pp. (**2011**)

New solar extreme-ultraviolet (EUV) irradiance observations from the NASA Solar Dynamics Observatory (SDO) EUV Variability Experiment provide full coverage in the EUV range from 0.1 to 106 nm and continuously at a cadence of 10 s for spectra at 0.1 nm resolution and even faster, 0.25 s, for six EUV bands. These observations can be decomposed into four distinct characteristics during flares. First, the emissions that dominate during the flare's impulsive phase are the transition region emissions, such as the He II 30.4 nm. Second, the hot coronal emissions above 5 MK dominate during the gradual phase and are highly correlated with the GOES X-ray. A third flare characteristic in the EUV is coronal dimming, seen best in the cool corona, such as the Fe IX 17.1 nm. As the post-flare loops reconnect and cool, many of the EUV coronal emissions peak a few minutes after the GOES X-ray peak. *One interesting variation of the post-eruptive loop reconnection is that warm coronal emissions (e.g., Fe XVI 33.5 nm) sometimes exhibit a second large peak separated from the primary flare event by many minutes to hours, with EUV emission originating not from the original flare site and its immediate vicinity, but rather from a volume of higher loops. We refer to this second peak as the EUV late phase.* The characterization of many flares during the SDO mission is provided, including quantification of the spectral irradiance from the EUV late phase that cannot be inferred from GOES X-ray diagnostics.

Extreme Ultraviolet Late-Phase Flares: Before and During the Solar Dynamics Observatory Mission

Thomas N. **Woods**

Solar Phys., Volume 289, Issue 9, pp 3391-3401, **2014; File**
http://arxiv.org/pdf/1401.5811v1.pdf
The solar extreme-ultraviolet (EUV) observations from the Solar Dynamics Observatory (SDO) have revealed interesting characteristics of warm coronal emissions, such as Fe xvi 335 Å emission, which peak soon after the hot coronal X-ray emissions peak during a flare and then sometimes peak for a second time hours after the X-ray flare peak. This flare type, with two warm coronal emission peaks but only one X-ray peak, has been named the EUV late phase (Woods et al., Astrophys. J. 739, 59, 2011). These flares have the distinct properties of i) having a complex magnetic-field structure with two initial sets of coronal loops, with one upper set overlaying a lower set, ii) having an eruptive flare initiated in the lower set and disturbing both loop sets, iii) having the hot coronal emissions emitted only from the lower set in conjunction with the X-ray peak, and iv) having the first peak of the warm coronal emissions associated with the lower set and its second peak emitted from the upper set many minutes to hours after the first peak and without a second X-ray enhancement. The disturbance of the coronal loops by the eruption is at about the same time, but the relaxation and cooling down of the heated coronal loops during the post-flare reconnections have different time scales with the longer, upper loops being significantly delayed from the lower loops. The difference in these cooling time scales is related to the difference between the two peak times of the warm coronal emission and is also apparent in the decay profile of the X-ray emissions having two distinct decays, with the first decay slope being steeper (faster) and the delayed decay slope being smaller (slower) during the time of the warm-coronal-emission second peak. The frequency and relationship of the EUV late-phase decay times between the Fe xvi 335 Å two flare peaks and X-ray decay slopes are examined using three years of SDO/EUV Variability Experiment (EVE) data, and the X-ray dual-decay character is then exploited to estimate the frequency of EUV late-phase flares during the past four solar cycles. This study indicates that the frequency of EUV late-phase flares peaks before and after each solar-cycle minimum.

NEW SOLAR EXTREME-ULTRAVIOLET IRRADIANCE OBSERVATIONS DURING FLARES

Thomas N. **Woods**1,9, Rachel Hock1, Frank Eparvier1, Andrew R. Jones1, Phillip C. Chamberlin2, James A. Klimchuk2, Leonid Didkovsky3, Darrell Judge3, John Mariska4, Harry Warren4, Carolus J. Schrijver5, David F. Webb6, Scott Bailey7 and W. Kent Tobiska
2011 ApJ 739 59**, File**
New solar extreme-ultraviolet (EUV) irradiance observations from the NASA Solar Dynamics Observatory (SDO) EUV Variability Experiment provide full coverage in the EUV range from 0.1 to 106 nm and continuously at a cadence of 10 s for spectra at 0.1 nm resolution and even faster, 0.25 s, for six EUV bands. These observations can be decomposed into four distinct characteristics during flares. First, the emissions that dominate during the flare's impulsive phase are the transition region emissions, such as the He II 30.4 nm. Second, the hot coronal emissions above 5 MK dominate during the gradual phase and are highly correlated with the GOES X-ray. A third flare characteristic in the EUV is coronal dimming, seen best in the cool corona, such as the Fe IX 17.1 nm. As the post-flare loops reconnect and cool, many of the EUV coronal emissions peak a few minutes after the GOES X-ray peak. One interesting variation of the post-eruptive loop reconnection is that warm coronal emissions (e.g., Fe XVI 33.5 nm) sometimes exhibit a second large peak separated from the primary flare event by many minutes to hours, with EUV emission originating not from the original flare site and its immediate vicinity, but rather from a volume of higher loops. We refer to this second peak as the EUV late phase. The characterization of many flares during the SDO mission is provided, including quantification of the spectral irradiance from the EUV late phase that cannot be inferred from GOES X-ray diagnostics.

Microflare Heating of a Solar Active Region Observed with NuSTAR, Hinode/XRT, and SDO/AIA

Paul J. **Wright**, Iain G. Hannah, Brian W. Grefenstette, Lindsay Glesener, Säm Krucker, Hugh S. Hudson, David M. Smith, Andrew J. Marsh, Stephen M. White, Matej Kuhar
ApJ **2017**
https://arxiv.org/pdf/1706.06108.pdf
http://iopscience.iop.org/article/10.3847/1538-4357/aa7a59/pdf
NuSTAR is a highly sensitive focusing hard X-ray (HXR) telescope and has observed several small microflares in its initial solar pointings. In this paper, we present the first joint observation of a microflare with NuSTAR and Hinode/XRT on **2015 April 29** at ~11:29 UT. This microflare shows heating of material to several million Kelvin, observed in Soft X-rays (SXRs) with Hinode/XRT, and was faintly visible in Extreme Ultraviolet (EUV) with SDO/AIA. For three of the four NuSTAR observations of this region (pre-, decay, and post phases) the spectrum is well fitted by a single thermal model of 3.2-3.5 MK, but the spectrum during the impulsive phase shows additional emission up to 10 MK, emission equivalent to A0.1 GOES class. We recover the differential emission measure (DEM) using SDO/AIA, Hinode/XRT, and NuSTAR, giving unprecedented coverage in temperature. We find the pre-flare DEM peaks at ~3 MK and falls off sharply by 5 MK; but during the microflare's impulsive phase the emission above 3 MK is brighter and extends to 10 MK, giving a heating rate of about 2.5×1025 erg s−1. As the NuSTAR spectrum is purely thermal we determined upper-limits on the possible non-thermal bremsstrahlung emission. We find that for the accelerated electrons to be the source of the heating requires a power-law spectrum of $\delta \geq 7$ with a low energy cut-off

Ec≲7 keV. In summary, this first NuSTAR microflare strongly resembles much more powerful flares.

Persistent Upflows and Downflows at Active Region boundaries Observed by SUTRI and AIA

Yuchuan **Wu**, Zhenyong Hou, Wenxian Li, Xianyong Bai, Yongliang Song, Xiao Yang, Ziyao Hu, Yuanyong Deng, Kaifan Ji

ApJ **965** 109 **2024**

https://arxiv.org/pdf/2403.07422.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/ad3358/pdf

Upflows and downflows at active region (AR) boundaries have been frequently observed with spectroscopic observations at extreme ultraviolet (EUV) passbands. In this paper, we report the coexistence of upflows and downflows at the AR boundaries with imaging observations from the Solar Upper Transition Region Imager (SUTRI) and the Atmospheric Imaging Assembly (AIA). With their observations from **2022 September 21 to 2022 September 30**, we find 17 persistent opposite flows occurring along the AR coronal loops. The upflows are prominent in the AIA 193 Åimages with a velocity of 50-200 km/s, while the downflows are best seen in the SUTRI 465 Åand AIA 131 Åimages with a slower velocity of tens of kilometers per second (characteristic temperatures (log T(K)) for 193 Å, 465 Åand 131 Åare 6.2, 5.7, 5.6, respectively). We also analyze the center-to-limb variation of the velocities for both upflows and downflows. The simultaneous observations of downflows and upflows can be explained by the chromosphere-corona mass-cycling process, in which the localized chromospheric plasma is impulsively heated to coronal temperature forming a upflow and then these upflows experience radiative cooling producing a downflow with the previously heated plasma returning to the lower atmosphere. In particular, the persistent downflows seen by SUTRI provide strong evidence of the cooling process in the mass cycle. For upflows associated with open loops, part of the plasma is able to escape outward and into the heliosphere as solar wind.

Highly Energetic Electrons Accelerated in Strong Solar Flares as a Preferred Driver of Sunquakes

H. **Wu**, Y. Dai, M. D. Ding

ApJL **943** L6 **2023**

https://arxiv.org/pdf/2301.02865.pdf

https://iopscience.iop.org/article/10.3847/2041-8213/acb0d1/pdf

Sunquakes are enhanced seismic waves excited in some energetic solar flares. Up to now, their origin has still been controversial. In this Letter, we select and study 20 strong flares in Solar Cycle 24, whose impulse phase is fully captured by the \emph{Reuven Ramaty High Energy Solar Spectroscopic Imager} (\emph{RHESSI}). For 11 out of 12 sunquake-active flares in our sample, the hard X-ray (HXR) emission shows a good temporal and spatial correlation with the white-light (WL) enhancement and the sunquake. Spectral analysis also reveals a harder photon spectrum that extends to several hundred keV, implying a considerable population of flare-accelerated nonthermal electrons at high energies. Quantitatively, the total energy of electrons above 300 keV in sunquake-active flares is systematically different from that in sunquake-quiet flares, while the difference is marginal for electrons above 50 keV. All these facts support highly energetic electrons as a preferred driver of the sunquakes. Such an electron-driven scenario can be reasonably accommodated in the framework of a recently proposed selection rule for sunquake generation. For the remaining one event, the sunquake epicenter is cospatial with a magnetic imprint, i.e., a permanent change of magnetic field on the photosphere. Quantitative calculation shows that the flare-induced downward Lorentz force can do enough work to power the sunquake, acting as a viable sunquake driver for this specific event. **9 Aug 2011, 24 Sep 2011, 2012 October 23, 27 Oct 2014,**

https://doi.org/10.3847/1538-4357/abdc20

The origin of hard X-rays and gamma-rays emitted from the solar atmosphere during occulted solar flares is still debated. The hard X-ray emissions could come from flaring loop tops rising above the limb or Coronal Mass Ejections (CME) shock waves, two by-products of energetic solar storms. For the shock scenario to work, accelerated particles must be released on magnetic field lines rooted on the visible disk and precipitate. We present a new Monte Carlo code that computes particle acceleration at shocks propagating along large coronal magnetic loops. A first implementation of the model is carried out for the **2014 September 1** event and the modeled electron spectra are compared with those inferred from Fermi Gamma-ray Burst Monitor (GBM) measurements. When particle diffusion processes are invoked our model can reproduce the hard electron spectra measured by GBM nearly ten minutes after the estimated on-disk hard X-rays appear to have ceased from the flare site.

Microwave imaging of a hot flux rope structure during the pre-impulsive stage of an eruptive M7.7 solar flare

Z. **Wu**, Y. Chen, G. Huang, H. Nakajima, H. Song, V. Melnikov, W. Liu, G. Li, K. Chandrashekhar, F. Jiao
ApJL 820 L29 **2016**
http://arxiv.org/pdf/1603.02777v1.pdf

Corona structures and processes during the pre-impulsive stage of solar eruption are crucial to understanding the physics leading to the subsequent explosive energy release. Here we present the first microwave imaging study of a hot flux rope structure during the pre-impulsive stage of an eruptive M7.7 solar flare, with the Nobeyama Radioheliograph (NoRH) at 17 GHz. The flux rope is also observed by the SDO/AIA in its hot passbands of 94 and 131 \AA\. In the microwave data, it is revealed as an overall arcade-like structure consisting of several intensity enhancements bridged by generally weak emissions, with brightness temperatures (TB) varying from ~10,000~K to ~20,000 K. Locations of microwave intensity enhancements along the structure remain relatively fixed at certain specific parts of the flux rope, indicating that the distribution of emitting electrons is affected by the large scale magnetic configuration of the twisted flux rope. Wavelet analysis shows a pronounced 2-min period of the microwave TB variation during the pre-impulsive stage of interest. The period agrees well with that reported for AIA sunward-contracting loops and upward ejective plasmoids (suggested to be reconnection outflows). This suggests that both periodicities are controlled by the same reconnection process that takes place intermittently at a 2-min time scale. We infer that at least a part of the emission is excited by non-thermal energetic electrons via the gyro-synchrotron mechanism. The study demonstrates the potential of microwave imaging in exploring the flux rope magnetic geometry and relevant reconnection process during the onset of solar eruption. **19 July 2012**

Research Note

Electron acceleration in the turbulent reconnecting current sheets in solar flares

G. P. **Wu**1 and G. L. Huang2
A&A 502, 341-344 (**2009**)
DOI: 10.1051/0004-6361/200811494

Context. We investigate the nonlinear evolution of the electron distribution in the presence of the strong inductive electric field in the reconnecting current sheets (RCS) of solar flares.
Aims. We aim to study the characteristics of nonthermal electron-beam plasma instability and its influence on electron acceleration in RCS.
Methods. Including the external inductive field, the one-dimensional Vlasov simulation is performed with a realistic mass ratio for the first time.
Results. Our principal findings are as follows: 1) the Buneman instability can be quickly excited on the timescale of 10^{-7} s for the typical parameters of solar flares. After saturation, the beam-plasma instabilities are excited due to the non-Maxwellian electron distribution; 2) the final velocity of the electrons trapped by these waves is of the same order as the phase speed of the waves, while the untrapped electrons continue to be accelerated; 3) the inferred anomalous resistance of the current sheet and the energy conversion rate are basically of the same order as those previously estimated, e.g., “the analysis of Martens”.
Conclusions. The Buneman instability is excited on the timescale of 10^{-7} s and the wave-particle resonant interaction limits the low-energy electrons to be further accelerated in RCS.

Is Flare Ribbon Fine Structure Related to Tearing in the Flare Current Sheet?

P. F. **Wyper**1 and D. I. Pontin2,3
2021 ApJ 920 102
https://iopscience.iop.org/article/10.3847/1538-4357/ac1943/pdf
https://doi.org/10.3847/1538-4357/ac1943
https://arxiv.org/pdf/2108.10966.pdf

Observations of solar flare ribbons show significant fine structure in the form of breaking wavelike perturbations and spirals. The origin of this structure is not well understood, but one possibility is that it is related to the tearing instability in the flare current sheet. Here we study this connection by constructing an analytical 3D magnetic field representative of an erupting flux rope with a flare current sheet below it. We introduce small-scale flux ropes representative of those formed during a tearing instability in the current layer, and use the squashing factor on the solar surface to identify the shape of the presumed flare ribbons and fine structure. Our analysis suggests there is a direct link between flare ribbon fine structure and flare current sheet tearing, with the majority of the ribbon fine structure related to oblique tearing modes. Depending upon the size, location, and twist of the small-scale flux ropes, breaking wavelike and spiral features within the hooks and straight sections of the flare ribbon can be formed that are qualitatively similar to observations. We also show that the handedness of the spirals/waves must be the same as the handedness of the hooks of the main ribbon. We conclude that tearing in the flare current layer is a likely explanation for spirals and wavelike features in flare ribbons. **2014 September 10**

THREE-DIMENSIONAL SIMULATIONS OF TEARING AND INTERMITTENCY IN CORONAL JETS

P. F. **Wyper**1, C. R. DeVore2, J. T. Karpen2, and B. J. Lynch

2016 ApJ 827 4

Observations of coronal jets increasingly suggest that local fragmentation and intermittency play an important role in the dynamics of these events. In this work, we investigate this fragmentation in high-resolution simulations of jets in the closed-field corona. We study two realizations of the embedded-bipole model, whereby impulsive helical outflows are driven by reconnection between twisted and untwisted field across the domed fan plane of a magnetic null. We find that the reconnection region fragments following the onset of a tearing-like instability, producing multiple magnetic null points and flux-rope structures within the current layer. The flux ropes formed within the weak-field region in the center of the current layer are associated with "blobs" of density enhancement that become filamentary threads as the flux ropes are ejected from the layer, whereupon new flux ropes form behind them. This repeated formation and ejection of flux ropes provides a natural explanation for the intermittent outflows, bright blobs of emission, and filamentary structure observed in some jets. Additional observational signatures of this process are discussed. Essentially all jet models invoke reconnection between regions of locally closed and locally open field as the jet-generation mechanism. Therefore, we suggest that this repeated tearing process should occur at the separatrix surface between the two flux systems in all jets. A schematic picture of tearing-mediated jet reconnection in three dimensions is outlined.

Spine-fan reconnection
The influence of temporal and spatial variation in the driver

P. F. **Wyper**1, R. Jain1 and D. I. Pontin

A&A 545, A78 (**2012**)

Context. From observations, the atmosphere of the Sun has been shown to be highly dynamic with perturbations of the magnetic field often lacking temporal or spatial symmetry. Despite this, studies of the spine-fan reconnection mode at 3D nulls have so far focused on the very idealised case with symmetric driving of a fixed spatial extent.

Aims. We investigate the spine-fan reconnection process for less idealised cases, focusing on asymmetric driving and drivers with different length scales. We look at the initial current sheet formation and whether the scalings developed in the idealised models are robust in more realistic situations.

Methods. The investigation was carried out by numerically solving the resistive compressible 3D magnetohydrodynamic equations in a Cartesian box containing a linear null point. The spine-fan collapse was driven at the null through tangential boundary driving of the spine foot points.

Results. We find significant differences in the initial current sheet formation with asymmetric driving. Notable is the displacement of the null point position as a function of driving velocity and resistivity (η). However, the scaling relations developed in the idealised case are found to be robust (albeit at reduced amplitudes) despite this extra complexity. Lastly, the spatial variation is also shown to play an important role in the initial current sheet formation through controlling the displacement of the spine foot points.

Conclusions. We conclude that during the early stages of spine-fan reconnection both the temporal and spatial nature of the driving play important roles, with the idealised symmetrically driven case giving a “best case” for the rate of current development and connectivity change. As the most interesting eruptive events occur in relatively short time frames this work clearly shows the need for high temporal and spatial knowledge of the flows for accurate interpretation of the reconnection scenario. Lastly, since the scalings developed in the idealised case remain robust with more complex driving we can be more confident of their use in interpreting reconnection in complex magnetic field structures.

A New Solar Hard X-ray Image Reconstruction Algorithm for ASO-S/HXI Based on Deep Learning.

Xia, Y., Su, Y., Liu, H. et al.

Sol Phys 299, 158 (**2024**).

https://doi.org/10.1007/s11207-024-02399-4

Most solar hard X-ray (HXR) imagers in the past and current solar missions obtain X-ray images via Fourier transform imaging technology, which requires proper imaging algorithms to reconstruct images from spatially-modulated or temporally-modulated signals. A variety of algorithms have been developed during the last 50 years for the characteristics of respective instruments. In this work, we present a new imaging algorithm developed based on deep learning for the Hard X-ray Imager (HXI) onboard the Advanced Space-based Solar Observatory (ASO-S) and the preliminary test results of the algorithm with both simulated data and observations. We first created a training dataset by obtaining modulation data from simulated HXR images of single, double and loop-shaped sources, respectively, and the patterns of HXI sub-collimators. Then, we introduced machine-learning algorithm to develop a pattern-based deep learning network model: HXI_DLA, which can directly produce an image from modulation counts. After training the model with simple sources, we tested DLA for simple sources, extended sources, and double sources for imaging dynamic range. Finally, we compared CLEAN and DLA images reconstructed from HXI observations of three flares. Overall, these imaging tests revealed that the current HXI_DLA method produces comparable image result to those

from the widely used imaging method CLEAN. In some cases, DLA images are even slightly better. Besides, HXI_DLA is super fast for imaging and parameter-free. Although this is only the first step towards a fully developed and practical DLA method, the tests have shown the potential of deep learning in the field of solar hard X-ray imaging.

Plasma heating and nanoflare caused by slow-mode wave in a coronal loop

Fanxiaoyu **Xia**, Tongjiang Wang, Yang Su, Jie Zhao, Qingmin Zhang, Astrid M. Veronig, Weiqun Gan
ApJL **936** L13 **2022**
https://arxiv.org/pdf/2208.10029.pdf
https://iopscience.iop.org/article/10.3847/2041-8213/ac8afe/pdf
We present a detailed analysis of a reflecting intensity perturbation in a large coronal loop that appeared as sloshing oscillation and lasted for at least one and a half periods. The perturbation is initiated by a microflare at one footpoint of the loop, propagates along the loop and is eventually reflected at the remote footpoint where significant brightenings are observed in all the AIA extreme-ultraviolet (EUV) channels. This unique observation provides us with the opportunity to better understand not only the thermal properties and damping mechanisms of the sloshing oscillation, but also the energy transfer at the remote footpoint. Based on differential emission measures (DEM) analysis and the technique of coronal seismology, we find that 1) the calculated local sound speed is consistent with the observed propagation speed of the perturbation during the oscillation, which is suggestive of a slow magnetoacoustic wave; 2) thermal conduction is the major damping mechanism of the wave but additional damping mechanism such as anomalous enhancement of compressive viscosity or wave leakage is also required to account for the rapid decay of the observed waves; 3) the wave produced a nanoflare at the remote footpoint, with a peak thermal energy of ∼1024−1025 erg. This work provides a consistent picture of the magnetoacoustic wave propagation and reflection in a coronal loop, and reports the first solid evidence of a wave-induced nanoflare. The results reveal new clues for further simulation studies and may help solving the coronal heating problem. **2014 June 10**

Detection of Energy Cutoffs in Flare-accelerated Electrons

Fanxiaoyu **Xia**1,2, Yang Su1,2, Wen Wang3, Linghua Wang3, Alexander Warmuth4, Weiqun Gan1,2, and Youping Li1,2
2021 ApJ 908 111
https://iopscience.iop.org/article/10.3847/1538-4357/abce5c/pdf
Energy cutoffs in electron distribution define the lower and upper limits on the energy range of energetic electrons accelerated in solar flares. They are crucial parameters for understanding particle acceleration processes and energy budgets. Their signatures have been reported in studies of flattened flare X-ray spectra, i.e., the impulsive emission of nonthermal bremsstrahlung from energetic electrons impacting ambient, thermal plasma. However, these observations have not provided unambiguous constraints on the cutoffs. Moreover, other processes may result in similar spectral features. Even the existence and necessity of cutoffs as physical parameters of energetic electrons have been under debate. Here we report a search for their signatures in flare-accelerated electrons with two approaches, i.e., in both X-ray spectra and solar energetic particle (SEP) events. These represent two different electron populations, but may contain information of the same acceleration process. By studying a special group of late impulsive flares, and a group of selected SEP events, we found evidence of cutoffs revealed in both X-ray spectra and SEP electron distributions. In particular, we found for the first time consistent low- and high-energy cutoffs in both hard X-ray-producing and escaping electrons in two events. We also showed the importance of high-energy cutoff in studies of spectral shapes. These results provide evidence of cutoffs in flare-accelerated energetic electrons and new clues for constraining electron distribution parameters and particle acceleration models. **23 Oct 2003, 14 Aug 2004, 7 Nov 2004, 6 Dec 2006, 18 Nov 2012, 16 Apr 2015**

PARTICLE ACCELERATION AND TRANSPORT DURING 3D CME ERUPTIONS

Qian **Xia**,1 Joel T. Dahlin,2 , ∗ Valentina Zharkova,1 and Spiro K. Antiochos3
ApJ **2020**
https://solargsm.com/wp-content/uploads/2020/04/xia_etal_ArmTP_apj2020.pdf
We calculate particle acceleration during corona mass ejection (CME) eruptions using combined magnetohydrodynamic (MHD) and test-particle models. The 2.5D/3D CMEs are generated via the breakout mechanism. In this scenario a reconnection at the “breakout” current sheet (CS) above the flux rope initiates the CME eruption by destabilizing a quasi-static force balance. Reconnection at the flare CS below the erupting flux rope drives the fast acceleration of the CME, which forms flare loops below and produces the energetic particles observed in flares. For test-particle simulations, two times are selected during the impulsive and decay phases of the eruption. Particles are revealed to be accelerated more efficiently in the flare CS rather than in the breakout CS even in the presence of large magnetic islands. Particles are first accelerated in the CSs (with or without magnetic islands) by the reconnection electric field mainly through particle curvature drift. We find, as expected, that accelerated particles precipitate into the chromosphere, or become trapped in the loop top by magnetic mirrors, or escape to interplanetary space along open field lines. Some trapped particles are reaccelerated, either via reinjection to the flare CS or through a local Betatron-

type acceleration associated with compression of the magnetic field. The energetic particles produce relatively hard energy spectra during the impulsive phase. During the gradual phase, the relaxation of magnetic field shear reduces the guiding field in the flare CS, which leads to a decrease in particle energization efficiency. Important implications of our results for observations of particle acceleration in the solar coronal jets are also discussed.

Particle acceleration in coalescent and squashed magnetic islands II. Particle-In-cell approach

Q.**Xia** and V. Zharkova

A&A 635, A116 **2020**

http://mpee.northumbria.ac.uk/staff/slmv5/kinetics/AA_islands_PIC_2col_accept2020.pdf

https://doi.org/10.1051/0004-6361/201936420

Aims. Particles are known to have efficient acceleration in reconnecting current sheets with multiple magnetic islands, formed during a reconnection process. Using test particle approach, the recent investigation of particle dynamics in 3D magnetic islands, or current sheets with multiple X- and O-null points revealed that the particle energy gains are higher in squashed magnetic islands than in coalescent ones. However, this approach did not consider the ambient plasma feedback to the presence of accelerated particles, which a□ects their distributions within the acceleration region.
Methods. In the current paper, we use the particle-in-cell (PIC) approach to investigate further particle acceleration in 3D Harris-type reconnecting current sheets with coalescent (merging) and squashed (contracting) magnetic islands with different magnetic field topologies, ambient densities ranging 10^8 - 10^{12} m^3, proton-to-electron mass ratios, and island aspect ratios.
Results. In current sheets with single or multiple X-nullpoints, accelerated particles of opposite charges are separated and ejected into the opposite semiplanes from the current sheet midplane, generating a strong polarisation electric field across a current sheet. Particles of the same charge form two populations: transit and bounced particles, with very different energy and asymmetric pitch-angle distributions, which can be distinguished from observations. In some cases the difference in energy gains by transit and bounced particles leads to turbulence generated by Buneman instability. In magnetic island topology, the different reconnection electric fields in squashed and coalescent islands impose different particle drift motions. This makes particle acceleration more efficient in squashed magnetic islands than in coalescent ones. The spectral indices of electron energy spectra are 4.2 for coalescent and 4.0 for squashed islands, which are lower than reported from the test-particle approach. The particles accelerated in magnetic islands are found trapped in the midplane of squashed islands, and shifted as clouds towards the X-nullpoints in coalescent ones.
Conclusions. In reconnecting current sheets with multiple X- and O-nullpoints particles are found accelerated on a much shorter spatial scale and gain higher energies than near a single X-nullpoint. The distinct density and pitch- angle distributions of particles with high and low energy detected with the PIC approach can help to distinguish the observational features of accelerated particles.

Particle acceleration in coalescent and squashed magnetic islands I. Test particle approach

Q.**Xia** and V. Zharkova

A&A **2018**

http://computing.unn.ac.uk/staff/slmv5/kinetics/xia_zharkova_islands_TP_aa18.pdf

Aims. Magnetic reconnection in large Harris-type reconnecting current sheets (RCSs) with a single X-nullpoint often leads to occurrence of magnetic islands with multiple O- and X-nullpoints. Over time these magnetic islands become squashed, or coalescent with two islands merging, as it has been observed indirectly during coronal mass ejection and by in-situ observations in the heliosphere and magnetotail. These points emphasize the importance of understanding the basic energising processes of ambient particles dragged into current sheets with magnetic islands of different configuration.
Methods. Trajectories of protons and electrons accelerated by a reconnection electric field are investigated using a test particle approach in RCSs with different 3D magnetic field topologies defined analytically for multiple X- and O-nullpoints. Trajectories, densities and energy distributions are explored for 106 thermal particles dragged into the current sheets from different sides and distances.
Results. This study confrms that protons and electrons accelerated in magnetic islands in a presence of strong guiding field are ejected from a current sheet into the opposite semiplanes with respect to its midplane. Particles are found to escape O-nullpoints only through the neighbouring X-nullpoints along (not across) the midplane following the separation law for electrons and protons in a given magnetic topology. Particles gain energy either inside O-nullpoints or in a vicinity of X-nullpoints that often leads to electron clouds formed about the X-nullpoint between the O-nullpoints. Electrons are shown to be able to gain sub-relativistic energies in a single magnetic island. Energy spectra of accelerated particles are close to power laws with spectral indices varying from 1.1 to 2.4. The more squashed the islands the larger the difference between the energy gains by transit and bounced particles. Their energy spectra are often with double maxima leading to fast growing turbulence.
Conclusions. Particles are shown to gain most energy in multiple X-nullpoints between O-nullpoints (or magnetic islands). This leads to a formation of electron clouds between magnetic islands. Particle energy gains are much larger in squashed islands than in coalescent ones. In summary, particle acceleration by a reconnection electric field in magnetic islands is much more effective than in an RCS with a single X-nullpoint.

The data center for the Spectrometer and Telescope for Imaging X-rays (STIX) on board Solar Orbiter https://datacenter.stix.i4ds.net/stix

Context. The Spectrometer and Telescope for Imaging X-rays (STIX) on board Solar Orbiter observes solar X-ray emission in the range of 4–150 keV and produces spectra and images of solar flares over a wide range of flare magnitudes. During nominal operation, STIX continuously generates data. A constant data flow requires fully automated data-processing pipelines to process and analyze the data, and a data platform to manage, visualize, and distribute the data products to the scientific community.
Aims. The STIX Data Center has been built to fulfill these needs. In this paper, we outline its main components to help the community better understand the tools and data it provides.
Methods. The STIX Data Center is operated at the University of Applied Sciences and Arts Northwestern Switzerland (FHNW) and consists of automated processing pipelines and a data platform. The pipelines process STIX telemetry data, perform common analysis tasks, and generate data products at different processing levels. They have been designed to operate fully automatically with minimal human intervention. The data platform provides web-based user interfaces and application programmable interfaces for searching and downloading STIX data products.
Results. The STIX Data Center has been operating successfully for more than two years. The platform facilitates instrument operations and provides vital support to STIX data users. 7 Oct 2022, 26 Jan 2023

Probing turbulence in solar flares from SDO/AIA emission lines

Xiaoyan **Xie**1 Gang Li2* Katharine K. Reeves11
Front. Astron. Space Sci. Volume 11 : 1383746 **2024** |
https://doi.org/10.3389/fspas.2024.1383746
https://www.frontiersin.org/journals/astronomy-and-space-sciences/articles/10.3389/fspas.2024.1383746/full
Multiple pieces of evidence have revealed the important role of turbulence in physical processes in solar eruptions, from particle acceleration to the suppression of conductive cooling. Radio observations of density variation have established a Kolmogorov-like spectrum for solar wind density disturbance. Close to the Sun, measurements from extreme ultraviolet (EUV) bands have been used to examine turbulence in the solar atmosphere. The Atmospheric Imaging Assembly onboard the Solar Dynamics Observatory (SDO/AIA) has been frequently used for diagnosing plasma properties due to its complex coverage of temperature response. We compute structure functions (SFs) using SDO/AIA emission measurements for two example of plasma sheets. With the relationship
of $v \sim b \sim \delta n$ and $\delta I \sim \delta(n0+\delta n)2 \sim \delta n \delta I \sim \delta(n0+\delta n)2 \sim \delta n$ (v, b, δn, and δI are turbulent velocity, magnetic field, number density, and intensity, respectively, and n0 is the background density), SFs of δI can be regarded as a proxy for those of the turbulent v and b fields in the plasma sheet. We show that by properly accounting for the radial dependence of the emission line intensity, an SF method is capable of probing the presence of turbulence from SDO/AIA emission lines. Compared to in situ observations, performing SFs on EUV emissions is advantageous in studying turbulence behavior in the wave-vector space, and it opens a new window for investigating turbulence from massive SDO/AIA observations.

Statistical Study of the Kinetic Features of Supra-arcade Downflows Detected from Multiple Solar Flares

Xiaoyan **Xie**1,2,3, Katharine K. Reeves2, Chengcai Shen2, and Joshua D. Ingram4,2
2022 ApJ 933 15
https://iopscience.iop.org/article/10.3847/1538-4357/ac695d/pdf
We have developed a tracking algorithm to determine the speeds of supra-arcade downflows (SADs) and set up a system to automatically track SADs and measure some interesting parameters. By conducting an analysis of six flares observed by the Atmospheric Imaging Assembly on the Solar Dynamics Observatory, we detect more smaller and slower SADs than prior work, due to the higher spatial resolution of our observational data. The inclusion of these events with smaller and slower SADs directly results in lower median velocities and widths than in prior work, but the fitted distributions and evolutions of the parameters still show good consistency with prior work. The observed distributions of the widths, speeds, and lifetimes of SADs are consistent with log-normal distributions, indicating that random and unstable processes are responsible for generating SADs during solar eruptions. Also, we find that the fastest SADs occur at approximately the middle of the height ranges. The number of SADs in each image versus time shows that there are "rest phases" of SADs, when few SADs are seen. These findings support the idea that SADs originate from a fluid instability. We compare our results with a numerical simulation that generates SADs using a mixture of the Rayleigh–Taylor instability and the Richtmyer–Meshkov instability, and find that the simulation generates quantities

that are consistent with our observational results. **2011 Oct 22, 2012 Jan 16, 2012 Jan 27, 2012 Jul 17, 2013 May 22, 2015 Jun 18,**

Numerical experiments on dynamic evolution of a CME-flare current sheet

Xiaoyan **Xie**, Zhixing Mei, Chengcai Shen, Qiangwei Cai, Jing Ye, Katharine K Reeves, Ilia I Roussev, Jun Lin
MNRAS Volume 509, Issue 1, January **2022**, Pages 406–420,
https://doi.org/10.1093/mnras/stab2954
In this paper, we performed magnetohydrodynamics numerical experiments to look into the dynamic behaviour of the current sheet (CS) between the coronal mass ejection (CME) and the associated solar flare, especially the CS oscillation and plasmoid motions in coronal conditions. During the evolution, the disrupting magnetic configuration becomes asymmetric first in the buffer region at the bottom of the CME bubble. The Rayleigh−Taylor instability in the buffer region and the deflected motion of the plasma driven by the termination shock at the bottom of the CME bubble cause the buffer region to oscillate around the y-axis. The local oscillation propagates downwards through the CS, prompting an overall CS oscillation. As the buffer region grows, the oscillation period becomes longer, increasing from about 30 s to about 16 min. Meanwhile, there is another separated oscillation with a period between 0.25 and 1.5 min in the cusp region of the flare generated by velocity shearing. The tearing mode instability yields formations of plasmoids inside the CS. The motions of all the plasmoids observed in the experiment accelerate, which implies that the large-scale CME/flare CS itself in the true eruptive event is filled with the diffusion region according the the standard theory of magnetic reconnection.

Study of Ribbon Separation and Magnetic Reconnection Rates in a Two-Ribbon Flare

W. **Xie**, H. Zhang, H. Wang
Solar Physics, Volume 254 Number 2, Page: 271 – 283, **2009**
In this paper, we present a study of the correlation between the speed of flare ribbon separation and the magnetic flux density during the **10 April 2001** solar flare. The study includes the section of the neutral line containing the flare core and its peripheral area. This event shows clear two-ribbon structure and inhomogeneous magnetic fields along the ribbons, so the spatial correlation and distribution of the flare and magnetic parameters can be studied. A weak negative correlation is found between the ribbon separation speed (V_r) and the longitudinal magnetic flux density (B_z). This correlation is the weakest around the peak of the flare. Spatially, the correlation is also weakest at the positions of the hard X-ray (HXR) sources. In addition, we estimate the magnetic reconnection rate (electric field strength in the reconnection region E_{rec}) by combining the speed of flare ribbons and the longitudinal magnetic flux density. During flare evolution, the time profiles of the magnetic reconnection rate are similar to that of the ribbon separation speed, and the speeds of ribbon separation are relatively slow in the strong magnetic fields (*i.e.*, V_r is negatively correlated with B_z). However, along the flare ribbons, E_{rec} fluctuates in a small range except near the HXR source. A localized enhancement of the reconnection rate corresponds to the position of the HXR source.

Extreme Red-wing Enhancements of UV Lines During the 2022 March 30 X1.3 Solar Flare

Yan **Xu**, Graham S. Kerr, Vanessa Polito, Nengyi Huang, Ju Jing, Haimin Wang
ApJ **958** 67 **2023**
https://arxiv.org/pdf/2309.05745.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/acf8c6/pdf
Here we present the study of a compact emission source during an X1.3 flare on **2022-March-30**. Within a ∼41∼s period (17:34:48 UT to 17:35:29 UT), IRIS observations show spectral lines of Mg II, C II and Si IV with extremely broadened, asymmetric red-wings. This source of interest (SOI) is compact, ∼ 1\arcsec.6, and is located in the wake of a passing ribbon. Two methods were applied to measure the Doppler velocities associated with these red wings: spectral moments and multi-Gaussian fits. The spectral moments method considers the averaged shift of the lines, which are 85 km s−1, 125 km s−1 and 115 km s−1 for the Mg II, C II and Si IV lines respectively. The red-most Gaussian fit suggests a Doppler velocity up to ∼160 km s−1 in all of the three lines. Downward mass motions with such high speeds are very atypical, with most chromospheric downflows in flares on the order 10-100 km s−1. Furthermore, EUV emission is strong within flaring loops connecting two flare ribbons located mainly to the east of the central flare region. The EUV loops that connect the SOI and its counterpart source in the opposite field are much less brightened, indicating that the density and/or temperature is comparatively low. These observations suggest a very fast downflowing plasma in transition region and upper chromosphere, that decelerates rapidly since there is no equivalently strong shift of the O I chromospheric lines. This unusual observation presents a challenge that models of the solar atmosphere's response to flares must be able to explain.

Multi-Passband Observations of A Solar Flare over the He I 10830 Å line

Yan **Xu**, Xu Yang, Graham S. Kerr, Vanessa Polito, Viacheslav M. Sadykov, Ju Jing, Wenda Cao, Haimin Wang
ApJ Letters **924** L18 **2022**
https://arxiv.org/pdf/2112.09949.pdf
https://iopscience.iop.org/article/10.3847/2041-8213/ac447c/pdf
https://doi.org/10.3847/2041-8213/ac447c
This study presents a C3.0 flare observed by the BBSO/GST and IRIS, on **2018-May-28** around 17:10 UT. The Near Infrared Imaging Spectropolarimeter (NIRIS) of GST was set to spectral imaging mode to scan five spectral positions at ± 0.8 Å, ± 0.4 Åand line center of He I 10830. At the flare ribbon's leading edge the line is observed to undergo enhanced absorption, while the rest of the ribbon is observed to be in emission. When in emission, the contrast compared to the pre-flare ranges from about 30 % to nearly 100 % at different spectral positions. Two types of spectra, "convex" shape with higher intensity at line core and "concave" shape with higher emission in the line wings, are found at the trailing and peak flaring areas, respectively. On the ribbon front, negative contrasts, or enhanced absorption, of about ∼10%−20% appear in all five wavelengths. This observation strongly suggests that the negative flares observed in He I 10830 with mono-filtergram previously were not caused by pure Doppler shifts of this spectral line. Instead, the enhanced absorption appears to be a consequence of flare energy injection, namely non-thermal collisional ionization of helium caused by the precipitation of high energy electrons, as found in our recent numerical modeling results. In addition, though not strictly simultaneous, observations of Mg II from the IRIS spacecraft, show an obvious central reversal pattern at the locations where enhanced absorption of He I 10830 is seen, which is in consistent with previous observations.

Transient rotation of photospheric vector magnetic fields associated with a solar flare

Yan **Xu**, Wenda Cao, Kwangsu Ahn, Ju Jing, Chang Liu, Jongchul Chae, Nengyi Huang, Na Deng, Dale E. Gary, Haimin Wang
Nature Communications **2018**
https://www.nature.com/articles/s41467-017-02509-w.pdf
https://arxiv.org/pdf/1801.03171.pdf
As one of the most violent eruptions on the Sun, flares are believed to be powered by magnetic reconnection. The fundamental physics involving the release, transfer and deposition of energy have been studied extensively. Taking advantage of the unprecedented resolution provided by the 1.6-m Goode Solar Telescope, here we show a sudden rotation of vector magnetic fields, about 12∘-20∘ counterclockwise, associated with a flare. Unlike the permanent changes reported previously, the azimuth-angle change is transient and co-spatial/temporal with Hα emission. The measured azimuth angle becomes closer to that in potential fields suggesting untwist of flare loops. The magnetograms were obtained in the near infrared at 1.56~μm, which is minimally affected by flare emission and no intensity profile change was detected. We believe that these transient changes are real and discuss the possible explanations in which the high energy electron beams or Alfve´n waves play a crucial role. **June 22, 2015**

Homologous Circular-ribbon Flares Driven by Twisted Flux Emergence

Z. **Xu**1, K. Yang2, Y. Guo2, J. Zhao3, Z. J. Zhao1, and L. Kashapova
2017 ApJ 851 30
http://sci-hub.tw/10.3847/1538-4357/aa9995
In this paper, we report two homologous circular-ribbon flares associated with two filament eruptions. They were well observed by the New Vacuum Solar Telescope and the Solar Dynamics Observatory on **2014 March 5**. Prior to the flare, two small-scale filaments enclosed by a circular pre-flare brightening lie along the circular polarity inversion line around the parasitic polarity, which has shown a continuous rotation since its first appearance. Two filaments eventually erupt in sequence associated with two homologous circular-ribbon flares and display an apparent writhing signature. Supplemented by the nonlinear force-free field extrapolation and the magnetic field squashing factor investigation, the following are revealed. (1) This event involves the emergence of magnetic flux ropes into a pre-existing polarity area, which yields the formation of a 3D null-point topology in the corona. (2) Continuous input of the free energy in the form of a flux rope from beneath the photosphere may drive a breakout-type reconnection occurring high in the corona, supported by the pre-flare brightening. (3) This initiation reconnection could release the constraint on the flux rope and trigger the MHD instability to first make filament F1 lose equilibrium. The subsequent more violent magnetic reconnection with the overlying flux is driven during the filament rising. In return, the eruption of filament F2 is further facilitated by the reduction of the magnetic tension force above. These two processes form a positive feedback to each other to cause the energetic mass eruption and flare.

Sudden Penumbral Reappearance and Umbral Motion Induced by an M7.9 Solar Flare

Zhe **Xu**1,2,3, Yunchun Jiang1,3, Jiayan Yang1,3, Junchao Hong1,3, and Haidong Li
2017 ApJL 840 L21

http://iopscience.iop.org.sci-hub.cc/2041-8205/840/2/L21/
The sudden flare-related changes of sunspot structures have been recognized as the photospheric responses to the solar eruptions in the corona. In this study, we report two distinctive sunspots variations associated with the flare SOL**2015-06-25**T08:16 (M7.9). Along the flaring polarity inversion line (PIL), the originally decayed penumbra showed a sudden reappearance, with the horizontal fields increasing in the direction of the penumbral fibrils aligned. On the other hand, the small umbra, where the reappearing penumbra rooted, had a sudden northeastward motion, toward the north part of a large sunspot located in the other side of PIL. Based on the calculation of Lorentz force changes, the area of penumbral reappearance mainly suffered a downward pressure, while the umbra region was dominated by the northeastward lateral pressure. These observations can be well understood as a result of coronal fields contraction, which can be deduced from the nonlinear force-free field extrapolation model. It also confirms the implosion idea that the restructuring of coronal fields could impact the solar surface and interior.

RAPID PENUMBRA AND LORENTZ FORCE CHANGES IN AN X1.0 SOLAR FLARE
Zhe **Xu**1,2, Yunchun Jiang1, Jiayang Yang1, Bo Yang1,2, and Yi Bi
2016 ApJ 820 L21
We present observations of the violent changes in photospheric magnetic structures associated with an X1.1 flare, which occurred in a compact ?-configuration region in the following part of AR 11890 on **2013 November 8**. In both central and peripheral penumbra regions of the small ? sunspot, these changes took place abruptly and permanently in the reverse direction during the flare: the inner/outer penumbra darkened/disappeared, where the magnetic fields became more horizontal/vertical. Particularly, the Lorentz force (LF) changes in the central/peripheral region had a downward/upward and inward direction, meaning that the local pressure from the upper atmosphere was enhanced/released. It indicates that the LF changes might be responsible for the penumbra changes. These observations can be well explained as the photospheric response to the coronal field reconstruction within the framework of the magnetic implosion theory and the back reaction model of flares.

Ultra-narrow Negative Flare Front Observed in Helium-10830~Å using the 1.6 m New Solar Telescope

Yan **Xu**, Wenda Cao, Mingde Ding, Lucia Kleint, Jiangtao Su, Chang Liu, Haisheng Ji, Jongchul Chae, Ju Jing, Kyuhyoun Cho, Kyungsuk Cho, Dale Gary, Haimin Wang
ApJ 819 89 **2016**
http://arxiv.org/pdf/1601.04729v1.pdf
https://iopscience.iop.org/article/10.3847/0004-637X/819/2/89/pdf
Solar flares are sudden flashes of brightness on the Sun and are often associated with coronal mass ejections and solar energetic particles which have adverse effects in the near Earth environment. By definition, flares are usually referred to bright features resulting from excess emission. Using the newly commissioned 1.6~m New Solar Telescope at Big Bear Solar Observatory, here we show a striking "negative" flare with a narrow, but unambiguous "dark" moving front observed in He I 10830 \AA, which is as narrow as 340 km and is associated with distinct spectral characteristics in H-alpha and Mg II lines. Theoretically, such negative contrast in He I 10830 \AA\ can be produced under special circumstances, by nonthermal-electron collisions, or photoionization followed by recombination. Our discovery, made possible due to unprecedented spatial resolution, confirms the presence of the required plasma conditions and provides unique information in understanding the energy release and radiative transfer in astronomical objects **2013 Aug. 17, 2014 Aug. 01**

Comparison of Emission Properties of two Homologous Flares in AR 11283

Yan **Xu**, Ju Jing, Shuo Wang, Haimin Wang
ApJ, **2014**
http://arxiv.org/pdf/1404.6577v1.pdf
Large, complex, active regions may produce multiple flares within a certain period of one or two days. These flares could occur in the same location with similar morphologies, commonly referred to as homologous flares. In **2011 September,** active region NOAA 11283 produced a pair of homologous flares on the **6th and 7th**, respectively. Both of them were white-light (WL) flares, as captured by the Helioseismic and Magnetic Imager (HMI) onboard the Solar Dynamics Observatory in visible continuum at 617.3 nm which is believed to originate from the deep solar atmosphere.We investigate the WL emission of these X-class flares with HMIs seeing-free imaging spectroscopy. The durations of impulsive peaks in the continuum are about 4 minutes. We compare the WL with hard X-ray (HXR) observations for the September 6 flare and find a good correlation between the continuum and HXR both spatially and temporally. In absence of RHESSI data during the second flare on September 7, the derivative of the GOES soft X-ray is used and also found to be well correlated temporally with the continuum. We measure the contrast enhancements, characteristic sizes, and HXR fluxes of the twin flares, which are similar for both flares, indicating analogous triggering and heating processes. However, the September 7 flare was associated with conspicuous sunquake signals whereas no

seismic wave was detected during the flare on September 6. Therefore, this comparison suggests that the particle bombardment may not play a dominant role in producing the sunquake events studied in this paper.

Anomalous resistivity in beam-return currents and hard-X ray spectra of solar flares

L. **Xu**1,2, L. Chen1 and D. J. Wu
A&A 550, A63 (**2013**)

Context. Observations of hard-X ray (HXR) spectra from solar flares show that there is noncollisional energy loss when energetic beam electrons are transported along the flare loop from their acceleration site above the looptop in the corona to the loop footpoints in the chromosphere.
Aims. This paper investigates anomalous (i.e., noncollisional) resistivity due to the effective collision by the wave-particle interaction in the beam-return current system of a flare and its effect on the HXR spectral evolution between the looptop and footpoint sources.
Methods. To attribute the noncollisional energy loss to an induced electric field by the beam current, the induced electric field is estimated by the spectral evolution between the looptop and footpoint sources, which is deduced from the standard thin-thick target model. To include collisional and anomalous resistivity caused by the ion-acoustic wave turbulence excited by the return current, the necessary excited level and the excited condition are discussed for the steady-state case in which the return current density driven by the induced electric field in terms of Ohm's law is required to be equal to the beam current density.
Results. The results show that including the anomalous resistivity can reasonably remove the discrepancy between observations and predictions. Meanwhile, the necessary excited level for the ion-acoustic turbulence is tens times of the thermal noise of electrostatic fluctuations in the background plasma, which is an ordinary and low excited level that is easily satisfied.
Conclusions. This indicates that the microscopic kinetics of plasma particles possibly play an important and critical role in understanding the dynamics of beam-return current systems in the solar atmosphere and in the physics of solar flares.

CHARACTERISTIC SIZE OF FLARE KERNELS IN THE VISIBLE AND NEAR-INFRARED CONTINUA

Yan **Xu**1, Wenda Cao2, Ju Jing1, and Haimin Wang
2012 ApJ 750 L7

In this Letter, we present a new approach to estimate the formation height of visible and near-infrared emission of an X10 flare. The sizes of flare emission cores in three wavelengths are accurately measured during the peak of the flare. The source size is the largest in the G band at 4308 Å and shrinks toward longer wavelengths, namely the green continuum at 5200 Å and NIR at 15600 Å, where the emission is believed to originate from the deeper atmosphere. This size-wavelength variation is likely explained by the direct heating model as electrons need to move along converging field lines from the corona to the photosphere. Therefore, one can observe the smallest source, which in our case is 065 ± 002 in the bottom layer (represented by NIR), and observe relatively larger kernels in upper layers of 103 ± 014 and 196 ± 027, using the green continuum and G band, respectively. We then compare the source sizes with a simple magnetic geometry to derive the formation height of the white-light sources and magnetic pressure in different layers inside the flare loop.

DUAL-STAGE RECONNECTION DURING SOLAR FLARES OBSERVED IN HARD X-RAY

Yan **Xu**1, Ju Jing1, Wenda Cao2, and Haimin Wang1
Astrophysical Journal Letters, 709:L142–L145, **2010** February, **File**

In this Letter, we present hard X-ray (HXR) observation by the *Reuven Ramaty High Energy Solar Spectroscopic Imager* of the **2003 October 29** X10 flare. Two pairs of HXR conjugate footpoints have been identified during the early impulsive phase. This geometric configuration is very much in the manner predicted by the "tether-cutting" scenario first proposed by Moore & Roumeliotis. The HXR light curves show that the outer pair of footpoints disappeared much faster than the other pair. This temporal behavior further confirms that this event is a good example of the "tether-cutting" model. In addition, we reconstructed a three-dimensional magnetic field based on the nonlinear force-free extrapolation and found that each pair of HXR footpoints were indeed linked by corresponding magnetic field lines.

High Resolution Observations of White-Light Emissions from the Opacity Minimum during an X-class Flare

Yan **Xu**, Wenda Cao, Ju Jing, and Haimin Wang
E-print, March **2010**, BBSO preprint #1432, **2010**, Astron. Nachr.

Using high cadence, high resolution near infrared (NIR) observations of the X10 white-light flare (WLF) on **2003 October 29**, we investigated the evolution of the core-halo structure of white-light emission during the two-second

period flare peak. We found that size and intensity of the halo remained almost constant in the range of 10~Mm^2. However, the core area was very compact and expanded rapidly from about 1~Mm^2 to 4~Mm^2.At the same time, the total emission of the core increased nearly twenty times. This distinct behavior indicates that different heating mechanisms might be responsible for core and halo emissions. In addition to the temporal analysis, we compared the intensity enhancements of the flare core and halo. The result shows that the halo contrast increased by about 8% compared to the flare-quiet region, which could be explained by a combination of direct-heating and backwarming models.

RHESSI HARD X-RAY IMAGING SPECTROSCOPY OF EXTENDED SOURCES AND THE PHYSICAL PROPERTIES OF ELECTRON ACCELERATION REGIONS IN SOLAR FLARES
Yan **Xu**, A. Gordon Emslie,1 and G. J. Hurford2
The Astrophysical Journal, 673:576–585, **2008**
http://www.journals.uchicago.edu/doi/pdf/10.1086/524184
In this study we present the results of a newapproach to studying the acceleration and propagation of bremsstrahlung producing electrons in solar flares. The method involves an analysis of the size of extended solar flare structures as a function of photon energy. Hard X-ray images from 10 M-class limb events, observed by the Reuven Ramaty High Energy Solar Spectroscopic Imager (RHESSI) to have the general form of a single extended source, were analyzed by forward fitting to the source visibilities in each energy band. On average the source sizes *l* increased slowlywith photon energy E as $l \sim E^{1/2}$. This behavior is consistent neither with the predictions of a single-loop thermal model nor with a model in which nonthermal electrons are injected into a constant-density structure from a compact acceleration region. While a nonuniform density distribution along the flare loop can in principle reconcile the data with a nonthermal collisional model with point-source injection, the resulting density profiles are highly questionable. On the other hand, the data are consistent with a nonthermal collisional model that incorporates an extended acceleration region, perhaps in combination with a localized thermal source. We present best-fit results on the density and length of this acceleration region. To our knowledge, this is the first quantitative empirical analysis of the physical characteristics of electron acceleration regions in solar flares.

Decay of Solar Pores Driven by Small-scale Magnetic Reconnection Episodes

Zhike **Xue**1,2,3, Xiaoli Yan1,3, Liheng Yang1,2,3, Jie Chen2, Jincheng Wang1,3, Qiaoling Li4, and Li Zhao1,3
2021 ApJL 919 L29
https://iopscience.iop.org/article/10.3847/2041-8213/ac2733/pdf
https://doi.org/10.3847/2041-8213/ac2733
We present the relationships between the disappearances of two small pores, magnetic cancellations, and magnetic reconnection episodes in the NOAA AR 12778 on 2020 October 26 with high-resolution observations of the New Vacuum Solar Telescope and the Solar Dynamics Observatory. Two emerging positive polarities (P1 and P2) approach a negative polarity (N1) with velocities of 0.26 and 0.42 km s−1, respectively. Then, two small-scale magnetic reconnection episodes occur between a series of magnetic loops that are rooted in these polarities. The reconnection inflow velocities are around 4.0 km s−1 which is faster than the movements of P1 and P2. Compared with the first magnetic reconnection episode, more magnetic free energy is released in the second reconnection episode due to the greater magnetic strength of P2. Subsequently, magnetic cancellation occurs first between P1 and N1, and then between P2 and N1. At the same time, the pores S1 (N1) and S2 (P2) decay and disappear. The area decay rate of the small pore S2 is estimated to be 7.3 Mm2 hr−1, which is larger than previously reported cases. And the flux decay rate of S2 is 5.1 × 1019 Mx hr−1, similar to the results obtained in the larger sunspots. We conclude that the magnetic reconnection episodes may be caused by both the movement of the magnetic polarities and the plasma dynamics themselves. The decay and disappearance of the small pores and the polarities are driven by magnetic reconnection episodes and then flux submergence. We suggest that a magnetic reconnection episode is a more efficient mechanism for the disappearance of solar pores.

Observations of Magnetic Reconnection with Large Separatrix Angles and Separatrix Jets above the Solar Surface

https://doi.org/10.3847/1538-4357/abfb71
We analyze six cases of magnetic reconnection with large separatrix angles and separatrix jets observed on the solar disk. The separatrix angle is defined as the angle between the two separatrices on the two sides of the outflow region. The plasma jets are observed immediately downstream of the separatrices. The morphological characteristics and magnetic field configurations of all magnetic reconnections are displayed. At the same time, we calculate several

physical parameters of each case, which include the inflow velocity (from 2.3 to 24 km s−1), the outflow velocity (from 1.9 to 43 km s−1), the separatrix jet velocity (from 13 to 82 km s−1), the width (from 0.42 × 103 to 1.2 × 103 km) and length (from 1.4 × 103 to 4.3 × 103 km) of the current sheet, and the separatrix angle θsep (from 72° to 128°). We find that the outflow velocity, the separatrix jet velocity, and the width and length of the current sheet are positively related to the inflow velocity, but the separatrix angle does not depend on the inflow velocity and it is related to the initial magnetic field configuration before magnetic reconnection. Meanwhile, the velocities of the outflow and the separatrix jet decrease with increasing $|\theta_{sep} - 90^{\circ}|$, indicating that when the separatrix angle is close to 90°, the jet and the outflow reach their maximum velocities. These observations are compared with the results of the theoretical model and the numerical simulation.

Thermodynamical Evolution of Supra-Arcade Downflows

Jianchao **Xue**, Yang Su, Hui Li, Xiaozhou Zhao

ApJ **898** 88 **2020**

https://arxiv.org/pdf/2007.11205.pdf

https://doi.org/10.3847/1538-4357/ab9a3d

Supra-arcade downflows (SADs) are dark, teardrop-shaped features descending upon flare arcades. They are thought to be the results of magnetic reconnection, but the detailed formation mechanism of SADs and their relationship to flare energy release are still unclear. In this work, we explore the thermodynamical properties of SADs in the **2011 October 22** limb flare using the observations of the Solar Dynamics Observatory/Atmospheric Imaging Assembly and an improved Differential Emission Measure (DEM) technique. Different heating events around SADs are identified and the propagation speeds of plasma heating are calculated. The first heating event starts with the increase of the emission measure at temperatures higher than 5 MK, about 2.8 minutes before the arrival of the first studied SAD. Its propagation speed is about 140 km/s, a little faster than the speed of the SAD. However, the other two events have fast propagation speeds more than 700 km/s. We suspect that the first heating event can be explained by adiabatic compression, but the others may have different causes. Besides, we observed that SADs can push away their surrounding spikes. The formation of SADs is further explained on the basis of patchy and bursty magnetic reconnection that reconnection outflows may push away surrounding plasma and leave dark lanes behind them. The reliability of the DEM results, heating and cooling mechanisms, and other SAD explanations are discussed.

Spectral and Imaging Observations of a Current Sheet Region in a Small-scale Magnetic Reconnection Event

Zhike **Xue**1,2, Xiaoli Yan1,2, Liheng Yang1,2, Jincheng Wang1,2, Song Feng3,Qiaoling Li1,2,4, Kaifan Ji1,2, and Li Zhao1,

2018 ApJL 858 L4

http://sci-hub.tw/http://iopscience.iop.org/2041-8205/858/1/L4/

We report a possible current sheet region associated with a small-scale magnetic reconnection event by using the spectral and imaging observations of the Interface Region Imaging Spectrograph(IRIS) and the magnetograms obtained by the Solar Dynamics Observatory on **2016 August 08**. The length and width of the current sheet region are estimated to be from 1.4 ± 0.1 Mm to 3.0 ± 0.3 Mm and from 0.34 ± 0.01 Mm to 0.64 ± 0.09 Mm, respectively. The evolutions of the length of the current sheet region are positively correlated with that of the width. These measurements are among the smallest reported. When the IRIS slit scans the current sheet region, the spectroscopic observations show that the Si iv line is broadened in the current sheet region and the plasma has a blueshifted feature at the middle and a redshifted feature at the ends of the current sheet region. The maximum measured blueshifted and redshifted Doppler velocities are −20.8 ± 0.9 and 34.1 ± 0.4 km s−1, respectively. Additionally, the electron number densities of the plasma in the current sheet region are computed to be around 1011 cm−3 based on the spectrums of the two O ivlines. The emergence, movement, and cancellation of a small sunspot with negative polarity are observed during the formation and shift of the current sheet region. We suggest that the occurrence and evolution of the magnetic reconnection are driven by the movement of the small sunspot in the photosphere.

Photospheric Pore Rotation Associated with a C-class Flare from Spectropolarimetric Observations with DKIST

Rahul **Yadav**, Maria D. Kazachenko, Andrey N. Afanasyev, Gianna Cauzzi, Kevin Reardon

ApJL **973** L10 **2024**

https://arxiv.org/pdf/2408.16956

https://iopscience.iop.org/article/10.3847/2041-8213/ad758d/pdf

We present high-resolution observations of a C4.1-class solar flare (SOL**2023-05-03T20**:53) in AR 13293 from the ViSP and VBI instruments at the DKIST. The fast cadence, good resolution, and high polarimetric sensitivity of ViSP data provide a unique opportunity to explore the photospheric magnetic fields before and during the flare. We infer the magnetic field vector in the photosphere from the Fe I 6302 line using Milne-Eddington inversions. Combined analysis of the inverted data and VBI images reveals the presence of two oppositely-polarity pores exhibiting rotational motion

both prior to and throughout the flare event. Data-driven simulations further reveal a complex magnetic field topology above the rotating pores, including a null-point-like configuration. We observed a 30% relative change in the horizontal component (δFh) of Lorentz force at the flare peak time and roughly no change in the radial component. We find that the changes in δFh are the most likely driver of the observed pore rotation. These findings collectively suggest that the back-reaction of magnetic field line reconfiguration in the corona may influence the magnetic morphology and rotation of pores in the photosphere on a significantly smaller scale.

A statistical study of magnetic field changes in the photosphere during solar flares using high-cadence vector magnetograms and their association with flare ribbons

Rahul **Yadav**, Maria D. Kazachenko
ApJ **944** 215 **2022**
https://arxiv.org/pdf/2210.14264.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/acaa9d/pdf
Abrupt and permanent photospheric magnetic field changes have been observed in many flares. It is believed that such changes are related to the reconfiguration of magnetic field lines, however, the real origin is still unclear. In this study we analyze 37 flares to understand the magnetic field vector changes in the photosphere using high-cadence (135 s) vector magnetograms obtained from the HMI/SDO. We also co-align these magnetogram sequences with flare ribbon images (1600 Å), obtained from the AIA/SDO, to understand how the field change is associated with the ribbon morphology. We find that the permanent change in the horizontal component lies near the polarity inversion line, whereas the vertical component pixels are less pronounced and distributed in small patches. We also find that the pixels exhibiting ultraviolet emission are not always associated with permanent field change. In 84% of 37 events the UV emission starts early by several minutes compared to the field change start time for the pixels showing both UV emission and permanent horizontal field change. The field change properties show no relation with the size of active regions, but are strongly related to the flare ribbon properties like ribbon magnetic flux and ribbon area. The permanent field change duration is strongly correlated with the GOES flaring duration, with an average value of 29% of total GOES flare time. Our analysis suggests that the change in photospheric magnetic field is caused by combination of two scenarios: contraction of flare loops driven by magnetic reconnection and coronal implosion. **15 Feb 2011**

On the radiative losses in the chromosphere during a C-class flare

Rahul **Yadav**, J. de la Cruz Rodríguez, Graham S. Kerr, C. J. Díaz Baso, Jorrit Leenaarts
A&A 665, A50 **2022**
https://arxiv.org/pdf/2207.02840
https://www.aanda.org/articles/aa/pdf/2022/09/aa43440-22.pdf
Solar flares release an enormous amount of energy in the corona. A substantial fraction of this energy is transported to the lower atmosphere, which results in chromospheric heating. The mechanisms that transport energy to the lower solar atmosphere during a flare are still not fully understood. We aim to estimate the temporal evolution of the radiative losses in the chromosphere at the footpoints of a C-class flare, in order to set observational constraints on the electron beam parameters of a RADYN flare simulation. We estimated the radiative losses from hydrogen, and singly ionized Ca and Mg using semi-empirical model atmospheres. To estimate the integrated radiative losses in the chromosphere the net cooling rates were integrated between the temperature minimum and the height where the temperature reaches 10 kK. The stratification of the net cooling rate suggests that the Ca IR triplet lines are responsible for most of the radiative losses in the flaring atmosphere. During the flare peak time, the contribution from Ca II H & K and Mg II h & k lines are strong and comparable to the Ca IR triplet (∼32 kW m−2). Since our flare is a relatively weak event the chromosphere is not heated above 11 kK, which in turn yields a subdued Ly{\alpha} contribution (∼7 kW m−2). The temporal evolution of total integrated radiative losses exhibits sharply-rising losses (0.4 kW m−2 s−1) and a relatively slow decay (0.23 kW~m−2 s−1). The maximum value of total radiative losses is reached around the flare peak time, and can go up to 175 kW m−2 for a single pixel located at footpoint. After a small parameter study, we find the best model-data consistency in terms of the amplitude of radiative losses and the overall atmospheric structure with a RADYN flare simulation in the injected energy flux of 5×1010 erg s−1 cm−2. **2019-05-06**

Stratification of physical parameters in a C-class solar flare using multi-line observations

Rahul **Yadav**, C. J. D. Baso, J. de la Cruz Rodr'iguez, F. Calvo, R. Morosin
A&A 649, A106 **2021**
https://arxiv.org/pdf/2011.02953.pdf
https://doi.org/10.1051/0004-6361/202039857
We present high-resolution and multi-line observations of a C2-class solar flare, occurred in NOAA AR 12740 on **May 6, 2019**. The rise, peak and decay phases of the flare were recorded continuously and quasi-simultaneously in the Ca II K line with the CHROMIS instrument, the Ca II 8542 and Fe I 6173 Å lines with the CRISP instrument at the SST. The observations in the chromospheric Ca II lines exhibit intense brightening near the flare footpoints. At these locations, a non-LTE inversion code was employed to infer the temperature, magnetic field, line-of-sight (LOS) velocity and

microturbulent velocity stratification in the flaring atmosphere. During the flare peak time, the LOS velocity shows both upflows and downflows around the flare footpoints in the upper chromosphere and lower chromosphere, respectively. Moreover, the temporal analysis of the LOS magnetic field at the flarepoints exhibits a maximum change of ~600 G. After the flare, the LOS magnetic field decreases to the non-flaring value, exhibiting no permanent or step-wise change. The analysis of response functions to the temperature, LOS magnetic field and velocity shows that the Ca II lines exhibit enhanced sensitivity to the deeper layers (i.e., log_t ~ -3) of the flaring atmosphere, whereas for the non-flaring atmosphere they are mainly sensitive around log_t ~ -4. We suggest that a fraction of the apparent increase in the LOS magnetic field at the flare footpoints may be due to the increase in the sensitivity of the Ca II 8542 Å line in the deeper layers, where the field strength is relatively stronger. The rest can be due to magnetic field reconfiguration during the flare. Our observations illustrate that even a less intense C-class flare can heat the deeper layers of the solar chromosphere, mainly at the flare footpoints, without affecting the photosphere.

TIME VARIATION AND STATISTICAL STUDIES OF MAGNETIC HELICITY INJECTION IN SOLAR MAGNETIC REGIONS

Tetsuya T. **Yamamoto**1 and T. Sakurai
Astrophysical Journal, 698:928–937, **2009**
http://www.iop.org/EJ/toc/-alert=43190/0004-637X/698/1
In this study, we analyzed the helicity injection in solar active regions statistically with the method proposed by Kusano et al. We investigated the variation in helicity injection as an active region evolves and the statistical distribution
of helicity injection against the magnetic flux (√) and the latitude. The temporal evolution of active regions is divided into three phases (“emergence,” “active,” and “decay” phases). We studied one emergence-phase region, 13 active-phase regions, and five decay-phase regions. The total number of helicity injection rates we obtained is 1476. We found the following results. The dispersions (standard deviations) in the helicity injection rates are proportional to $\sqrt{}^{-0.47}$ in the active-phase regions and to $\sqrt{}^{-0.34}$ in the decay-phase regions. The dispersion for the emergence-phase region, 0.046 day^{-1}, is larger than those for the active-phase regions, 0.004–0.03 day^{-1}, and those for the decay-phase regions, 0.004–0.01 day^{-1}. The average helicity injection rates of the active-phase regions show the latitude dependence, which is consistent with the “hemispheric rule” of helical structures in the solar atmosphere, while those of the decay-phase regions are inconsistent with the hemispheric rule. The average helicity injection rates for the active-phase regions, 0.003–0.03 day^{-1}, are larger than that for the emergence-phase region, 0.0045 day^{-1}, and those for the decay-phase regions, $<$0.002 day^{-1}. These dependences of the helicity injection rates give us clues on the generation mechanism of helicity and the evolution of the magnetic field in the solar convection zone.

A Data-constrained Magnetohydrodynamic Simulation of the X1.0 Solar Flare of 2021 October 28

Daiki **Yamasaki**, Satoshi Inoue, Yumi Bamba, Jeongwoo Lee, Haimin Wang
ApJ **940** 119 **2022**
https://arxiv.org/pdf/2210.14563 **File**
https://iopscience.iop.org/article/10.3847/1538-4357/ac9df4/pdf
The solar active region NOAA 12887 produced a strong X1.0 flare on **2021 October 28**, which exhibits X-shaped flare ribbons and a circle-shaped erupting filament. To understand the eruption process with these characteristics, we conducted a data-constrained magnetohydrodynamics simulation using a nonlinear force-free field of the active region about an hour before the flare as the initial condition. Our simulation reproduces the filament eruption observed in the Ha images of GONG and the 304 angstrom images of SDO/AIA and suggests that two mechanisms can possibly contribute to the magnetic eruption. One is the torus instability of the pre-existing magnetic flux rope (MFR), and the other is upward pushing by magnetic loops newly formed below the MFR via continuous magnetic reconnection between two sheared magnetic arcades. The presence of this reconnection is evidenced by the SDO/AIA observations of the 1600 angstrom brightening in the footpoints of the sheared arcades at the flare onset. To clarify which process is more essential for the eruption, we performed an experimental simulation in which the reconnection between the sheared field lines is suppressed. In this case too, the MFR could erupt, but at a much reduced rising speed. We interpret this result as indicating that the eruption is not only driven by the torus instability, but additionally accelerated by newly formed and rising magnetic loops under continuous reconnection.

Evolution of the Non-potential Magnetic Field in the Solar Active Region 12673 Based on a Nonlinear Force-free Modeling

Daiki **Yamasaki**, Satoshi Inoue, Shin'ichi Nagata, Kiyoshi Ichimoto
ApJ **908** 132 **2021**
https://arxiv.org/pdf/2012.01008.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/abcfbb/pdf

https://doi.org/10.3847/1538-4357/abcfbb
Active region (AR) 12673 produced many M-class and several X-class flares, one of which being an X9.3 flare, which is recorded as the largest solar flare in solar cycle 24. We studied the evolution of the three-dimensional flare-productive magnetic field within AR 12673, using a time series of nonlinear force-free field extrapolations of every 12 hours from September 4th 00:00 UT to 6th 00:00 UT. Our analysis found that three magnetic flux ropes (MFRs) are formed by September 4th, one of which produced the X9.3 flare on September 6th. One MFR has positive magnetic twist which is a different sign from other two MFRs. Since the temporal evolution of the magnetic flux of the MFR accumulating the positive twist is consistent with the profile of the GOES X-ray flux well observed from September 4th to 6th, we suggest that the formation of the MFR having the positive twist is closely related to the occurrence of the M-class flares including an M5.5 flare. We further found a magnetic null in the magnetic field surrounding the MFRs, in particular, above the MFR having positive twist before the M5.5 flare which is the largest M-flare observed during this period. By comparing with the AIA 1600 angstrom images, we found that the footpoints of the overlying field lines are anchored to the area where the brightening was initially observed. Therefore, we suggest that reconnection induced by the torus instability of the positively twisted MFR at the null possibly drived the M5.5 flare. **4 Sep 2017**

Extreme Solar Flare Prediction Using Residual Networks with HMI Magnetograms and Intensitygrams

Juyoung **Yun**, Jungmin Shin
SPAICE Conference **2024**
https://arxiv.org/pdf/2405.14750
Solar flares, especially C, M, and X class, pose significant risks to satellite operations, communication systems, and power grids. We present a novel approach for predicting extreme solar flares using HMI intensitygrams and magnetograms. By detecting sunspots from intensitygrams and extracting magnetic field patches from magnetograms, we train a Residual Network (ResNet) to classify extreme class flares. Our model demonstrates high accuracy, offering a robust tool for predicting extreme solar flares and improving space weather forecasting. Additionally, we show that HMI magnetograms provide more useful data for deep learning compared to other SDO AIA images by better capturing features critical for predicting flare magnitudes. This study underscores the importance of identifying magnetic fields in solar flare prediction, marking a significant advancement in solar activity prediction with practical implications for mitigating space weather impacts. **2022-01-16**

Characteristic time of stellar flares on Sun-like stars

Y **Yan**, H He, C Li, A Esamdin, B L Tan, L Y Zhang, H Wang
MNRAS: Letters, Volume 505, Issue 1, **2021**, Pages L79–L83,
https://doi.org/10.1093/mnrasl/slab055
https://academic.oup.com/mnrasl/article-abstract/505/1/L79/6297375
Using the short-cadence data (1-min interval) of the Kepler space telescope, we conducted a statistical analysis for the characteristic time of stellar flares on Sun-like stars (SLS). Akin to solar flares, stellar flares show rise and decay light-curve profiles, which reflect the two distinct phases (rise phase and decay phase) of the flare process. We derived characteristic times of the two phases for stellar flares of SLS, resulting in a median rise time of about 5.9 min and a median decay time of 22.6 min. It is found that both the rise time and the decay time of the stellar flares follow a lognormal distribution. The peak positions of the lognormal distributions for flare rise time and decay time are 3.5 min and 14.8 min, respectively. These time values for stellar flares are similar to the time-scale of solar flares, which supports the idea that stellar flares and solar flares have the same physical mechanism. The statistical results obtained in this work for SLS can be a benchmark of flare characteristic times when comparing with other types of stars.

Research progress based on observations of the New Vacuum Solar Telescope **Review**

Xiaoli **Yan**, Zhong Liu, Jun Zhang, Zhi Xu
SCIENCE CHINA Technological Sciences **2019**
https://arxiv.org/pdf/1910.09127.pdf
The purpose of this paper is to introduce the main scientific results made by the one-meter New Vacuum Solar Telescope (NVST), which was put into commission on 2010. NVST is one of the large aperture solar telescopes in the world, located on the shore of Fuxian lake of Yunnan province in China, aiming at serving solar physicists by providing them with high resolution photospheric and chromospheric observational data. Based on the data from NVST and complementary observations from space (e.g., Hinode, SDO and IRIS, etc), dozens of scientific papers have been published with a wide range of topics concentrating mainly on dynamics and activities of fine-scale magnetic structures and their roles in the eruptions of active-region filaments and flares. The achievements include dynamic characteristics of photospheric bright points, umbral dots, penumbral waves, and sunspot/light bridge oscillation, observational evidence of small-scale magnetic reconnection, and fine-scale dynamic structure of prominences. All these new results will shed light on the better understanding of solar eruptive activities. Data release, observation proposals, and future research subjects are introduced and discussed.

Bright points. Umbral dot, penumbral wave. Sunspot light bridge. Formation, fine-scale structures, and eruption mechanism of solar filaments. Fine structure of solar prominences. Filament formation. Magnetic structures of active-region filaments. Filament eruption. Small-scale magnetic reconnection in the solar eruptions. Release of twist in a filament by magnetic reconnection. Interchange magnetic reconnection between a filament and nearby open fields. Magnetic reconnection between a twisted arch filament system and coronal loops. Magnetic reconnection between two active-region filaments. Oscillatory magnetic reconnection. Small-scale eruptive activities. Mini-filaments and jets. Formation and trigger mechanism of solar flares

Simultaneous observation of a flux rope eruption and magnetic reconnection during an X-class solar flare

X.L. **Yan**, L.H. Yang, Z.K. Xue, Z.X. Mei, D.F. Kong, J.C. Wang, Q.L. Li
ApJL **853** L18 **2018**
https://arxiv.org/pdf/1801.02738.pdf
https://iopscience.iop.org/article/10.3847/2041-8213/aaa6c2/pdf
In this letter, we present a spectacular eruptive flare (X8.2) associated with a coronal mass ejection (CME) on **2017 September 10** at the west limb of the Sun. A flux rope eruption is followed by the inflow, the formation of a current sheet and a cusp structure, which were simultaneously observed during the occurrence of this flare. The hierarchical layers of the cusp-shaped structure are well observed in 131 \AA\ observation. The scenario that can be created from these observations is very consistent with the predictions of some eruptive models. Except for the characteristics mentioned above in the process of the flare predicted by classical eruption models, the current sheet separating into several small current sheets is also observed at the final stage of the flux rope eruption. The quantitative calculation of the velocities and accelerations of the inflow, hot cusp structure, and post-flare loops is presented. The width of the current sheet is estimated to be about 3 [Math Processing Error] [Math Processing Error] km. These observations are very useful to understand the process of solar eruptions.

Successive X-class flares and coronal mass ejections driven by shearing motion and sunspot rotation in active region NOAA 12673

X.L. **Yan**, J.C. Wang, G.M. Pan, D.F. Kong, Z.K. Xue, L.H. Yang, Q.L. Li
2018 *ApJ* **856** 79
https://arxiv.org/pdf/1801.02290.pdf
http://sci-hub.tw/http://iopscience.iop.org/0004-637X/856/1/79/
We present a clear case study on the occurrence of two successive X-class flares including a decade-class flare (X9.3) and two coronal mass ejections (CMEs) triggered by shearing motion and sunspot rotation in active region NOAA 12673 on 2017 September 6. A shearing motion between the main sunspots with opposite polarities started on September 5 and even lasted after the second X-class flare on September 6. Moreover, the main sunspot with negative polarity rotated around its umbral center and another main sunspot with positive polarity also exhibited a slow rotation. The sunspot with negative polarity at the northwest of active region also began to rotate counter-clockwise before the onset of the first X-class flare. The successive formation and eruption of two S-shaped structures were closely related to the counter-clockwise rotation of three sunspots. It is also found that the rotation of sunspots is faster during four hours prior to the onset of the flares than the period before. The existence of a flux rope is found prior to the onset of two flares by using non-linear force free field extrapolation based on the vector magnetograms observed by SDO/HMI. These results suggest that shearing motion and sunspot rotation play an important role in the buildup of the free energy and the formation of flux ropes in the corona which produces solar flares and CMEs.

The Eruption of a Small-scale Emerging Flux Rope as the Driver of an M-class Flare and of a Coronal Mass Ejection

X. L. **Yan**1,2,3, C. W. Jiang4, Z. K. Xue1,3, J. C. Wang1,5, E. R. Priest6, L. H. Yang1,3, D. F. Kong1,2,3, W. D. Cao7, and H. S. Ji8
2017 ApJ 845 18
https://arxiv.org/pdf/1707.00073.pdf
http://sci-hub.cc/10.3847/1538-4357/aa7e29
Solar flares and coronal mass ejections are the most powerful explosions in the Sun. They are major sources of potentially destructive space weather conditions. However, the possible causes of their initiation remain controversial. Using high-resolution data observed by the New Solar Telescope of Big Bear Solar Observaotry, supplemented by Solar Dynamics Observatoryobservations, we present unusual observations of a small-scale emerging flux rope near a large sunspot, whose eruption produced an M-class flare and a coronal mass ejection. The presence of the small-scale flux rope was indicated by static nonlinear force-free field extrapolation as well as data-driven magnetohydrodynamics modeling of the dynamic evolution of the coronal three-dimensional magnetic field. During the emergence of the flux

rope, rotation of satellite sunspots at the footpoints of the flux rope was observed. Meanwhile, the Lorentz force, magnetic energy, vertical current, and transverse fields were increasing during this phase. The free energy from the magnetic flux emergence and twisting magnetic fields is sufficient to power the M-class flare. These observations present, for the first time, the complete process, from the emergence of the small-scale flux rope, to the production of solar eruptions. **24 Aug 2015**

SUNSPOT ROTATION, SIGMOIDAL FILAMENT, FLARE, AND CORONAL MASS EJECTION: THE EVENT ON 2000 FEBRUARY 10

X. L. **Yan**1,2, Z. Q. Qu1, D. F. Kong1,2, and C. L. Xu

2012 ApJ 754 16

We find that a sunspot with positive polarity had an obvious counterclockwise rotation and resulted in the formation and eruption of an inverse S-shaped filament in NOAA Active Region 08858 from **2000 February 9 to 10**. The sunspot had two umbrae which rotated around each other by 195° within about 24 hr. The average rotation rate was nearly 8° hr–1. The fastest rotation in the photosphere took place during 14:00 UT to 22:01 UT on February 9, with a rotation rate of nearly 16° hr–1. The fastest rotation in the chromosphere and the corona took place during 15:28 UT to 19:00 UT on February 9, with a rotation rate of nearly 20° hr–1. Interestingly, the rapid increase of the positive magnetic flux occurred only during the fastest rotation of the rotating sunspot, the bright loop-shaped structure, and the filament. During the sunspot rotation, the inverse S-shaped filament gradually formed in the EUV filament channel. The filament experienced two eruptions. In the first eruption, the filament rose quickly and then the filament loops carrying the cool and the hot material were seen to spiral counterclockwise into the sunspot. About 10 minutes later, the filament became active and finally erupted. The filament eruption was accompanied with a C-class flare and a halo coronal mass ejection. These results provide evidence that sunspot rotation plays an important role in the formation and eruption of the sigmoidal active-region filament.

PARTICLE ACCELERATION BY FAST MODES IN SOLAR FLARES

Huirong **Yan**,1 A. Lazarian,2 and Vahe´ Petrosian3

Astrophysical Journal, 684:1461-1468, **2008**

http://www.journals.uchicago.edu/toc/apj/2008/684/2

We address the problem of particle acceleration in solar flares by fast modes which may be excited during the reconnection and undergo cascade and are subjected to damping.We extend the calculations beyond the quasi-linear approximation and compare the acceleration and scattering by transit time damping and gyroresonance interactions. We find that the acceleration is dominated by the so-called transit time damping mechanism. We estimate the total energy transferred into particles and show that our approach provides sufficiently accurate results.We compare this rate with the energy-loss rate. Scattering by fast modes appears to be sufficient to prevent the protons from escaping the system during the acceleration. Confinement of electrons, on the other hand, requires the existence of plasma waves. Electrons can be accelerated to GeV energies through the process described here for solar flare conditions.

Rapid rotation of a sunspot associated with flares:

X. L. **Yan** and Z. Q. Qu

A&A 468 (**2007**) 1083-1088 (Section 'The Sun')

http://www.aanda.org/10.1051/0004-6361:20077064

Active region NOAA 10424 observed on August 5, 2003 is studied in detail by using TRACE, SOHO/MDI, BBSO H α monograph, and GOES data.

It is shown that there is a close relationship between the sunspot rotation and the emerging kinked magnetic Ω-loops, where the flares occur.

A Possible Mechanism for "Late Phase" in Stellar White-Light Flares

Kai E. **Yang**, Xudong Sun, Graham S. Kerr, Hugh S. Hudson

https://arxiv.org/pdf/2310.19316.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/ad077d/pdf

M-dwarf flares observed by the \textit{Transiting Exoplanet Survey Satellite} (\textit{TESS}) sometimes exhibit a "peak-bump" light-curve morphology, characterized by a secondary, gradual peak well after the main, impulsive peak. A similar "late phase" is frequently detected in solar flares observed in the extreme-ultraviolet from longer hot coronal loops distinct from the impulsive flare structures. White-light emission has also been observed in off-limb solar flare loops. Here, we perform a suite of one-dimensional hydrodynamic loop simulations for M-dwarf flares inspired by these solar examples. Our results suggest that coronal plasma condensation following impulsive flare heating can yield high electron number density in the loop, allowing it to contribute significantly to the optical light curves via free-bound

and free-free emission mechanisms. Our simulation results qualitatively agree with \textit{TESS} observations: the longer evolutionary time scale of coronal loops produces a distinct, secondary emission peak; its intensity increases with the injected flare energy. **We argue that coronal plasma condensation is a possible mechanism for the \textit{TESS} late-phase flares.**

Image Super-resolution Methods for FY-3E X-EUVI 195 Å Solar Images

Qinglin **Yang**1,2, Zhou Chen2,3,4, Rongxin Tang2,3, Xiaohua Deng2,3, and Jinsong Wang4
2023 ApJS 265 36
https://iopscience.iop.org/article/10.3847/1538-4365/acb3b9/pdf
olar eruptions and the solar wind are sources of space weather disturbances, and extreme-ultraviolet (EUV) observations are widely used to research solar activity and space weather forecasts. Fengyun-3E is equipped with the Solar X-ray and Extreme Ultraviolet Imager, which can observe EUV imaging data. Limited by the lower resolution, however, we research super-resolution techniques to improve the data quality. Traditional image interpolation methods have limited expressive ability, while deep-learning methods can learn to reconstruct high-quality images through training on paired data sets. There is a wide variety of super-resolution models. We try these three representative models: Real-ESRGAN combined with generative adversarial networks, residual channel-attention networks (RCAN) based on channel attention, and SwinIR, based on self-attention. Instruments on different satellites differ in observation time, angle, and resolution, so we selected Solar Dynamics Observatory/Atmospheric Imaging Assembly (SDO/AIA) 193 Å images with similar wavelengths as a reference and used a feature-based method for image registration to eliminate slight deformations to build training data sets. Finally, we compare the above methods in their evaluation metrics and visual quality. RCAN has the highest peak signal-to-noise ratio and structural similarity evaluation. Real-ESRGAN model is the best in the Learned Perceptual Image Patch Similarity index, and its results visually show that it has more highly detailed textures. The corrected super-resolution results can complement the SDO/AIA data to provide solar EUV images with a higher temporal resolution for space weather forecasting and solar physics research. **2021-10-28, 2022-06-08**

Weak Bidirectional Outflows and Flare Current Sheet in a Solar Coronal Jet Driven by the Eruption of a Minifilament

Jiayan **Yang**1, Junchao Hong1, Bo Yang1, Yi Bi1, and Zhe Xu1
2023 ApJ 942 86
https://iopscience.iop.org/article/10.3847/1538-4357/aca66f/pdf
Different from the classical emerging-flux model for solar jets, recent studies proposed that the great majority of solar coronal jets are triggered by minifilament eruptions and two magnetic reconnection processes should take place during the course, named as external reconnection (breakout reconnection) and internal reconnection (flare reconnection). With the excellent data of the Solar Dynamics Observatory, we present the observational signatures of these two magnetic reconnection processes during a solar coronal jet that occurred in a huge coronal hole of northern hemisphere. The jet was triggered by the eruption of a minifilament that located at a coronal bright point in the coronal hole. Weak bidirectional outflows were observed when the erupting minifilament approached the ambient open field, ejecting along the triggered jet spire and the jet base simultaneously. In addition, a flare current sheet occurred after the eruption of the minifilament, connecting the jet spire and the jet bright point (or flare). We suggest the occurrence of the weak bidirectional outflows and the flare current sheet correspond to the external and the internal reconnections, respectively. Prior to the eruption of the minifilament and the jet, photospheric magnetic flux cancellation maintained for more than 7 hr in the source region, and the positive flux decreased for about 28.6% during this period. So, consistent with the recent observations, the trigger mechanism of the minifilament eruption and the following jet in this event may be flux cancellation rather than flux emergence. **2011 May 29**

Formation of a Solar Filament by Magnetic Reconnection and Associated Chromospheric Evaporation and Subsequent Coronal Condensation

Bo **Yang**, Jiayan Yang, Yi Bi, Junchao Hong, Zhe Xu
ApJ Letters **2021**
https://arxiv.org/pdf/2110.10951.pdf
We present the first observation of a solar filament formed by magnetic reconnection and associated chromospheric evaporation and subsequent coronal condensation. Driven by shearing motion during flux emergence, a sequential tether-cutting reconnection processes occurred and resulted in an M1.3 confined flare accompany with the formation of a sigmoid structure. It is found that the flare had a conjugate compact footpoint brightenings, which correspond to the footpoints of the sigmoid. Furthermore, observational evidence of explosive evaporation is well diagnosed at the conjugate footpoint brightenings in the impulsive phase of the flare. After the flare, continuous cool condensations formed at about the middle section of the sigmoid and then moved in opposite directions along the sigmoid, eventually leading to the formation of the filament. These observations suggest that magnetic reconnection not only can form the magnetic field structure of the filament, but also heat their chromospheric footpoints during their formation and drive chromospheric evaporation. As a result, the heated chromospheric plasma may be evaporated into the magnetic field

structure of the filament, where the accumulated hot plasma might suffer from thermal instability or thermal non-equilibrium, causing catastrophic cooling and coronal condensation to form the cool dense material of the filament. This observation lends strong support to the evaporative-condensation model and highlights the crucial role of magnetic reconnection in forming both the magnetic field structure and the cool dense material of filaments. **2014 February 2**

Radiative Hydrodynamic Simulations of the Spectral Characteristics of Solar White-light Flares

Yu-Tong **Yang**, Jie Hong, Ying Li, Ming-De Ding, Hui Li
Research in Astronomy and Astrophysics (RAA) Volume 21, Issue 1, id.001, **2021**
https://arxiv.org/pdf/2007.08850.pdf
As one of the most violent activities in the solar atmosphere, white-light flares (WLFs) are generally known for their enhanced white-light (or continuum) emission, which primarily originates in the solar lower atmosphere. However, we know little about how white-light emission is produced. In this study, we aim to investigate the response of the continua at 3600Åand 4250Å and also the Hα and Lyα lines during WLFs modeled with radiative hydrodynamics simulations. We take non-thermal electron beams as the energy source for the WLFs in two different initial atmospheres and vary their parameters. Our results show that the model with non-thermal electron beam heating can clearly show enhancements in the continua at 3600Å and 4250Å\ as well as in the Hα and Lyα lines. A larger electron beam flux, a smaller spectral index, or a penumbral initial atmosphere leads to a stronger emission increase at 3600Å, 4250Å and in the Hα line. For the Lyα line, however, it is more preferably enhanced in a quiet-Sun initial atmosphere with a larger spectral index of the electron beam. It is also notable that the continua at 3600Å and 4250Å and the Hα line exhibit a dimming at the beginning of the heating and reach their peak emissions later than the peak time of the heating function, while the Lyα line does not show such behaviors. These results can be served as a reference for analyzing future WLF observations.

Imaging and spectral study on the null point of a fan-spine structure during a solar flare

Shuhong **Yang**, Qingmin Zhang, Zhi Xu, Jun Zhang, Ze Zhong, Yang Guo
ApJ 898:101 **2020**
https://arxiv.org/pdf/2005.09613.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ab9ac7/pdf
Using the multi-instrument observations, we make the first simultaneous imaging and spectral study on the null point of a fan-spine magnetic topology during a solar flare. When magnetic reconnection occurs at the null point, the fan-spine configuration brightens in the (extreme-)ultraviolet channels. In the Hα images, the fan-spine structure is partly filled and outlined by the bi-directional material flows ejected from the reconnection site. The extrapolated coronal magnetic field confirms the existence of the fan-spine topology. Before and after the flare peak, the total velocity of the outflows is estimated to be about 60 km s−1. During the flare, the Si IV line profile at the reconnection region is enhanced both in the blue-wing and red-wing. At the flare peak time, the total velocity of the outflows is found to be 144 km s−1. Superposed on the Si IV profile, there are several deep absorption lines with the blueshift of several tens of km s−1. The reason is inferred to be that the bright reconnection region observed in Si IV channel is located under the cooler material appearing as dark features in the Hα line. The blueshifted absorption lines indicate the movement of the cooler material toward the observer. The depth of the absorption lines also depends on the amount of cooler material. These results imply that this kind of spectral profiles can be used as a tool to diagnose the properties of cooler material above reconnection site. **22 March 2019**.

Two-step evolution of a rising flux rope resulting in a confined solar flare

Shuhong **Yang**, Jun Zhang, Qiao Song, Yi Bi, Ting Li
ApJ **878** 38 **2019**
https://arxiv.org/pdf/1905.00808.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ab1f67/pdf
Combining the Solar Dynamics Observatory and the New Vacuum Solar Telescope observations, we study a confined flare triggered by a rising flux rope within the trailing sunspots of active region 12733. The flux rope lying above the sheared polarity inversion line can be constructed through magnetic extrapolation but could not be detected in multi-wavelength images at the pre-flare stage. The conspicuous shearing motions between the opposite-polarity fields in the photosphere are considered to be responsible for the flux rope formation. The maximum twist of the flux rope is as high as -1.76, and then the flux rope rises due to the kink instability. Only when the flare starts can the flux rope be observed in high-temperature wavelengths. The differential emission measure results confirm that this flux rope is a high-temperature structure. Associated with the rising flux rope, there appear many post-flare loops and a pair of flare ribbons. When the rising flux rope meets and reconnects with the large-scale overlying field lines, a set of large-scale twisted loops are formed, and two flare ribbons propagating in opposite directions appear on the outskirts of the former ribbons, indicating that the twist of the flux rope is transferred to a much larger system. These results imply that the external reconnection between the rising flux rope and the large-scale overlying loops plays an important role in the confined flare formation. **26 January 2019**

Observational Evidence of Magnetic Reconnection Associated with Magnetic Flux Cancellation

Bo **Yang**1,2,3, Jiayan Yang1,2, Yi Bi1,2, Junchao Hong1,2, Haidong Li1,2, Zhe Xu1,2,4, and Hechao Chen
2018 ApJ 861 135 DOI 10.3847/1538-4357/aac37f

Using high spatial and temporal data from the Solar Dynamics Observatory (SDO) and the Interface Region Imaging Spectrograph (IRIS), several observational signatures of magnetic reconnection in the course of magnetic flux cancellation are presented, including two loop–loop interaction processes, multiple plasma blob ejections, and a sheet-like structure that appeared above the flux cancellation sites with a Y-shaped and an inverted Y-shaped end. The IRIS 1400 Å observations show that the plasma blobs were ejected from the tip of the Y-shaped ends of the sheet-like structure. Obvious photospheric magnetic flux cancellation occurred after the first loop–loop interaction and continued until the end of the observation. Complemented by the nonlinear force-free field extrapolation, we found that two sets of magnetic field lines, which revealed an X-shaped configuration, aligned well with the interacted coronal loops. Moreover, a magnetic null point was found to be situated at about 0.9 Mm height, which was right above the flux cancellation sites and located between the two sets of magnetic field lines. These results suggest that the flux cancellation might be a result of the submergence of magnetic field lines following a magnetic reconnection that occurs in the lower atmosphere of the Sun, and the ejected plasma blobs should be plasmoids created in the sheet-like structure due to the tearing-mode instability. This observation reveals a detailed magnetic field structure and a dynamic process above the flux cancellation sites and will help us to understand magnetic reconnection in the lower atmosphere of the Sun.

Mini-filament Eruptions Triggering Confined Solar Flares Observed by ONSET and SDO

Shuhong **Yang**, Jun Zhang
ApJL **2018**
https://arxiv.org/pdf/1806.01763.pdf

Using the observations from the Optical and Near-infrared Solar Eruption Tracer and the Solar Dynamics Observatory, we study an M5.7 flare in AR 11476 on **2012 May 10** and a micro-flare in the quiet Sun on **2017 March 23**. Before the onset of each flare, there is a reverse S-shaped filament above the polarity inversion line. Then the filaments become unstable and begin to rise. The rising filaments gain the upper hand over the tension force of the dome-like overlying loops and thus successfully erupt outward. The footpoints of the reconnecting overlying loops successively brighten and are observed as two flare ribbons, while the newly formed low-lying loops appear as the post-flare loops. These eruptions are similar to the classical model of successful filament eruptions associated with coronal mass ejections. However, the erupting filaments in this study move along large-scale lines and eventually reach the remote solar surface, i.e., no filament material is ejected into the interplanetary space. Thus both the flares are confined ones. These results reveal that some successful filament eruptions can trigger confined flares. Our observations also imply that this kind of filament eruptions may be ubiquitous on the Sun, from active regions with large flares to the quiet Sun with micro-flares.

Automated Solar Flare Detection and Feature Extraction in High-Resolution and Full-Disk H αα Images

Meng **Yang**, Yu Tian, Yangyi Liu, Changhui Rao
Solar Physics May **2018**, 293:81
https://link.springer.com/content/pdf/10.1007%2Fs11207-018-1300-y.pdf

In this article, an automated solar flare detection method applied to both full-disk and local high-resolution Hαα images is proposed. An adaptive gray threshold and an area threshold are used to segment the flare region. Features of each detected flare event are extracted, e.g. the start, peak, and end time, the importance class, and the brightness class. Experimental results have verified that the proposed method can obtain more stable and accurate segmentation results than previous works on full-disk images from Big Bear Solar Observatory (BBSO) and Kanzelhöhe Observatory for Solar and Environmental Research (KSO), and satisfying segmentation results on high-resolution images from the Goode Solar Telescope (GST). Moreover, the extracted flare features correlate well with the data given by KSO. The method may be able to implement a more complicated statistical analysis of Hαα solar flares.

Observationally quantified reconnection providing a viable mechanism for active region coronal heating

Kai E. **Yang**, Dana W. Longcope, M. D. Ding, Yang Guo
2018
https://arxiv.org/pdf/1802.06206.pdf

The heating of the Sun's corona has been explained by several different mechanisms including wave dissipation and magnetic reconnection. While both have been shown capable of supplying the requisite power, neither has been used in a quantitative model of observations fed by measured inputs. Here we show that impulsive reconnection is capable of producing an active region corona agreeing both qualitatively and quantitatively with extreme-ultraviolet observations. We calculate the heating power proportional to the velocity difference between magnetic footpoints and the photospheric plasma, called the non-ideal velocity. The length scale of flux elements reconnected in the corona is found to be around 160 km. The differential emission measure of the model corona agrees with that derived using multi-wavelength images. Synthesized extreme-ultraviolet images resemble observations both in their loop-dominated appearance and their intensity histograms. This work provides compelling evidence that impulsive reconnection events are a viable mechanism for heating the corona.

Block-induced complex structures building the flare-productive solar active region 12673

Shuhong **Yang**, Jun Zhang, Xiaoshuai Zhu, Qiao Song
ApJL **849** L21 **2017**
https://arxiv.org/pdf/1710.06545.pdf
http://sci-hub.tw/10.3847/2041-8213/aa9476
Solar active region (AR) 12673 produced 4 X-class, 27 M-class, and numerous lower class flares during its passage across the visible solar disk in **September 2017**. Our study is to answer the questions why this AR was so flare-productive and how the X9.3 flare, the largest one of the last decade, took place. We find that there was a sunspot in the initial several days, and then two bipolar regions emerged nearby it successively. Due to the standing of the pre-existing sunspot, the movement of the bipoles was blocked, while the pre-existing sunspot maintained its quasi-circular shaped umbra only with the disappearance of a part of penumbra. Thus, the bipolar patches were significantly distorted, and the opposite polarities formed two semi-circular shaped structures. After that, two sequences of new bipolar regions emerged within the narrow semi-circular zone, and the bipolar patches separated along the curved channel. The new bipoles sheared and interacted with the previous ones, forming a complex topological system, during which numerous flares occurred. At the highly sheared region, a great deal of free energy was accumulated. On **September 6,** one negative patch near the polarity inversion line began to rapidly rotate and shear with the surrounding positive fields, and consequently the X9.3 flare erupted. Our results reveal that the block-induced complex structures built the flare-productive AR and the X9.3 flare was triggered by an erupting filament due to the kink instability. To better illustrate this process, a block-induced eruption model is proposed for the first time.

A STATISTICAL STUDY OF FLARE PRODUCTIVITY ASSOCIATED WITH SUNSPOT PROPERTIES IN DIFFERENT MAGNETIC TYPES OF ACTIVE REGIONS

Ya-Hui **Yang**1, Min-Shiu Hsieh2, Hsiu-Shan Yu3, and P. F. Chen4
2017 ApJ 834 150 **File**
http://sci-hub.cc/doi/10.3847/1538-4357/834/2/150
It is often believed that intense flares preferentially originate from the large-size active regions (ARs) with strong magnetic fields and complex magnetic configurations. This work investigates the dependence of flare activity on the AR properties and clarifies the influence of AR magnetic parameters on the flare productivity, based on two data sets of daily sunspot and flare information as well as the GOES soft X-ray measurements and HMI vector magnetograms. By considering the evolution of magnetic complexity, we find that flare behaviors are quite different in the short- and long-lived complex ARs and the ARs with more complex magnetic configurations are likely to host more impulsive and intense flares. Furthermore, we investigate several magnetic quantities and perform the two-sample Kolmogorov–Smirnov test to examine the similarity/difference between two populations in different types of ARs. Our results demonstrate that the total source field strength on the photosphere has a good correlation with the flare activity in complex ARs. It is noted that intense flares tend to occur at the regions of strong source field in combination with an intermediate field-weighted shear angle. This result implies that the magnetic free energy provided by a complex AR could be high enough to trigger a flare eruption even with a moderate magnetic shear on the photosphere. We thus suggest that the magnetic free energy represented by the source field rather than the photospheric magnetic complexity is a better quantity to characterize the flare productivity of an AR, especially for the occurrence of intense flares.

OBSERVATIONS OF THE GROWTH OF AN ACTIVE REGION FILAMENT

Bo **Yang**1,2, Yunchun Jiang1, Jiayan Yang1, Yi Bi1,2, and Haidong Li
2016 ApJ 830 16
We present observations of the growth of an active region filament caused by magnetic interactions among the filament and its adjacent superpenumbral filament (SF) and dark thread-like structures (T). Multistep reconnections are identified during the whole growing process. Magnetic flux convergence and cancellation occurring at the positive footpoint region of the filament is the first step reconnection, which resulted in the filament bifurcating into two sets of intertwined threads. One set anchored in situ, while the other set moved toward and interacted with the SF and part of T.

This indicates the second step reconnection, which gave rise to the disappearance of the SF and the formation of a long thread-like structure that connects the far ends of the filament and T. The long thread-like structure further interacted with the T and then separated into two parts, representing the third step reconnection. Finally, another similar long thread-like structure, which intertwined with the fixed filament threads, appeared. H α observations show that this twisted structure is a longer sinistral filament. Based on the observed photospheric vector magnetograms, we performed a non-linear force-free field extrapolation to reconstruct the magnetic fields above the photosphere and found that the coronal magnetic field lines associated with the filament consists of two twisted flux ropes winding around each other. These results suggest that magnetic interactions among filaments and their adjacent SFs and T could lead to the growth of the filaments, and the filament is probably supported in a flux rope.

Quantifying the Topology and Evolution of a Magnetic Flux Rope Associated with Multi-flare Activities

Kai **Yang**, Yang Guo, M. D. Ding
ApJ **824** 148 **2016**
http://arxiv.org/pdf/1604.07502v1.pdf
Magnetic flux rope (MFR) plays an important role in solar activities. A quantitative assessment of the topology of an MFR and its evolution is crucial for a better understanding of the relationship between the MFR and the associated activities. In this paper, we investigate the magnetic field of active region 12017 from **2014 March 28 to 29**, where 12 flares were triggered by the intermittent eruptions of a filament (either successful or confined). Using the vector magnetic field data from the Helioseismic and Magnetic Imager on board the \textit{Solar Dynamics Observatory}, we calculate the magnetic energy and helicity injection in the active region, and extrapolate the 3D magnetic field with a nonlinear force-free field model. From the extrapolations, we find an MFR that is cospatial with the filament. We further determine the configuration of this MFR by a closed quasi-separatrix layer (QSL) around it. Then, we calculate the twist number and the magnetic helicity for the field lines composing the MFR. The results show that the closed QSL structure surrounding the MFR gets smaller as a consequence of the flare occurrence. We also find that the flares in our sample are mainly triggered by kink instability. Moreover, the twist number varies more sensitively than other parameters to the occurrence of flares.

On the 2012 October 23 circular ribbon flare: emission features and magnetic topology

Kai **Yang**, Yang Guo, M. D. Ding
2015 *ApJ* **806** 171
http://arxiv.org/pdf/1505.02914v1.pdf
Circular ribbon flares are usually related to spine-fan type magnetic topology containing null-points. In this paper, we investigate an X-class circular ribbon flare on 2012 October 23, using the multi-wavelength data from the \textit{Solar Dynamics Observatory}, \textit{Hinode}, and the \textit{Ramaty High Energy Solar Spectroscopic Imager}. In \ion{Ca}{2} H emission, the flare showed three ribbons with two highly elongated ones inside and outside a quasi-circular one, respectively. A hot channel was displayed in the extreme ultraviolet (EUV) emissions that infers the existence of a magnetic flux rope. Two hard X-ray (HXR) sources in the 12--25 keV energy band were located at the footpoints of this hot channel. Using a nonlinear force-free magnetic field extrapolation, we identify three topological structures: (1) a 3D null-point, (2) a flux rope below the fan of the null-point, and (3) a large-scale quasi-separatrix layers (QSL) induced by the quadrupolar-like magnetic field of the active region. We find that the null-point is embedded within the large-scale QSL. In our case, all three identified topological structures must be considered to explain all the emission features associated with the observed flare. Besides, the HXR sources are regarded as the consequence of the reconnection within or near the border of the flux rope.

Magnetic reconnection between small-scale loops observed with the New Vacuum Solar Telescope

Shuhong **Yang**, Jun Zhang, and Yongyuan Xiang
ApJL, **798** L11 **2015**.
Animations: http://ourstar.bao.ac.cn/~shuhongyang/files/apjl_reconnection/
Using the high tempo-spatial resolution H α images observed with the New Vacuum Solar Telescope, we report the solid observational evidence of magnetic reconnection between two sets of small-scale anti-parallel loops with an X-shaped topology. The reconnection process contains two steps: a slow step with the duration of more than several tens of minutes, and a rapid step lasting for only about three minutes. During the slow reconnection, two sets of anti-parallel loops reconnect gradually, and new loops are formed and stacked together. During the rapid reconnection, the anti-parallel loops approach each other quickly, and then the rapid reconnection takes place, resulting in the disappearance of former loops. In the meantime, new loops are formed and separate. The region between the approaching loops is brightened, and the thickness and length of this region are determined to be about 420 km and 1.4 Mm, respectively. During the rapid reconnection process, obvious brightenings at the reconnection site and apparent material ejections

outward along reconnected loops are observed. These observed signatures are consistent with predictions by reconnection models. We suggest that the successive slow reconnection changes the conditions around the reconnection site and triggers instabilities, thus leading to the rapid approach of the anti-parallel loops and resulting in the rapid reconnection. **2014 February 3,**

Fine Structures and Overlying Loops of Confined Solar Flares

Shuhong **Yang**, Jun Zhang, and Yongyuan Xiang
ApL, 793 L28 **2014**
http://arxiv.org/pdf/1412.1314v1.pdf
http://arxiv.org/pdf/1409.0471v1.pdf
Using the H$ α observations from the New Vacuum Solar Telescope at Fuxian Solar Observatory, we focus on the fine structures of three confined flares and the issue why all the three flares are confined instead of eruptive. All the three confined flares take place successively at the same location and have similar morphologies, so can be termed homologous confined flares. In the simultaneous images obtained by the Solar Dynamics Observatory, many large-scale coronal loops above the confined flares are clearly observed in multi-wavelengths. At the pre-flare stage, two dipoles emerge near the negative sunspot, and the dipolar patches are connected by small loops appearing as arch-shaped H$ α fibrils. There exists a reconnection between the small loops, and thus the H$ α fibrils change their configuration. The reconnection also occurs between a set of emerging H$ α fibrils and a set of pre-existing large loops, which are rooted in the negative sunspot, a nearby positive patch, and some remote positive faculae, forming a typical three-legged structure. During the flare processes, the overlying loops, some of which are tracked by activated dark materials, do not break out. These direct observations may illustrate the physical mechanism of confined flares, i.e., magnetic reconnection between the emerging loops and the pre-existing loops triggers flares and the overlying loops prevent the flares from being eruptive. 2013 October 12

Magnetic-Reconnection Generated Shock Waves as a Driver of Surges

Heesu **Yang**, Jongchul Chae , Eun-Kyung Lim, Kyoung-Sun Lee , Hyungmin Park , Dong-uk Song , Kyuhyoun Cho
E-print, April **2014**; ApJL
http://astro.snu.ac.kr/~yang/ms_hsyang.pdf
We found that a surge consists of multiple shock features. In our high spatio-temporal spectroscopic observation of the surge using Fast Imaging Solar Spectrograph of the 1.6 meter New Solar Telescope at Big Bear Solar Observatory, each shock is identified with the sudden appearance of an absorption feature at the blue wings of the Ca II 8542 ? line and Hα line that gradually shifts to the red wings. The shock features are overlapped with one another with an time interval of 110 s, which is much shorter than the duration of each shock feature 300 - 400 s. This finding suggests that the multiple shocks may not have been originated from a train of sinusoidal waves generated by oscillations and flows in the photosphere. As we found the signature of the magnetic flux cancellations at the base of the surge, we conclude that the multiple shock waves in charge of the surge were generated by the magnetic reconnection in the low atmosphere associated with the flux cancellation.

Characteristics of the Photospheric Magnetic Field Associated with Solar Flare Initiation

Ya-Hui **Yang**1, P. F. Chen2, Min-Shiu Hsieh3, S. T. Wu4, Han He5, and Tsung-Che Tsa
2014 ApJ 786 72
The physical environment governing the solar flare initiation is not fully understood, although there are significant efforts to address the relationship between magnetic non-potential parameters and early flare signatures. In this study, we attempt to characterize the flare initiation based on the processed Helioseismic and Magnetic Imager vector magnetograms, Atmospheric Imaging Assembly 1600 Å, and RHESSI hard X-ray observations. Three flare events, the M6.6 flare on **2011 February 13**, the X2.2 flare on **2011 February 15**, and the X2.1 flare on **2011 September 6**, in two active regions AR 11158 and AR 11283 are investigated. We analyze the source field strength in the photosphere, which is defined as the magnitude of the observed magnetic field deviation from the potential field. It is found that one of the strong source field regions above the magnetic polarity inversion line well connects the initial bright kernels of two conjugate ribbons. The results imply that the distribution of the photospheric source field strength can be used to locate the initiation site of flaring loops regardless of the configuration of pre-flare magnetic fields or the evolution of active regions. Moreover, the field configuration in the strong source field regions tends to become more inclined after flares, which is consistent with the coronal implosion scenario. We also employ a fast method to derive the total current density from the photospheric vector magnetogram in the framework of force-free field. This method can provide fast

estimation of photospheric current density within a reasonable accuracy without appealing for the more accurate calculation from a model extrapolation.

Properties of Solar Ephemeral Regions at the Emergence Stage

Shuhong **Yang**, Jun Zhang
E-print, Dec **2013**; ApJ
For the first time, we statistically study the properties of ephemeral regions (ERs) and quantitatively determine their parameters at the emergence stage based on a sample of 2988 ERs observed by the Solar Dynamics Observatory. During the emergence process, there are three kinds of kinematic performances, i.e., separation of dipolar patches, shift of ER's magnetic centroid, and rotation of ER's axis. The average emergence duration, flux emergence rate, separation velocity, shift velocity, and angular speed are 49.3 min, 2.6 ? 10^15 Mx s^−1, 1.1 km s^−1, 0.9 km s^−1, and 0degr.6 min^−1, respectively. At the end of emergence, the mean magnetic flux, separation distance, shift distance, and rotation angle are 9.3 ? 10^18 Mx, 4.7 Mm, 1.1 Mm, and 12degr.9, respectively. We also find that the higher the ER magnetic flux is, (1) the longer the emergence lasts, (2) the higher the flux emergence rate is, (3) the further the two polarities separate, (4) the lower the separation velocity is, (5) the larger the shift distance is, (6) the slower the ER shifts, and (7) the lower the rotation speed is. However, the rotation angle seems not to depend on the magnetic flux. Not only at the start time, but also at the end time, the ERs are randomly oriented in both the northern and the southern hemispheres. Besides, neither the anticlockwise rotated ERs, nor the clockwise rotated ones dominate the northern or the southern hemisphere.

Hard X-ray Footpoint Asymmetry

Ya-Hui **YANG**
RHESSI Science Nugget, No. 212, Nov **2013**
http://sprg.ssl.berkeley.edu/~tohban/wiki/index.php/Hard_X-ray_Footpoint_Asymmetry
Our statistical results show that 75% of the strong HXR footpoints coincide with the weaker magnetic field strengths, which is qualitatively consistent with the prediction of an asymmetric magnetic mirror scenario. Even so, it must be emphasized that the properties of HXR footpoint asymmetry are also affected by other transport effects and coronal acceleration process besides the asymmetric magnetic mirror. It is difficult to attribute the footpoint asymmetry purely to a single effect for solar flares. It would be worthwhile to investigate further the causes of footpoint asymmetry reversal during different flaring periods or between different energy ranges.

Magnetic Nonpotentiality in Photospheric Active Regions as a Predictor of Solar Flares

Xiao **Yang**, GangHua Lin, HongQi Zhang, XinJie Mao
E-print, Aug **2013**, **2013** ApJ 774 L27
Based on several magnetic nonpotentiality parameters obtained from the vector photospheric active region magnetograms obtained with the Solar Magnetic Field Telescope at the Huairou Solar Observing Station over two solar cycles, a machine learning model has been constructed to predict the occurrence of flares in the corresponding active region within a certain time window. The Support Vector Classifier, a widely used general classifier, is applied to build and test the prediction models. Several classical verification measures are adopted to assess the quality of the predictions. We investigate different flare levels within various time windows, and thus it is possible to estimate the rough classes and erupting times of flares for particular active regions. Several combinations of predictors have been tested in the experiments. The True Skill Statistics are higher than 0.36 in 97% of cases and the Heidke Skill Scores range from 0.23 to 0.48. The predictors derived from longitudinal magnetic fields do perform well, however they are less sensitive in predicting large flares. Employing the nonpotentiality predictors from vector fields improves the performance of predicting large flares of magnitude geqM5.0 and geqX1.0.

ASYMMETRY OF HARD X-RAY EMISSIONS AT CONJUGATE FOOTPOINTS IN SOLAR FLARES

Ya-Hui **Yang**1, C. Z. Cheng2,3, Säm Krucker4,5, Min-Shiu Hsieh6, and Nai-Hwa Chen
2012 ApJ 756 42
The chromospheric double hard X-ray (HXR) sources generally appear at the conjugate footpoints of flaring loops with asymmetric flux distributions. The behavior of such HXR footpoint asymmetry should be affected by several effects simultaneously and cannot be attributed to a single effect easily. In this study, we attempt to address the properties of photospheric magnetic fields in the areas coinciding with asymmetric HXR footpoints based on RHESSI observations during 2002-2009. A total of 172 time intervals in 22 flares closed to the solar disk center with available pre-flare MDI magnetograms are investigated. The strong HXR footpoint is found to preferentially (75%) locate at the region with weak magnetic field strength, which is qualitatively consistent with the asymmetric magnetic mirror scenario. The HXR

footpoint fluxes become more asymmetric when the footpoints move to the areas with more asymmetric field strength. A feature of asymmetry reversal between different energy ranges is observed in some flares, although no significant energy dependence of footpoint asymmetry is found in our statistical results. We also investigated the possible causes of time-dependent HXR footpoint asymmetry by examining the **2004 November 4** M5.4 flare and the **2004 November 6** M3.6 flare. By comparing the estimated asymmetry quantities with the HXR light curves, the asymmetry reversal in the late period of the M5.4 flare is mainly attributed to the difference of coronal energy release or acceleration processes in different periods, while it is associated with the location changes of HXR footpoints moving to different magnetic field regions in the M3.6 flare.

A Statistical Study on Photospheric Magnetic Nonpotentiality of Active Regions and Its Relationship with Flares During Solar Cycles 22 - 23

Xiao **Yang**, HongQi Zhang, Yu Gao, Juan Guo and GangHua Lin

E-print, July **2012**, Solar Phys**.** Volume 280, Number 1 (2012), 165-181

A statistical study is carried out on the photospheric magnetic nonpotentiality in solar active regions and its relationship with associated flares. We select 2173 photospheric vector magnetograms from 1106 active regions observed by the Solar Magnetic Field Telescope at Huairou Solar Observing Station, National Astronomical Observatories of China, in the period of 1988 ? 2008, which covers most of the 22nd and 23rd solar cycles. We have computed the mean planar magnetic shear angle (overline{Deltaphi}), mean shear angle of the vector magnetic field (overline{Deltapsi}), mean absolute vertical current density (overline{|Jz|}), mean absolute current helicity density (overline{|hc|}), absolute twist parameter (α av|), mean free magnetic energy density (overline{ hofree}), effective distance of the longitudinal magnetic field (dE), and modified effective distance (dEm) of each photospheric vector magnetogram. Parameters overline{|hc|}, overline{ hofree}, and dEm show higher correlations with the evolution of the solar cycle. The Pearson linear correlation coefficients between these three parameters and the yearly mean sunspot number are all larger than 0.59. Parameters overline{Deltaphi}, overline{Deltapsi}, overline{|Jz|}, α av|, and dE show only weak correlations with the solar cycle, though the nonpotentiality and the complexity of active regions are greater in the activity maximum periods than in the minimum periods. All of the eight parameters show positive correlations with the flare productivity of active regions, and the combination of different nonpotentiality parameters may be effective in predicting the flaring probability of active regions.

ESTIMATION OF THE RECONNECTION ELECTRIC FIELD IN THE 2003 OCTOBER 29 X10 FLARE

Ya-Hui **Yang**1, C. Z. Cheng1,2,3, Säm Krucker4,5 and Min-Shiu

2011 ApJ 732 15

The electric field in the reconnecting current sheet of the 2003 October 29 X10 flare is estimated to be a few kV m–1 in this study, based on the rate of change in the photospheric magnetic flux in the newly brightened areas of Transition Region and Coronal Explorer (TRACE) UV ribbons. For comparison, the motion speed of Reuven Ramaty High Energy Solar Spectroscopic Imager (RHESSI) hard X-ray (HXR) footpoints and the photospheric magnetic field strength are also used for the electric field calculation. This X10 flare event is selected due to its distinct two-phase HXR kernel motion, two arcade systems with different magnetic shear, and the high cadence and complete coverage of the TRACE 1600 Å Michelson Doppler Imager (MDI) magnetogram and RHESSI HXR observations. We pay particular attention to the electric field characteristics in different flare phases, as well as the temporal correlation with the HXR emission and its power-law spectral index and the photospheric magnetic field strength. We found that in the early impulsive phase, the reconnection electric field peaks just before the HXR emission peaks and the energy spectrum hardens. The result is consistent with the scenario that more particles are accelerated to higher energies by larger reconnection electric fields and then precipitate into the lower chromosphere to produce stronger HXR emissions. Such a particle acceleration mechanism plays its most significant role in the impulsive phase of this flare. In addition, our results provide evidence that the highly sheared magnetic field lines are mapped to the magnetic reconnection diffusion region to produce a large reconnection electric field.

Magnetic helicity accumulation and tilt angle evolution of newly emerging active regions

S. **Yang**1, 2, H. Zhang1, and J. Büchner2

A&A 502, 333-340 (**2009**)

DOI: 10.1051/0004-6361/200810032

Context. It has been known for years that there is a general dominance of negative (positive) helicity of active regions (ARs) in the northern (southern) solar hemisphere. For a better understanding of the role of helicity in the evolution of

active regions, it is necessary to know more about the accumulation of helicity during the emergence of active regions. In particular, different conclusions were drawn in the past about the relationship between the accumulated helicity and the writhe of active regions.
Aims. We investigate the accumulation of helicity in newly emerging simple bipolar solar active regions. We also investigate the relation between the accumulated helicity and writhe.
Methods. We obtain helicity accumulation by applying Fast Fourier Transforms (FFT) and local correlation tracking (LCT) to MDI data. We deduce the writhe of the active regions according to the evolution of the tilt angle between the connecting line of the weighting centers of opposite polarities in the ARs.

Results. It is found that the accumulated helicity is proportional to the exponent of magnetic flux $(|H| \propto \Phi^{1.85})$ in the 58 selected newly emerged simple ARs. 74% of ARs have a negative (positive) helicity when the above defined tilt angle rotates clockwise (counter-clockwise). This means that the accumulated helicity and writhe have the same sign for most of the investigated ARs according to the tilt angle evolution of ARs. We also found that 56% (57.6%) of these ARs in the northern (southern) photosphere provide negative (positive) helicity to the corona in the course of the emergence of magnetic flux.

MAGNETIC HELICITY EXCHANGE BETWEEN NEIGHBORING ACTIVE REGIONS

S. **Yang**, J. B¨ uchner2, and H. Zhang1
Astrophysical Journal, 695:L25–L30, **2009** April
http://www.iop.org/EJ/toc/-alert=43192/1538-4357/695/1
Addressing the long-lasting problem of the magnetic helicity distribution in the solar corona, a proof for magnetic helicity exchange between two neighboring emerging active regions (ARs) was found: when AR 9188 emerged, it first started to accumulate positive helicity, while the later neighboring emerging AR 9192 accumulated negative helicity. At a later time, after the bright connecting loops became visible between the two ARs, AR 9188 also suddenly started to gain negative helicity. At the same time AR 9192 started to loose negative helicity. It was found that the magnetic helicity fluxes of the two ARs changed simultaneously by almost the same amount. At one instant it was even possible to determine that the connecting loop between the two ARs carried negative helicity. We excluded the possibility that magnetic flux emergence was causing the observed variation of the magnetic helicity. Hence, magnetic helicity was indeed transferred from the late emerging AR 9192 to AR 9188 via an unbalanced magnetic torque along the loop. Such kinds of helicity transfer might be a common mechanism of redistribution of magnetic helicity in the solar atmosphere, which has just not been widely observed yet.

A STATISTICAL STUDY OF HARD X-RAY FOOTPOINT MOTIONS IN LARGE SOLAR FLARES

Ya-Hui **Yang**1, C. Z. Cheng1,2, S¨am Krucker3, R. P. Lin3,4, andW. H. Ip
Astrophysical Journal, 693:132–139, **2009** March 1
A statistical analysis of the temporal evolution of hard X-ray (HXR) footpoint motions in 27 M- and X-class solar flares observed by the Reuven Ramaty High Energy Solar Spectroscopic Imager is presented. Extreme UV images from TRACE and SOHO/EIT, Hα images, and magnetograms from SOHO/MDI are used to put the HXR footpoint motions in context of flare ribbons and the magnetic neutral line. Footpoint motions are often found to be complex making a statistical analysis difficult. In an attempt to simplify the analysis, each event was searched for motions predominantly parallel and predominantly perpendicular to the neutral line or flare ribbons. Four kinds of complex motions are described and their relationships to the possible magnetic reconnection processes are discussed. In the soft X-ray (SXR) rise phase, motions along the neutral line or flare ribbons are most common (20 out of 27) and only two events show perpendicular motions (for the remaining five events a simple classification was not possible). However, at later times around the SXR peak, perpendicular motion is more frequently observed (~ 40%) than motions along the neutral line or ribbons ~ 27%). The preference of HXR kernels appearing at the footpoints of highly-sheared magnetic loops at the start of the SXR rise phase is consistent with the magnetic reconnection theory that the reconnection occurring at sheared magnetic arcade field lines produces most HXR energy release in the impulsive phase of large flares.

Widespread Occurrence of High-Velocity Upflows in Solar Active Regions

S. L. **Yardley**, D. H. Brooks, D. Baker
A&A 650, L10 **2021**
https://arxiv.org/pdf/2106.01396.pdf
https://www.aanda.org/articles/aa/pdf/2021/06/aa41131-21.pdf
https://doi.org/10.1051/0004-6361/202141131

We performed a systematic study of 12 active regions (ARs) with a broad range of areas, magnetic flux and associated solar activity in order to determine whether there are upflows present at the AR boundaries and if these upflows exist, whether there is a high speed asymmetric blue wing component present in the upflows. To identify the presence and locations of the AR upflows we derive relative Doppler velocity maps by fitting a Gaussian function to {\it Hinode}/EIS Fe XII 192.394\,Å line profiles. To determine whether there is a high speed asymmetric component present in the AR upflows we fit a double Gaussian function to the Fe XII 192.394\,Å mean spectrum that is computed in a region of interest situated in the AR upflows. Upflows are observed at both the east and west boundaries of all ARs in our sample with average upflow velocities ranging between -5 to -26~km s−1. A blue wing asymmetry is present in every line profile. The intensity ratio between the minor high speed asymmetric Gaussian component compared to the main component is relatively small for the majority of regions however, in a minority of cases (8/30) the ratios are large and range between 20 to 56~\%. These results suggest that upflows and the high speed asymmetric blue wing component are a common feature of all ARs. **31 Jan 2011, 15 Apr 2011**

A Comparative Study of Confined and Eruptive Solar Flares using Microwave Observations

Yashiro, S.; Akiyama, S.; Masuda, S.; Shimojo, M.; Asai, A.; Imada, S.; Gopalswamy, N.
American Geophysical Union, Fall Meeting **2015**, **abstract** #SH43B-2447
It is well known that about 10% X-class solar flares are not associated with coronal mass ejections (CMEs). These flares are referred to as confined flares, which are not associated with mass or energetic particles leaving the Sun. However, electrons are accelerated to MeV energies as indicated by the presence of microwave emission with a turnover frequency of ~15 GHz (Gopalswamy et al. 2009, IAU Symposium 257, p. 283). In this paper, we extend the study of confined flares to lower soft X-ray flare sizes (M and above) that occurred in the time window of the Nobeyama Radioheliograph (NoRH). We also make use of the microwave spectral information from the Nobeyama Radio Polarimeters (NoRP). During 1996 - 2014, NoRH and NoRP observed 663 flares with size M1.0 or larger. Using the CME observations made by SOHO/LASCO and STEREO/SECCHI, we found 215 flares with definite CME association (eruptive flares) and 202 flares that definitely lacked CMEs (confined flares). The remaining 146 flares whose CME association is unclear are excluded from the analysis. We examined the peak brightness temperature and the spatial size obtained by NoRH. Although there is a large overlap between the two populations in these properties, we found that microwave sources with the largest spatial extent and highest brightness temperature are associated with eruptive flares. Spectral analysis using NoRP data showed a tendency that more confined flares had higher turnover frequency (≥17 GHz). We also compare the NoRH images with the photospheric magnetograms to understand the difference in the magnetic structure of the two types of flare sources.

Three-dimensional simulation of thermodynamics on confined turbulence in a large-scale CME-flare current sheet

Jing **Ye**, John C. Raymond, Zhixing Mei, Qiangwei Cai, Yuhao Chen, Yan Li, Jun Lin
ApJ **2023**
https://arxiv.org/pdf/2308.09496.pdf
Turbulence plays a key role for forming the complex geometry of the large-scale current sheet (CS) and fast energy release in a solar eruption. In this paper, we present full 3D high-resolution simulations for the process of a moderate Coronal Mass Ejection (CME) and the thermodynamical evolution of the highly confined CS. Copious elongated blobs are generated due to tearing and plasmoid instabilities giving rise to a higher reconnection rate and undergo the splitting, merging and kinking processes in a more complex way in 3D. A detailed thermodynamical analysis shows that the CS is mainly heated by adiabatic and numerical viscous terms, and thermal conduction is the dominant factor that balances the energy inside the CS. Accordingly, the temperature of the CS reaches to a maximum of about 20 MK and the range of temperatures is relatively narrow. From the face-on view in the synthetic Atmospheric Imaging Assembly 131 A˚, the downflowing structures with similar morphology to supra-arcade downflows are mainly located between the post-flare loops and loop-top, while moving blobs can extend spikes higher above the loop-top. The downward-moving plasmoids can keep the twisted magnetic field configuration until the annihilation at the flare loop-top, indicating that plasmoid reconnection dominates in the lower CS. Meanwhile, the upward-moving ones turn into turbulent structures before arriving at the bottom of the CME, implying that turbulent reconnection dominates in the upper CS. The spatial distributions of the turbulent energy and anisotropy are addressed, which show a significant variation in the spectra with height.

Detailed analysis of dynamic evolution of three Active Regions before flare and CME occurrence at the photospheric level

Yudong **Ye**, M. B. Korsos, R. Erdelyi
Advances in Space Research Volume 61, Issue 2, 15 January **2018**, Pages 673-682
https://arxiv.org/pdf/1801.00430.pdf
We present a combined analysis of the applications of the weighted horizontal magnetic gradient (denoted as WG_M in Korsos et al., ApJ, 802, L21, 2015) method and the magnetic helicity tool (Berger & Field, JFM, 147, 133, 1984)

employed for three active regions (ARs), namely NOAA AR11261, AR11283 and AR11429. All three active regions produced series flares and CMEs. We followed the evolution of the components of the WG_M and the magnetic helicity before the flare and CME occurrences. We found an unique and mutually shared behavior, called the U-shaped pattern, of the weighted distance component of WG_M and of the shearing component of the helicity flux before the flare and CME eruptions. This common pattern is associated with the decreasing-receding phase yet reported only known to be a necessary feature prior to solar flare eruption(s), but found now at the same time in the evolution of the shearing helicity parameter. This result leads to the conclusion that (i) the shearing motion of photospheric magnetic field may be a key driver for the solar eruption in addition to the flux emerging process, and that (ii) the found decreasing-approaching pattern in the evolution of shearing helicity may be another precursor indicator for improving the forecasting of solar eruptions. **30/07/-04/08/ 2011, 06-09/09/2011, 05-10/03/2012**

Irreversible Rapid Changes of Magnetic Field Associated with the 2012 October 23 Circular Near-limb X1.8 Flare

Dandan **Ye**, Chang Liu, Haimin Wang
Research in Astronomy and Astrophysics **(**RAA) **2016**
http://arxiv.org/pdf/1602.02080v1.pdf
It has been found that photospheric magnetic fields can change in accordance with the three-dimensional magnetic field restructuring following solar eruptions. Previous studies mainly use vector magnetic field data taken for events near the disk center. In this paper, we analyze the magnetic field evolution associated with the 2012 October 23 X1.8 flare in NOAA AR 11598 that is close to the solar limb, using both the 45 s cadence line-of-sight and 12 minute cadence vector magnetograms from the Helioseismic and Magnetic Imager on board Solar Dynamic Observatory. This flare is classified as a circular-ribbon flare with spine-fan type magnetic topology containing a null point. In the line-of-sight magnetograms, there are two apparent polarity inversion lines (PIL). The PIL closer to the limb is affected more by the projection effect. Between these two PILs there lie positive polarity magnetic fields, which are surrounded by negative polarity fields outside the PILs. We find that after the flare, both the apparent limb-ward and disk-ward negative fluxes decrease, while the positive flux in-between increases. We also find that the horizontal magnetic fields have a significant increase along the disk-ward PIL, while in surrounding area, they decrease. Synthesizing the observed field changes, we conclude that the magnetic fields collapse toward the surface above the disk-ward PIL as depicted in the coronal implosion scenario, while the peripheral field turns to a more vertical configuration after the flare. We also suggest that this event is an asymmetric circular-ribbon flare: a flux rope is likely present above the disk-ward PIL. Its eruption causes the instability of the entire fan-spine structure and the implosion near that PIL.

Automated Driving for Global Nonpotential Simulations of the Solar Corona

Anthony R. **Yeates**1 and Prantika Bhowmik1
2022 ApJ 935 13
https://iopscience.iop.org/article/10.3847/1538-4357/ac7de4/pdf
We describe a new automated technique for active region emergence in coronal magnetic field models, based on the inversion of the electric field locally from a single line-of-sight magnetogram for each region. The technique preserves the arbitrary shapes of magnetic field distribution associated with individual active regions and incorporates emerging magnetic helicity (twist) in a parametrized manner through a noninductive electric field component. We test the technique with global magnetofrictional simulations of the coronal magnetic field during Solar Cycle 24 Maximum from 2011 June 1 to 2011 December 31. The active regions are determined in a fully automated and objective way using Spaceweather HMI Active Region Patch (SHARP) data. Our primary aim is to constrain two free parameters in the emergence algorithm: the duration of emergence and the twist parameter for each individual active region. While the duration has a limited effect on the resulting coronal magnetic field, changing the sign and amplitude of the twist parameters profoundly influences the amount of nonpotentiality generated in the global coronal magnetic field. We explore the possibility of constraining both the magnitude and sign of the twist parameter using estimates of the current helicity derived from vector magnetograms and supplied in the SHARP metadata for each region. Using the observed sign of twist for each region reduces the overall nonpotentiality in the corona, highlighting the importance of scatter in the emerging active region helicities. **17 Nov 2012**

Modulational Instability of Fast Sausage Mode as One of the Possible Mechanisms for Quasiperiodic Pulsations during Solar Flares

Naga Varun **Yelagandula**1
2021 ApJ 923 131
https://iopscience.iop.org/article/10.3847/1538-4357/ac2e07/pdf
https://doi.org/10.3847/1538-4357/ac2e07
Quasiperiodic pulsations (QPPs) are frequently observed in the entire range of the electromagnetic spectrum during solar flares, and there can be many possible mechanisms leading to this phenomenon. In the present work, we demonstrate the possibility of the generation of QPPs by a nonlinear fast sausage mode in a coronal loop. The coronal loop itself is represented by an infinitely long homogenous magnetic flux tube, which in many cases is a good

approximation, and the nonlinearity of the fast sausage mode is modeled by the nonlinear Schrödinger equation (NSE) with a cubic nonlinearity. We have shown that the frequency-renormalized plane wave solution, which happens to be an exact solution of the NSE, transforms into a series of quasiperiodic oscillations (QPOs) due to the so-called modulational instability or the Benjamin–Feir instability. Our numerical solutions show that such QPOs evolve at almost every point above a certain height along the magnetic flux tube, which represents the coronal loop. As the fast sausage mode perturbs the plasma density strongly, the density perturbations caused by the QPOs of the nonlinear fast sausage mode correspondingly modulate the radiation throughout the electromagnetic spectrum, resulting in the emergence of the corresponding QPPs. This mechanism should therefore be able to describe some of the observed QPPs.

Feature Selection on a Flare Forecasting Testbed: A Comparative Study of 24 Methods

Atharv **Yeoleka**, Sagar Patel, Shreejaa Talla, Krishna Rukmini Puthucode, Azim Ahmadzadeh, Viacheslav M. Sadykov, Rafal A. Angryk

IEEE ICDM 2021, SFE-TSDM Workshop **2021**

https://arxiv.org/pdf/2109.14770.pdf

The Space-Weather ANalytics for Solar Flares (SWAN-SF) is a multivariate time series benchmark dataset recently created to serve the heliophysics community as a testbed for solar flare forecasting models. SWAN-SF contains 54 unique features, with 24 quantitative features computed from the photospheric magnetic field maps of active regions, describing their precedent flare activity. In this study, for the first time, we systematically attacked the problem of quantifying the relevance of these features to the ambitious task of flare forecasting. We implemented an end-to-end pipeline for preprocessing, feature selection, and evaluation phases. We incorporated 24 Feature Subset Selection (FSS) algorithms, including multivariate and univariate, supervised and unsupervised, wrappers and filters. We methodologically compared the results of different FSS algorithms, both on the multivariate time series and vectorized formats, and tested their correlation and reliability, to the extent possible, by using the selected features for flare forecasting on unseen data, in univariate and multivariate fashions. We concluded our investigation with a report of the best FSS methods in terms of their top-k features, and the analysis of the findings. We wish the reproducibility of our study and the availability of the data allow the future attempts be comparable with our findings and themselves.

Application of Deep Reinforcement Learning to Major Solar Flare Forecasting

Kangwoo **Yi**1, Yong-Jae Moon1,2, and Hyun-Jin Jeong2

2023 ApJS 265 34

https://iopscience.iop.org/article/10.3847/1538-4365/acb76d/pdf

In this study, we present the application of deep reinforcement learning to the forecasting of major solar flares. For this, we consider full-disk magnetograms at 00:00 UT from the Solar and Heliospheric Observatory/Michelson Doppler Imager (1996–2010) and the Solar Dynamics Observatory/Helioseismic and Magnetic Imager (2011–2019), as well as Geostationary Operational Environmental Satellite X-ray flare data. We apply Deep Q-Network (DQN) and Double DQN, which are popular deep reinforcement learning methods, to predict "Yes or No" for daily M- and X-class flare occurrence. The reward functions, consisting of four rewards for true positive, false positive, false negative, and true negative, are used for our models. The major results of this study are as follows. First, our deep-learning models successfully predict major solar flares with good skill scores, such as HSS, F1, TSS, and ApSS. Second, the performance of our models depends on the reward function, learning method, and target agent update time. Third, the performance of our deep-learning models is noticeably better than that of a convolutional neural network (CNN) model with the same structure: 0.38 (CNN) to 0.44 (ours) for HSS, 0.47 to 0.52 for F1, 0.53 to 0.59 for TSS, and 0.09 to 0.12 for ApSS.

Visual Explanation of a Deep Learning Solar Flare Forecast Model and Its Relationship to Physical Parameters

Kangwoo **Yi**1, Yong-Jae Moon1,2, Daye Lim2, Eunsu Park2, and Harim Lee2

2021 ApJ 910 8

https://iopscience.iop.org/article/10.3847/1538-4357/abdebe/pdf

https://doi.org/10.3847/1538-4357/abdebe

In this study, we present a visual explanation of a deep learning solar flare forecast model and its relationship to physical parameters of solar active regions (ARs). For this, we use full-disk magnetograms at 00:00 UT from the Solar and Heliospheric Observatory/Michelson Doppler Imager and the Solar Dynamics Observatory/Helioseismic and Magnetic Imager, physical parameters from the Space-weather HMI Active Region Patch (SHARP), and Geostationary Operational Environmental Satellite X-ray flare data. Our deep learning flare forecast model based on the Convolutional Neural Network (CNN) predicts "Yes" or "No" for the daily occurrence of C-, M-, and X-class flares. We interpret the model using two CNN attribution methods (guided backpropagation and Gradient-weighted Class Activation Mapping [Grad-CAM]) that provide quantitative information on explaining the model. We find that our deep learning flare forecasting model is intimately related to AR physical properties that have also been distinguished in previous studies as holding significant predictive ability. Major results of this study are as follows. First, we

successfully apply our deep learning models to the forecast of daily solar flare occurrence with TSS = 0.65, without any preprocessing to extract features from data. Second, using the attribution methods, we find that the polarity inversion line is an important feature for the deep learning flare forecasting model. Third, the ARs with high Grad-CAM values produce more flares than those with low Grad-CAM values. Fourth, nine SHARP parameters such as total unsigned vertical current, total unsigned current helicity, total unsigned flux, and total photospheric magnetic free energy density are well correlated with Grad-CAM values.

Forecast of Major Solar X-Ray Flare Flux Profiles Using Novel Deep Learning Models

Kangwoo **Yi**, Yong-Jae Moon, Gyungin Shin, and Daye Lim
2020 ApJL 890 L5
https://doi.org/10.3847/2041-8213/ab701b
In this Letter, we present the application of a couple of novel deep learning models to the forecast of major solar X-ray flare flux profiles. These models are based on a sequence-to-sequence framework using long short-term memory cell and an attention mechanism. For this, we use Geostationary Operational Environmental Satellite 10 X-ray flux data from 1998 August to 2006 April. Seven hundred sixty events are used for training and 85 for testing. The models forecast 30 minutes of X-ray flux profiles during the rise phase of the solar flare with a minute time cadence. We evaluate the models using the 10-fold cross-validation and rms error (RMSE) based on flux profiles and RMSE based on its peak flux. For comparison we consider two simple deep learning models and four conventional regression models. Major results of this study are as follows. First, we successfully apply our deep learning models to the forecast of solar flare X-ray flux profiles, without any preprocessing to extract features from data. Second, our proposed models outperform the other models. Third, our models achieve better performance for forecasting X-ray flux profiles with low-peak fluxes than those with high-peak fluxes. Fourth, our models successfully predict flare duration with high correlations for both all cases and cases at peak times. Our study indicates that our deep learning models can be useful for forecasting time-series data in astronomy and space weather, even for impulsive events such as major flares.

Formation Mechanism of Soft X-Ray Transient Trans-Equatorial Loop System

Masaki **Yokoyama** · Satoshi Masuda
Solar Phys (**2009**) 254: 285–296
The Soft X-ray Telescope (SXT) onboard *Yohkoh* often observed large-scale coronal loops connecting two active regions situated in opposite hemispheres. These are the trans-equatorial loop systems (TLSs). The formation mechanism of TLSs is not yet known. We analyzed a TLS observed simultaneously with *Yohkoh*/SXT and a coronagraph (SOHO/LASCO-C1). SOHO/LASCO-C1 observed loop expansion and eruption at the west solar limb. *Yohkoh*/SXT observed a rising motion (chromospheric evaporation) of hot and dense plasmas from the active regions located at the footpoints of the loop. Important results of our analyses are that (1) the loop eruption and the rising motion of the plasmas were simultaneous, (2) the TLS had a cusp-like appearance, and (3) the highest temperature region of the TLS was located above the bright loop seen in soft X rays. These observational results (loop expansion, eruption, and chromospheric evaporation) suggest that this bright (high-density) TLS was created by the same mechanism by which a solar flare occurs, namely, magnetic reconnection. In this paper, we propose a formation mechanism of the TLS that forms between two independent active regions. **28-30 May 1998**

The first OPEA model for solar X-ray flares

E **Yoldaş**, H A Dal
MNRAS, Volume 517, Issue 2, December **2022**, Pages 1937–1945,
https://doi.org/10.1093/mnras/stac2814
In this study, the flares detected in the solar hard X-ray (λ0.5–4.0 Å) data accumulated by the Geostationary Operational Environmental Satellite (GOES) from 2001 March–May were analysed. For the first time in the literature, the One Phase Exponential Association (OPEA) model was derived for the Sun and, for the first time, over X-ray data. 1014 flares were detected in the analysis. Contrary to expectations, it was seen that the flares can be modelled with three different OPEA models, not one model. The Plateau value was found to be 5.053 ± 0.110 s with the half-time of 2316.12 s for the flares during 2001 March, while it was 5.676 ± 0.138 s with the half-time of 3967.59 s for 2001 April and 5.338 ± 0.080 s with the half-time of 2755.66 s for 2001 May. The results indicate that the models exhibit a fluctuation in their form time by time. This means that there is a phenomenon that changes the energy of flares obtained in three consecutive months. We also demonstrate that the linear parts of the flare cumulative frequency distributions obtained in these data interestingly show a separation.

The Temperature and Density of a Solar Flare Kernel Measured from Extreme Ultraviolet Lines of O IV

Peter R. **Young**
ApJ **966** 102 **2024**
https://arxiv.org/pdf/2401.12390.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ad37fc/pdf

Previously-unexplored diagnostics of O IV in the extreme ultraviolet region 260-280 A are used to derive a temperature and density for a solar flare kernel observed on **2012 March 9** with the Extreme ultraviolet Imaging Spectrometer on the Hinode satellite. Seven lines from the 2s 2p^2 - 2s 2p 3s transition array between 271.99 and 272.31 A are both temperature and density sensitive relative to the line at 279.93 A. The temperature, T, is constrained with the 268.02/279.93 ratio, giving a value of log (T/K)=5.10 +/- 0.03. The ratio 272.13/279.93 then yields an electron number density, N_e, of log (N_e/cm^-3) = 12.55 with a lower limit of 11.91, and an upper limit of 14.40. The O IV emitting volume is estimated to be 0.4 arcsec (300 km) across. Additional O IV lines at 196, 207 and 260 A are consistent with the derived temperature and density but have larger uncertainties from the radiometric calibration and blending. Density diagnostics of O V and Mg VII from the same spectrum are consistent with a constant pressure of 10^17.0 K cm^-3 through the transition region. The temperature derived from O IV supports recent results that O IV is formed around 0.15 dex lower at high densities compared to standard "zero-density" ionization balance calculations.

A Spectroscopic Measurement of High Velocity Spray Plasma from an M-class Flare and Coronal Mass Ejection

Peter R. **Young**
Adv. Sp. Research Volume 71, Issue 4, 15 February **2023**, Pages 1900-1906
https://arxiv.org/pdf/2204.09542.pdf
https://doi.org/10.1016/j.asr.2022.06.002
Coronal mass ejection spray plasma associated with the M1.5-class flare of **16 February 2011** is found to exhibit a Doppler blue-shift of 850 km/s - the largest value yet reported from ultraviolet (UV) or extreme ultraviolet (EUV) spectroscopy of the solar disk and inner corona. The observation is unusual in that the emission line (Fe XII 193.51 A) is not observed directly, but the Doppler shift is so large that the blue-shifted component appears in a wavelength window at 192.82 A, intended to observe lines of O V, Fe XI and Ca XVII. The Fe XII 195.12 A emission line is used as a proxy for the rest component of 193.51 A. The observation highlights the risks of using narrow wavelength windows for spectrometer observations when observing highly-dynamic solar phenomena. The consequences of large Doppler shifts for ultraviolet solar spectrometers, including the upcoming Multi-slit Solar Explorer (MUSE) mission, are discussed.

Solar Ultraviolet Bursts **Review**

Peter R. **Young**, Hui Tian, Hardi Peter, Robert J. Rutten, Chris J. Nelson, Zhenghua Huang, ...
Space Science Reviews December **2018**, 214:120
https://link.springer.com/content/pdf/10.1007%2Fs11214-018-0551-0.pdf
https://arxiv.org/pdf/1805.05850.pdf
The term "ultraviolet (UV) burst" is introduced to describe small, intense, transient brightenings in ultraviolet images of solar active regions. We inventorize their properties and provide a definition based on image sequences in transition-region lines. Coronal signatures are rare, and most bursts are associated with small-scale, canceling opposite-polarity fields in the photosphere that occur in emerging flux regions, moving magnetic features in sunspot moats, and sunspot light bridges. We also compare UV bursts with similar transition-region phenomena found previously in solar ultraviolet spectrometry and with similar phenomena at optical wavelengths, in particular Ellerman bombs. Akin to the latter, UV bursts are probably small-scale magnetic reconnection events occurring in the low atmosphere, at photospheric and/or chromospheric heights. Their intense emission in lines with optically thin formation gives unique diagnostic opportunities for studying the physics of magnetic reconnection in the low solar atmosphere.

A Si IV/O IV electron density diagnostic for the analysis of IRIS solar spectra

P.R. **Young**, F.P. Keenan, R.O. Milligan, H. Peter
ApJ **2018**
https://arxiv.org/pdf/1803.01721.pdf
Solar spectra of ultraviolet bursts and flare ribbons from the Interface Region Imaging Spectrograph (IRIS) have suggested high electron densities of >1012 cm−3 at transition region temperatures of 0.1 MK, based on large intensity ratios of Si IV λ1402.77 to O IV λ1401.16. In this work a rare observation of the weak O IV λ1343.51 line is reported from an X-class flare that peaked at 21:41 UT on **2014 October 24**. This line is used to develop a theoretical prediction of the Si IV λ1402.77 to O IV λ1401.16 ratio as a function of density that is recommended to be used in the high density regime. The method makes use of new pressure-dependent ionization fractions that take account of the suppression of dielectronic recombination at high densities. It is applied to two sequences of flare kernel observations from the October 24 flare. The first shows densities that vary between 3×1012 to 3×1013 cm−3 over a seven minute period, while the second location shows stable density values of around 2×1012 cm−3 over a three minute period.

The 2014 March 29 X-flare: sub-arcsecond resolution observations of Fe XXI 1354.1

Peter **Young**, Hui Tian, Sarah Jaeggli
ApJ, **799** 218 **2014**
http://arxiv.org/pdf/1409.8603v1.pdf
The Interface Region Imaging Spectrometer (IRIS) is the first solar instrument to observe ~10 MK plasma at subarcsecond spatial resolution through imaging spectroscopy of the Fe XXI 1354.1 forbidden line. IRIS observations of the X1 class flare that occurred on 2014 March 29 at 17:48 UT reveal Fe XXI emission from both the flare ribbons and the post-flare loop arcade. Fe XXI appears at the ribbon locations around 75 seconds after the ribbons appear in the chromospheric continuum, and 1354.1 shows blue-shifts of 100-200 km/s, suggesting hot plasma upflow into the corona. The Fe XXI ribbon emission is compact with a spatial extent of <2", and can extend beyond the chromospheric ribbon locations. Examples are found of both decreasing and increasing blue-shift in the direction away from the ribbon locations, and blue-shifts were present for at least 6 minutes after the flare peak. The post-flare loop arcade, seen in Atmospheric Imaging Assembly (AIA) 131 A filtergram images that are dominated by Fe XXI, exhibited bright loop-tops with an asymmetric intensity distribution. The sizes of the loop-tops are resolved by IRIS at > 1", and line widths in the loop-tops are not broader than in the loop-legs suggesting the loop-tops are not sites of enhanced turbulence. Line-of-sight speeds in the loop arcade are typically <10 km/s, and mean non-thermal motions fall from 43 km/s at the flare peak to 26 km/s six minutes later. If the average velocity in the loop arcade is assumed to be at rest, then it implies a new reference wavelength for the Fe XXI line of 1354.106 +/- 0.023 A.

PROPERTIES OF A SOLAR FLARE KERNEL OBSERVED BY HINODE AND SDO

P. R. **Young**1, G. A. Doschek2, H. P. Warren2, and H. Hara
2013 ApJ 766 127
Flare kernels are compact features located in the solar chromosphere that are the sites of rapid heating and plasma upflow during the rise phase of flares. An example is presented from a M1.1 class flare in active region AR 11158 observed on **2011 February 16** 07:44 UT for which the location of the upflow region seen by EUV Imaging Spectrometer (EIS) can be precisely aligned to high spatial resolution images obtained by the Atmospheric Imaging Assembly (AIA) and Helioseismic and Magnetic Imager (HMI) on board the Solar Dynamics Observatory (SDO). A string of bright flare kernels is found to be aligned with a ridge of strong magnetic field, and one kernel site is highlighted for which an upflow speed of 400 km s–1 is measured in lines formed at 10-30 MK. The line-of-sight magnetic field strength at this location is 1000 G. Emission over a continuous range of temperatures down to the chromosphere is found, and the kernels have a similar morphology at all temperatures and are spatially coincident with sizes at the resolution limit of the AIA instrument (400 km). For temperatures of 0.3-3.0 MK the EIS emission lines show multiple velocity components, with the dominant component becoming more blueshifted with temperature from a redshift of 35 km s–1 at 0.3 MK to a blueshift of 60 km s–1 at 3.0 MK. Emission lines from 1.5-3.0 MK show a weak redshifted component at around 60-70 km s–1 implying multi-directional flows at the kernel site. Significant non-thermal broadening corresponding to velocities of 120 km s–1 is found at 10-30 MK, and the electron density in the kernel, measured at 2 MK, is 3.4 × 1010 cm–3. Finally, the Fe XXIV λ192.03/λ255.11 ratio suggests that the EIS calibration has changed since launch, with the long wavelength channel less sensitive than the short wavelength channel by around a factor two.

High-precision density measurements in the solar corona - I.=Analysis methods and results for Fe XII and Fe XIII:

P. R.**Young**, T.Watanabe, H.Hara and J. T.Mariska
A&A 495 (**2009**) 587-606
Aims. The EUV Imaging Spectrometer (EIS) instrument on board the Hinode satellite has access to some of the best coronal density diagnostics, and the high sensitivity of the instrument now allows electron number density, N_e, measurements to an unprecedented precision of up to $\pm$5% in active regions. This paper gives a thorough overview of data analysis issues for the best diagnostics of Fe XII and Fe XIII and assesses the accuracy of the measurements. Methods. Two density diagnostics each from Fe XII (λ186.88/λ195.12 and λ196.64/λ195.12) and Fe XIII (λ196.54/λ202.04 and λ203.82/λ202.04) are analysed in two active region datasets from 2007 May 3 and 6 that yield densities in the range $8.5 \leq \log(N_e/\mathrm{cm}^{-3}) \leq 11.0$. The densities are derived using v5.2 of the CHIANTI atomic database. Blending, line fitting, and instrumental issues are discussed, and line fit parameters presented. Results. The Fe XII and Fe XIII diagnostics show broadly the same trend in density across the active region, consistent with their similar temperatures of formation. However, the high precision of the EIS measurements demonstrates significant discrepancies of up to 0.5 dex in derived $\log N_e$ values, with Fe XII always giving higher densities than Fe XIII. The discrepancies may partly be due to real physical differences between the emitting regions of the two

plasmas, but the dominant factor lies in the atomic models of the two ions. Two specific problems are identified for Fe XII λ196.64 and Fe XIII λ203.82: the former is found to be underestimated in strength by the CHIANTI atomic model, while the high-density limit of the λ203.82/λ202.04 ratio appears to be inaccurate in the CHIANTI atomic model. The small grating tilt of the EIS instrument is found to be very significant when deriving densities from emission lines separated by more than a few angstroms. Revised wavelengths of 196.518 ± 0.003 Å and 196.647 ± 0.003 Å are suggested for the Fe XIII λ196.54 and Fe XII λ196.64 lines, respectively.

On the intensity ratio variation of the Si IV 1394/1403 Å lines during solar flares

Hao-Cheng **Yu**, J. Hong, M. D. Ding

A&A **2023**

https://arxiv.org/pdf/2306.08296.pdf

Context. The Si IV lines at 1394 Å and 1403 Å form in the solar atmosphere at a temperature of ∼104.8 K. They are usually considered optically thin, but their opacity can be enhanced during solar flares. Traditionally, the intensity ratio of these lines are used as an indicator of the optical thickness. However, observations have shown a wavelength-dependent intensity ratio profile r(Δλ) of the the 1394 Å to 1403 Å lines.
Aims. We aim to study the variation of the intensity ratio profile in solar flares and the physical reasons behind it.
Method. The Si IV lines and their intensity ratio profiles are calculated from the one-dimensional radiative hydrodynamics flare model with non-thermal electron heating.
Result. During flares, r(Δλ) is smaller than 2 at the line core but larger than 2 at the line wings. We attribute the deviation of the ratio from 2 to two effects: the resonance scattering effect and the opacity effect. Resonance scattering increases the population ratio of the upper levels of the two lines, and as a result, increases r(Δλ), in all wavelengths. The opacity effect decreases r(Δλ), especially at the line core where the opacity is larger. These two effects compete with each other and cause the U-shape of r(Δλ).

Imaging and Spectroscopic Observations of the Dynamic Processes in Limb Solar Flares

Ke **Yu**, Y. Li, Jie Hong, De-Chao Song, M. D. Ding

ApJ **935** 8 **2022**

https://arxiv.org/pdf/2207.05925.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/ac7e46/pdf

We investigate various dynamic processes including magnetic reconnection, chromospheric evaporation, and coronal rain draining in two limb solar flares through imaging and spectroscopic observations from the Interface Region Imaging Spectrograph (IRIS) and the Atmospheric Imaging Assembly (AIA) on board the Solar Dynamics Observatory. In the early phase of the flares, a bright and dense loop-top structure with a cusp-like shape can be seen in multi-wavelength images, which is co-spatial with the hard X-ray 25--50 keV emission. In particular, intermittent magnetic reconnection downflows are detected in the time-space maps of AIA 304 Å. The reconnection downflows are manifested as redshifts on one half of the loops and blueshifts on the other half in the IRIS Si {\sc iv} 1393.76 Å line due to a projection effect. The Si {\sc iv} profiles exhibit complex features (say, multi-peak) with a relatively larger width at the loop-top region. During the impulsive phase, chromospheric evaporation is observed in both AIA images and the IRIS Fe {\sc xxi} 1354.08 Å line. Upward motions can be seen from AIA 131 Å images. The Fe {\sc xxi} line is significantly enhanced and shows a good Gaussian shape. In the gradual phase, warm rains are observed as downward moving plasmas in AIA 304 Å images. Both the Si {\sc iv} and Fe {\sc xxi} lines show a relatively symmetric shape with a larger width around the loop top. These results provide observational evidence for various dynamic processes involved in and are crucial to understand the energy release process of solar flares. **2014 October 29 and 30**

Statistical Studies on Modified Neupert Effect★

YU Wen-hui a b c, LI You-ping a b, GAN Wei-qun a b

Chinese Astronomy and Astrophysics Volume 45, Issue 1, **2021**, Pages 82-98

https://doi.org/10.1016/j.chinastron.2021.02.006

https://www.sciencedirect.com/science/article/abs/pii/S0275106221000060

https://sci-hub.ru/10.1016/j.chinastron.2021.02.006

The qualitative description of the Neupert effect is that there is a causal relationship between the pulse component (hard X-ray, microwave burst) and the gradual component (soft X-ray emission) in a flare. The initial energy of the flare is released in the form of accelerating particles. The energetic particles produce HXR (hard X-ray) via nonthermal electron-ion bremsstrahlung as they lose their energies in the chromosphere. The SXR (soft X-ray) emission of the flare is the response of energetic particles injected into the chromosphere. According to the quantitative description of the classic Neupert effect, SXR should reach maximum instantly at the end of HXR emission (sign of nonthermal electron injection). However, previous observations have found that for quite a number of flares the SXR peak time (t2) is significantly later than the end time of HXR (t1) ($\tau=t2-t1,\tau>0$), deviating from the classic Neupert effect. In order to study the events deviating from the classic Neupert effect or not, we checked the RHESSI (Reuven Ramaty High

Energy Solar Spectroscopic Imager) and GOES (Geostationary Operational Environmental Satellites) events list from 2002 to 2015, and found out flare samples that have simple lightcurves at 25–50 keV together with other criteria. A total of 276 flare samples were finally selected. We have analysed the τ distribution of these flares, as well as the relationship between the loop length (represented by the distance between two footpoint sources d) and τ. We found that: (1) 227 sample flares present τ>0, which means that about 82% of total samples deviate from the classical Neupert effect; (2) there is a roughly linear correlation between τ and d, that is, the longer the loop is, the later the maximum time of SXR with respect to the end of HXR; (3) there seems to have a critical distance, within which the classic Neupert effect works. These results confirm the necessity of modifying Neupert effect, and expound its physical significance. **2002-02-26, 2002−11−14, 2005−05−16, 2013−07−04, 2013-10-22**

Magnetic Reconnection during the Post-impulsive Phase of a Long-duration Solar Flare: Bidirectional Outflows as a Cause of Microwave and X-Ray Bursts

Sijie **Yu** (余思捷)1, Bin Chen (陈彬)1, Katharine K. Reeves2, Dale E. Gary1, Sophie Musset3,4, Gregory D. Fleishman1, Gelu M. Nita1, and Lindsay Glesener4

2020 ApJ 900 17

https://arxiv.org/pdf/2007.10443.pdf **File**

https://doi.org/10.3847/1538-4357/aba8a6

Magnetic reconnection plays a crucial role in powering solar flares, production of energetic particles, and plasma heating. However, where the magnetic reconnections occur, how and where the released magnetic energy is transported, and how it is converted to other forms remain unclear. Here we report recurring bidirectional plasma outflows located within a large-scale plasma sheet observed in extreme-ultraviolet emission and scattered white light during the post-impulsive gradual phase of the X8.2 solar flare on **2017 September 10**. Each of the bidirectional outflows originates in the plasma sheet from a discrete site, identified as a magnetic reconnection site. These reconnection sites reside at very low altitudes (<180 Mm, or 0.26 R ⊙) above the top of the flare arcade, a distance only <3% of the total length of a plasma sheet that extends to at least 10 R ⊙. Each arrival of sunward outflows at the loop-top region appears to coincide with an impulsive microwave and X-ray burst dominated by a hot source (10–20 MK) at the loop top and a nonthermal microwave burst located in the loop-leg region. We propose that the reconnection outflows transport the magnetic energy released at localized magnetic reconnection sites outward in the form of kinetic energy flux and/or electromagnetic Poynting flux. The sunward-directed energy flux induces particle acceleration and plasma heating in the post-flare arcades, observed as the hot and nonthermal flare emissions.

IRIS Si IV Line Profiles at Flare Ribbons as Indications of Chromospheric Condensation

Ke **Yu**, Y. Li, M. D. Ding, D. Li, Yi-An Zhou, Jie Hong

ApJ **896** 154 **2020**

https://arxiv.org/pdf/2005.02029.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/ab9014/pdf

We present temporal variations of the Si IV line profiles at the flare ribbons in three solar flares observed by the Interface Region Imaging Spectrograph (IRIS). In the M1.1 flare on **2014 September 6** and the X1.6 flare on **2014 September 10**, the Si IV line profiles evolve from wholly redshifted to red-wing enhanced with the flare development. However, in the B1.8 flare on **2016 December 2**, the Si IV line profiles are wholly redshifted throughout the flare evolution. We fit the wholly redshifted line profiles with a single Gaussian function but the red-asymmetric ones with a double Gaussian function to deduce the corresponding Doppler velocities. In addition, we find that hard X-ray emission above 25 keV shows up in the two large flares, implying a nonthermal electron beam heating. In the microflare, there only appears weak hard X-ray emission up to 12 keV, indicative of a thermal heating mostly. We interpret the redshifts or red asymmetries of the Si IV line at the ribbons in the three flares as spectral manifestations of chromospheric condensation. We propose that whether the line appears to be wholly redshifted or red-asymmetric depends on the heating mechanisms and also on the propagation of the condensation.

Magnetic Reconnection During the Post-Impulsive Phase of a Long-Duration Solar Flare: Bi-Directional Outflows as a Cause of Microwave and X-ray Bursts

Sijie **Yu** (1), Bin Chen (1), Katharine K. Reeves (2), Dale E. Gary (1), Sophie Musset (3 and 4), Gregory D. Fleishman (1), Gelu M. Nita (1), Lindsay Glesener (4)

ApJ Volume 900, Issue 1, id.17 **2020**

https://arxiv.org/pdf/2007.10443.pdf **File**

Magnetic reconnection plays a crucial role in powering solar flares, production of energetic particles, and plasma heating. However, where the magnetic reconnections occur, how and where the released magnetic energy is transported, and how it is converted to other forms remain unclear. Here we report recurring bi-directional plasma outflows located within a large-scale plasma sheet observed in extreme ultraviolet emission and scattered white light during the post-impulsive gradual phase of the X8.2 solar flare on **2017 September 10**. Each of the bi-directional outflows originates in the plasma sheet from a discrete site, identified as a magnetic reconnection site. These reconnection sites reside at very

low altitudes (<180 Mm, or 0.26 R⊙) above the top of the flare arcade, a distance only <3% of the total length of a plasma sheet that extends to at least 10 R⊙. Each arrival of sunward outflows at the looptop region appears to coincide with an impulsive microwave and X-ray burst dominated by a hot source (10-20 MK) at the looptop, which is immediately followed by a nonthermal microwave burst located in the loopleg region. We propose that the reconnection outflows transport the magnetic energy released at localized magnetic reconnection sites outward in the form of kinetic energy flux and/or electromagnetic Poynting flux. The sunward-directed energy flux induces particle acceleration and plasma heating in the post-flare arcades, observed as the hot and nonthermal flare emissions.

Possible Detection of Subsecond-Period Propagating Magnetohydrodynamics Waves in Post-Reconnection Magnetic Loops during a Two-Ribbon Solar Flare

Sijie **Yu** (1), Bin Chen
ApJ **872** 71 **2019**
https://arxiv.org/pdf/1901.05379.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/aaff6d/pdf
https://web.njit.edu/~binchen/download/publications/Yu_Chen_2019/Yu_Chen_2019.pdf
Solar flares involve the sudden release of magnetic energy in the solar corona. Accelerated nonthermal electrons have been often invoked as the primary means for transporting the bulk of the released energy to the lower solar atmosphere. However, significant challenges remain for this scenario, especially in accounting for the large number of accelerated electrons inferred from observations. Propagating magnetohydrodynamics (MHD) waves, particularly those with subsecond/second-scale periods, have been proposed as an alternative means for transporting the released flare energy likely alongside the electron beams, while observational evidence remains elusive. Here we report a possible detection of such waves in the late impulsive phase of a two-ribbon flare. This is based on ultra-high cadence dynamic imaging spectroscopic observations of a peculiar type of decimetric radio bursts obtained by the Karl G. Jansky Very Large Array. Radio imaging at each time and frequency pixel allows us to trace the spatiotemporal motion of the source, which agrees with the implications of the frequency drift pattern in the dynamic spectrum. The radio source, propagating at 1000--2000 km s−1 in projection, shows close spatial and temporal association with transient brightenings on the flare ribbon. In addition, multitudes of subsecond-period oscillations are present in the radio emission. We interpret the observed radio bursts as \edit1{short-period} MHD wave packets propagating along newly reconnected magnetic flux tubes linking to the flare ribbon. The estimated energy flux carried by the waves is comparable to that needed for accounting for the plasma heating during the late impulsive phase of this flare. **2014 November 01**

Short-term Solar Flare Level Prediction Using a Bayesian Network Approach

*Daren **Yu**, Xin Huang, Huaning Wang, Yanmei Cui, Qinghua Hu, and Rui Zhou*
ApJ **710** 869-877, **2010**
A Bayesian network approach for short-term solar flare level prediction has been proposed based on three sequences of photospheric magnetic field parameters extracted from *Solar and Heliospheric Observatory*/Michelson Doppler Imager longitudinal magnetograms. The magnetic measures, the maximum horizontal gradient, the length of neutral line, and the number of singular points do not have determinate relationships with solar flares, so the solar flare level prediction is considered as an uncertainty reasoning process modeled by the Bayesian network. The qualitative network structure which describes conditional independent relationships among magnetic field parameters and the quantitative conditional probability tables which determine the probabilistic values for each variable are learned from the data set. Seven sequential features—the maximum, the mean, the root mean square, the standard deviation, the shape factor, the crest factor, and the pulse factor—are extracted to reduce the dimensions of the raw sequences. Two Bayesian network models are built using raw sequential data (BN_R) and feature extracted data (BN_F), respectively. The explanations of these models are consistent with physical analyses of experts. The performances of the BN_R and the BN_F appear comparable with other methods. More importantly, the comprehensibility of the Bayesian network models is better than other methods.

SHORT-TERM SOLAR FLARE PREDICTION USING MULTIRESOLUTION PREDICTORS

Daren Yu1, Xin Huang1, Qinghua Hu1, Rui Zhou1, Huaning Wang2 and Yanmei Cui3
ApJ 709 321-326, **2010**
Multiresolution predictors of solar flares are constructed by a wavelet transform and sequential feature extraction method. Three predictors—the maximum horizontal gradient, the length of neutral line, and the number of singular points—are extracted from *Solar and Heliospheric Observatory*/Michelson Doppler Imager longitudinal magnetograms. A maximal overlap discrete wavelet transform is used to decompose the sequence of predictors into four frequency bands. In each band, four sequential features—the maximum, the mean, the standard deviation, and the root mean square—are extracted. The multiresolution predictors in the low-frequency band reflect trends in the evolution of newly

emerging fluxes. The multiresolution predictors in the high-frequency band reflect the changing rates in emerging flux regions. The variation of emerging fluxes is decoupled by wavelet transform in different frequency bands. The information amount of these multiresolution predictors is evaluated by the information gain ratio. It is found that the multiresolution predictors in the lowest and highest frequency bands contain the most information. Based on these predictors, a C4.5 decision tree algorithm is used to build the short-term solar flare prediction model. It is found that the performance of the short-term solar flare prediction model based on the multiresolution predictors is greatly improved.

Short-Term Solar Flare Prediction Using a Sequential Supervised Learning Method

Daren **Yu**[1], Xin Huang[1], Huaning Wang[2] and Yanmei Cui

Solar Phys. Volume 255, Number 1, p. 91-105, **2009**

Solar flares are powered by the energy stored in magnetic fields, so evolutionary information of the magnetic field is important for short-term prediction of solar flares. However, the existing solar flare prediction models only use the current information of the active region. A sequential supervised learning method is introduced to add the evolutionary information of the active region into a prediction model. The maximum horizontal gradient, the length of the neutral line, and the number of singular points extracted from SOHO/MDI longitudinal magnetograms are used in the model to describe the nonpotentiality and complexity of the photospheric magnetic field. The evolutionary characteristics of the predictors are analyzed by using autocorrelation functions and mutual information functions. The analysis results indicate that a flare is influenced by the 3-day photospheric magnetic field information before flare eruption. A sliding-window method is used to add evolutionary information of the predictors into machine learning algorithms, then C4.5 decision tree and learning vector quantization are employed to predict the flare level within 48 hours. Experimental results indicate that the performance of the short-term solar flare prediction model within the sequential supervised learning framework is significantly improved.

A Compact Source for Quasi-Periodic Pulsation in an M-class Solar Flare

Ding **Yuan**, Song Feng, Dong Li, Zhongjun Ning, Baolin Tan

ApJL **886** L25 **2019**

https://arxiv.org/pdf/1911.05217.pdf

sci-hub.se/10.3847/2041-8213/ab5648

Quasi-periodic pulsations (QPP) are usually found in the light curves of solar and stellar flares, they carry the features of time characteristics and plasma emission of the flaring core, and could be used to diagnose the coronas of the Sun and remote stars. In this study, we combined the Atmospheric Imaging Assembly (AIA) onboard the Solar Dynamics Observatory and the Nobeyama Radioheliograph (NoRH) to observe an M7.7 class flare occurred at active region 11520 on **19 July 2012**. A QPP was detected both in the AIA $131\unit{Å}$ bandpass and the NoRH $17\unit{GHz}$ channel, it had a period of about four minutes. In the spatial distribution of Fourier power, we found that this QPP originated from a compact source and that it overlapped with the X-ray source above the loop top. The plasma emission intensities in the AIA $131\unit{Å}$ bandpass were highly correlated within this region. The source region is further segmented into stripes that oscillated with distinctive phases. Evidence in this event suggests that this QPP was likely to be generated by intermittent energy injection into the reconnection region.

Multi-layered Kelvin-Helmholtz Instability in the Solar Corona

Ding **Yuan**, Yuandeng Shen, Yu Liu, Xueshang Feng, Rony Keppens

ApJ **2019**

https://arxiv.org/pdf/1910.05710.pdf

The Kelvin-Helmholtz (KH) instability is commonly found in many astrophysical, laboratory, and space plasmas. It could mix plasma components of different properties and convert dynamic fluid energy from large scale structure to smaller ones. In this study, we combined the ground-based New Vacuum Solar Telescope (NVST) and the Solar Dynamic Observatories (SDO) / Atmospheric Imaging Assembly (AIA) to observe the plasma dynamics associated with active region 12673 on **09 September 2017**. In this multi-temperature view, we identified three adjacent layers of plasma flowing at different speeds, and detected KH instabilities at their interfaces. We could unambiguously track a typical KH vortex and measure its motion. We found that the speed of this vortex suddenly tripled at a certain stage. This acceleration was synchronized with the enhancements in emission measure and average intensity of the 193 Å data. We interpret this as evidence that KH instability triggers plasma heating. The intriguing feature in this event is that the KH instability observed in the NVST channel was nearly complementary to that in the AIA 193 Å. Such a multi-thermal energy exchange process is easily overlooked in previous studies, as the cold plasma component is usually not visible in the extreme ultraviolet channels that are only sensitive to high temperature plasma emissions. Our finding indicates that embedded cold layers could interact with hot plasma as invisible matters. We speculate that this process could occur at a variety of length scales and could contribute to plasma heating.

Forward Modelling of Standing Kink Modes in Coronal Loops II. Applications

Ding **Yuan**, Tom Van Doorsselaere
2016
http://arxiv.org/pdf/1602.07598v1.pdf
Magnetohydrodynamic waves are believed to play a significant role in coronal heating, and could be used for remote diagnostics of solar plasma. Both the heating and diagnostic applications rely on a correct inversion (or backward modelling) of the observables into the thermal and magnetic structures of the plasma. However, owing to the limited availability of observables, this is an ill-posed issue. Forward Modelling is to establish a plausible mapping of plasma structuring into observables. In this study, we set up forward models of standing kink modes in coronal loops and simulate optically thin emissions in the extreme ultraviolet bandpasses, and then adjust plasma parameters and viewing angles to match three events of transverse loop oscillations observed by the Solar Dynamics Observatory/Atmospheric Imaging Assembly. We demonstrate that forward models could be effectively used to identify the oscillation overtone and polarization, to reproduce the general profile of oscillation amplitude and phase, and to predict multiple harmonic periodicities in the associated emission intensity and loop width variation.

Forward Modelling of Standing Slow Modes in Flaring Coronal Loops

D. **Yuan**, T. Van Doorsselaere, D. Banerjee, P. Antolin
ApJ **807** 98 **2015**
http://arxiv.org/pdf/1504.07475v1.pdf
Standing slow mode waves in hot flaring loops are exclusively observed in spectrometers and are used to diagnose the magnetic field strength and temperature of the loop structure. Due to the lack of spatial information, the longitudinal mode cannot be effectively identified. In this study, we simulate standing slow mode waves in flaring loops and compare the synthesized line emission properties with SUMER spectrographic and SDO/AIA imaging observations. We find that the emission intensity and line width oscillations are a quarter period out of phase with Doppler shift velocity both in time and spatial domain, which can be used to identify a standing slow mode wave from spectroscopic observations. However, the longitudinal overtones could be only measured with the assistance of imagers. We find emission intensity asymmetry in the positive and negative modulations, this is because the contribution function pertaining to the atomic emission process responds differently to positive and negative temperature variations. One may detect \textbf{half} periodicity close to the loop apex, where emission intensity modulation is relatively small. The line-of-sight projection affects the observation of Doppler shift significantly. A more accurate estimate of the amplitude of velocity perturbation is obtained by de-projecting the Doppler shift by a factor of $1-2\theta/\pi$rather than the traditionally used $\cos\theta$. \textbf{If a loop is heated to the hotter wing, the intensity modulation could be overwhelmed by background emission, while the Doppler shift velocity could still be detected to a certain extent.

Distinct propagating fast wave trains associated with flaring energy releases

D. **Yuan**1, Y. Shen2, Y. Liu2, V. M. Nakariakov1,3, B. Tan4 and J. Huan
A&A 554, A144 (**2013**)
Context. Large-scale fast waves with perturbation of the EUV emission intensity are well resolved in both temporal and spatial scale by SDO/AIA. These waves are prone to propagate along the magnetic field line.
Aims. We aim to probe the link between propagating fast wave trains and flaring energy releases. By measuring the wave parameters, we reveal their nature and investigate the potential to diagnose the energy source and waveguide.
Methods. The spatial and temporal evolution of the wave amplitude and propagating speed are studied. The correlation of individual wave trains with flare-generated radio bursts is tested.
Results. The propagating wave pattern comprises distinct wave trains with varying periods and wavelengths. This characteristic signature is consistent with the patterns formed by waveguide dispersion, when different spectral components propagate at different phase and group speeds. The wave train releases are found to be highly correlated in start time with the radio bursts emitted by the non-thermal electrons that were accelerated in bursty energy releases. The wave amplitude is seen to reach the maximum midway during its course. This can be caused by a combined effect of the waveguide spread in the transverse direction and density stratification. The transverse amplitude distribution perpendicular to the wave vector is found to follow approximately a Gaussian profile. The spatial structure is consistent with the kink mode that is polarised along the line-of-sight. The propagating speed is subject to deceleration from ~735−845 km s-1 to ~600 km s-1. This could be caused by the decrease in the local Alfvén speed and/or the projection effect.

Magnetic field re-configuration associated with a slow rise eruptive X1.2 flare in NOAA active region 11944

Kyung Lim, and Wenda Cao
Front. Astron. Space Sci. 9:816523 **2022**
https://www.frontiersin.org/articles/10.3389/fspas.2022.816523/full
https://doi.org/10.3389/fspas.2022.816523
http://www.bbso.njit.edu/~vayur/ar11944_final.pdf **File**
Using multi-wavelength observations, we analysed magnetic field variations associated with a gradual X1.2 flare that erupted on **January 7, 2014** in active region (AR) NOAA 11944 located near the disk center. A fast coronal mass ejection (CME) was observed following the flare, which was noticeably deflected in the south-west direction. A chromospheric filament was observed at the eruption site prior to and after the flare. We used SDO/HMI data to perform non-linear force-free field (NLFFF) extrapolation of coronal magnetic fields above the AR and to study the evolution of AR magnetic fields prior to the eruption. The extrapolated (model) data allowed us to detect signatures of several magnetic flux ropes (MFRs) present at the eruption site several hours before the event. The eruption site was located under slanted sunspot fields with a varying decay index of 1.0-1.5. That might have caused the erupting fields to slide along this slanted magnetic boundary rather than vertically erupt, thus explaining the slow rise of the flare as well as the observed direction of the resulting CME. We employed sign-singularity tools to quantify the evolutionary changes in the model twist and observed current helicity data, and found rapid and coordinated variations of current systems in both data sets prior to the event as well as their rapid exhaustion after the event onset.

High-resolution Observations of a White-light Flare with NST

V. **Yurchyshyn**1,2, P. Kumar2, V. Abramenko3,4, Y. Xu5, P. R. Goode1, K.-S. Cho2,6, and E.-K. Lim
2017 ApJ 838 32
Using high-resolution data from the New Solar Telescope, we studied fine spatial and temporal details of an M1.3 white-light (WL) flare, which was one of three homologous solar flares (C6.8, M1.3, and M2.3) observed in close proximity to the west solar limb on **2014 October 29** in NOAA active region 12192. We report that the TiO WL flare consists of compact and intense cores surrounded by less intense spatial halos. The strong and compact WL cores were measured to be Mm across, with an area of about 1014 cm2. Several TiO features were not cospatial with Hα flare ribbons and were displaced toward the disk center by about 500 km, which suggests that the TiO and Hα radiation probably did not originate in the same chromospheric volume. The observed TiO intensity enhancements are not normally distributed and are structured by the magnetic field of the penumbra.

The biggest solar telescope finds still smaller scales for white-light flare kernels.

Multiwavelength Observations of a Slow Raise, Multi-Step X1.6 Flare and the Associated Eruption

Yurchyshyn, V., Kumar, P., Cho, K.S., Lim, E.K., & Abramenko, V.
ApJ 812 172 **2015**
http://www.bbso.njit.edu/~vayur/x1.6flare.pdf
Using multi-wavelength observations we studied a slow rise, multi-step X1.6 flare that began on **November 7, 2014** as a localized eruption of core fields inside a \delta-sunspot and later engulfed the entire active region. This flare event was associated with formation of two systems of post eruption arcades and several J-shaped flare ribbons showing extremely fine details, irreversible changes in the photospheric magnetic fields, and it was accompanied by a fast and wide coronal mass ejection. Data from the Solar Dynamics Observatory, IRIS spacecraft along with the ground based data from the New Solar Telescope (NST) present evidence that i) the flare and the eruption were directly triggered by a flux emergence that occurred inside a \delta--sunspot at the boundary between two umbrae; ii) this event represented an example of the formation of an unstable flux rope observed only in hot AIA channels (131 and 94 Å) and LASCO C2 coronagraph images; iii) the global post eruption arcade spanned the entire AR and was due to global scale reconnection occurring at heights of about one solar radii, indicating on the global spatial and temporal scale of the eruption.

High Resolution Observations of Chromospheric Jets in Sunspot Umbra

Yurchyshyn, V., Abramenko, V., Kosovichev, A., and Goode, P.
E-print, April **2014,** ApJ, 787 58, **2014**
http://www.bbso.njit.edu/~vayur/spikes/VYurchyshyn_Spikes.pdf
Recent observations of sunspot's umbra suggested that it may be finely structured at a sub-arcsecond scale representing a mix of hot and cool plasma elements. In this study we report the first detailed observations of the umbral spikes, which are cool jet-like structures seen in the chromosphere of an umbra. The spikes are cone-shaped features with a typical height of 0.5-1.0 Mm and a width of about 0.1 Mm. Their life time ranges from 2 to 3 min and they tend to re-

appear at the same location. The spikes are not associated with photospheric umbral dots and they rather tend to occur above darkest parts of the umbra, where magnetic fields are strongest. The spikes exhibit up and down oscillatory motions and their spectral evolution suggests that they might be driven by upward propagating shocks generated by photospheric oscillations. It is worth noting that triggering of the running penumbral waves seems to occur during the interval when the spikes reach their maximum height. **14 June 2013**

ON THE ORIGIN OF INTERGRANULAR JETS

V. B. **Yurchyshyn**1, P. R. Goode1, V. I. Abramenko1 and O. Steiner
BBSO Preprint 1484, **2011, 2011** ApJ 736 L35

We observe that intergranular jets, originating in the intergranular space surrounding individual granules, tend to be associated with granular fragmentation, in particular, with the formation and evolution of a bright granular lane (BGL) within individual granules. The BGLs have recently been identified as vortex tubes by Steiner et al. We further discover the development of a well-defined bright grain located between the BGL and the dark intergranular lane to which it is connected. Signatures of a BGL may reach the lower chromosphere and can be detected in off-band Hα images. Simulations also indicate that vortex tubes are frequently associated with small-scale magnetic fields. We speculate that the intergranular jets detected in the New Solar Telescope (NST) data may result from the interaction between the turbulent small-scale fields associated with the vortex tube and the larger-scale fields existing in the intergranular lanes. The intergranular jets are much smaller and weaker than all previously known jet-like events. At the same time, they appear much more numerous than the larger events, leading us to the speculation that the total energy release and mass transport by these tiny events may not be negligible in the energy and mass-flux balance near the temperature minimum atop the photosphere. The study is based on the photospheric TiO broadband (1.0 nm) filter data acquired with the 1.6 m NST operating at the Big Bear Solar Observatory. The data set also includes NST off-band Hα images collected through a Zeiss Lyot filter with a passband of 0.025 nm.

Variations of Current Helicity in Active Region 10930 as Inferred from Hinode Spectropolarimeter Data and Cancellation Exponent

V. **Yurchyshyn**, V. Abramenko and H. Watanabe
BBSO #1464, **2010; File;** Proceedings of Hinode 3 meeting, ASP Conference Series

Current helicity derived from vector magnetograms possesses a well-pronounced scaling behavior, which can be studied by introducing a signed measure and calculating the power-law exponent (cancellation exponent). The time variations of this exponent seem to be related to flare activity of an active region. Here we focus on changes of current helicity in active region NOAA 10930 as derived from a set of Hinode spectropolarimeter data. Our findings are that the cancellation exponent first strongly increased on Dec 11 then rapidly decreased after a small sunspot-satellite developed. Afterward, the cancellation exponent began its gradual increase without significant new magnetic flux emergence. These two different modes of behavior may indicate different processes that ultimately led to an eruption: the first process is rapid injection of current helicity, while the second process is gradual redistribution of injected helicity over all spatial scales in the active region.

Magnetic Field, Hα, and RHESSI Observations of the 2002 July 23 Gamma-Ray Flare

Yurchyshyn, Vasyl; Wang, Haimin; Abramenko, Valentyna; Spirock, Thomas J.; Krucker, Säm
Astrophysical Journal, 605:546–553, **2004; File**

In this paper we examine two aspects of the **2002 July 23** gamma-ray flare by using multiwavelength observations. First, the data suggest that the interaction of the erupted field with an overlying large-scale coronal field can explain the offset between the gamma-ray and the hard X-ray sources observed in this event. Second, we pay attention to rapid and permanent changes in the photospheric magnetic field associated with the flare. MDI and BBSO magnetograms show that the following magnetic flux had rapidly decreased by 1 ; 10^{20} Mx immediately after the flare, while the leading polarity was gradually increasing for several hours after the flare. Our study also suggests that the changes were most probably associated with the emergence of new flux and the reorientation of the magnetic field lines. We interpret the magnetograph and spectral data for this event in terms of the tether-cutting model.

Ejection of cool plasma into the hot corona⋆

P. **Zacharias**1⋆⋆, H. Peter2 and S. Bingert
A&A 532, A112 (**2011**)

Context. The corona is highly dynamic and shows transient events on various scales in space and time. Most of these features are related to changes in the magnetic field structure or impulsive heating caused by the conversion of magnetic to thermal energy.
Aims. We investigate the processes that lead to the formation, ejection and fall of a confined plasma ejection that was observed in a numerical experiment of the solar corona. By quantifying physical parameters such as mass, velocity, and orientation of the plasma ejection relative to the magnetic field, we provide a description of the nature of this particular plasma ejection.
Methods. The time-dependent three-dimensional magnetohydrodynamic (3D MHD) equations are solved in a box extending from the chromosphere, which serves as a reservoir for mass and energy, to the lower corona. The plasma is heated by currents that are induced through field line braiding as a consequence of photospheric motions included in the model. Spectra of optically thin emission lines in the extreme ultraviolet range are synthesized, and magnetic field lines are traced over time. We determine the trajectory of the plasma ejection and identify anomalies in the profiles of the plasma parameters.
Results. Following strong heating just above the chromosphere, the pressure rapidly increases, leading to a hydrodynamic explosion above the upper chromosphere in the low transition region. The explosion drives the plasma, which needs to follow the magnetic field lines. The ejection is then moving more or less ballistically along the loop-like field lines and eventually drops down onto the surface of the Sun. The speed of the ejection is in the range of the sound speed, well below the Alfvén velocity.
Conclusions. The plasma ejection observed in a numerical experiment of the solar corona is basically a hydrodynamic phenomenon, whereas the rise of the heating rate is of magnetic nature. The granular motions in the photosphere lead (by chance) to a strong braiding of the magnetic field lines at the location of the explosion that in turn is causing strong currents which are dissipated. Future studies need to determine if this process is a ubiquitous phenomenon on the Sun on small scales. Data from the Atmospheric Imaging Assembly on the Solar Dynamics Observatory (AIA/SDO) might provide the relevant information.

Unraveling the Trigger Mechanism of Explosive Reconnection in Partially Ionized Solar Plasma

Abdullah **Zafar**, Lei Ni, Jun Lin, Ahmad Ali
ApJ **2024**
https://arxiv.org/pdf/2407.01915
Plasmoid instability is usually accounted for the onset of fast reconnection events observed in astrophysical plasmas. However, the measured reconnection rate from observations can be one order of magnitude higher than that derived from MHD simulations. In this study, we present the results of magnetic reconnection in the partially ionized low solar atmosphere based on 2.5D magnetohydrodynamics (MHD) simulations. The whole reconnection process covers two different fast reconnection phases. In the first phase, the slow Sweet-Parker reconnection transits to the plasmoid-mediated reconnection, and the reconnection rate reaches about 0.02. In the second phase, a faster explosive reconnection appears, with the reconnection rate reaching above 0.06. At the same time, a sharp decrease in plasma temperature and density at the principle X-point is observed which is associated with the strong radiative cooling, the ejection of hot plasma from the local reconnection region or the motion of principle X-point from hot and denser region to cool and less dense one along the narrow current sheet. This causes gas pressure depletion and the increasing of magnetic diffusion at the main X-point, resulting in the local Petschek-like reconnection and a violent and rapid increase in the reconnection rate. This study for the first time reveals a common phenomenon that the plasmoid dominated reconnection transits to an explosive faster reconnection with the rate approaching the order of 0.1 in partially ionized plasma in the MHD scale.

Rayleigh–Taylor Instability and Excitation of Super-Dreicer Electric Fields in the Solar Chromosphere

V. V. **Zaitsev**, P. V. Kronshtadtov, A. V. Stepanov
Solar Phys. Volume 291, Issue 11, pp 3451–3459 **2016**
Within the framework of the long-standing so-called “number problem” in the physics of solar flares, we consider the excitation of a super-Dreicer electric field at the leading edge of the electric current pulse that occurs at the chromospheric legs of a coronal magnetic loop as a result of the magnetic Rayleigh–Taylor instability. It is shown that for a sufficiently strong electric current, \(I_{0} \ge 10^{10}~\mbox{A}\), the current pulse propagates in the non-linear mode and generates a strong longitudinal electric field \(E_{z}\), which strongly depends on the current (\(E_{z} \propto I_{0}^{3}\)) and can exceed the Dreicer field (\(E_{z} > E_{\mathrm{D}}\)). In this case, the bulk of electrons in the site of the current pulse is in a runaway mode, and the energy release rate in the chromosphere increases

significantly. Super-Dreicer electric fields also provide injection of protons into the regime of acceleration by Langmuir turbulence generated by fast electrons at the leading edge of the electric current pulse. The electric field at the pulse edge can exceed the Dreicer field starting from the chromosphere level with the number density \(n \approx 10^{13}~\mbox{cm}^{-3}\). At a lower current \(I_{0} < 10^{10}~\mbox{A}\), a super-Dreicer mode at the higher levels of the chromosphere with \(n < 10^{12}~\mbox{cm}^{-3}\) occurs.

Particle Acceleration and Plasma Heating in the Chromosphere

V. V. **Zaitsev**, A. V. Stepanov

Solar Phys. Volume 290, Issue 12, pp 3559-3572 **2015**

We propose a new mechanism of electron acceleration and plasma heating in the solar chromosphere, based on the magnetic Rayleigh–Taylor instability. The instability develops at the chromospheric footpoints of a flare loop and deforms the local magnetic field. As a result, the electric current in the loop varies, and a resulting inductive electric field appears. A pulse of the induced electric field, together with the pulse of the electric current, propagates along the loop with the Alfvén velocity and begins to accelerate electrons up to an energy of about 1 MeV. Accelerated particles are thermalized in the dense layers of the chromosphere with the plasma density n≈1014--1015 cm−3, heating them to a temperature of about several million degrees. Joule dissipation of the electric current pulse heats the chromosphere at heights that correspond to densities n≤1011--1013 c. Observations with the New Solar Telescope at Big Bear Solar Observatory indicate that chromospheric footpoints of coronal loops might be heated to coronal temperatures and that hot plasma might be injected upwards, which brightens ultra-fine loops from the photosphere to the base of the corona. Thereby, recent observations of the Sun and the model we propose stimulate a déjà vu – they are reminiscent of the concept of the chromospheric flare.

A SOHO/UVCS study of coronal outflows at the edge of an active region complex

L. **Zangrilli**1 and G. Poletto

A&A 545, A8 (**2012**)

Context. In the past, active regions (ARs) have been suggested as a possible source of the slow solar wind. Their role as solar wind contributors has recently been supported by HINODE observations at low coronal levels.

Aims. Our purpose is to determine whether outflows at the edges of ARs can be detected in higher layers of the corona, supporting the low-corona evidence for the occurrence of wind streams from ARs.

Methods. Data acquired by SOHO/UVCS on January 2, 1998, at altitudes ranging from 1.5 to 2.3 solar radii at mid latitudes, were used to infer the physical properties of an AR complex at the time of its limb passage. To this end, the Doppler dimming technique was applied to UVCS observations of the H i Lyα and O vi doublet lines at 1031.9 and 1037.6 Å.

Results. Outflow speeds (and electron densities) were inferred: outflows, at speeds increasing with height, turn out to be confined within a narrow channel at the edge of closed loop systems within the AR. Our results are compared with those obtained by other authors with different techniques.

Conclusions. Our results support the assumption that ARs are sources of slow wind. To our knowledge these are the first direct measurements of AR flows in the intermediate corona. Tentative profiles of the speed vs. heliocentric altitudes at heliocentric distances between ≈ 1.5 and ≈ 2.3 solar radii show that AR flows are faster than streams from equatorial coronal holes.

Investigating and comparing the IRIS spectral lines Mg II, Si IV, and C II for flare precursor diagnostics

Jonas **Zbinden**1,2,⋆, Lucia Kleint1,2 and Brandon Panos1,2

A&A, 689, A72 (**2024**)

https://www.aanda.org/articles/aa/pdf/2024/09/aa47824-23.pdf

Context. Reliably predicting solar flares can mitigate the risks of technological damage and enhance scientific output by providing reliable pointings for observational campaigns. Flare precursors in the spectral line Mg II have been identified.

Aims. We extend previous studies by examining the presence of flare precursors in additional spectral lines, such as Si IV and C II, over longer time windows, and for more observations.

Methods. We trained neural networks and XGBoost decision trees to distinguish spectra observed from active regions that lead to a flare and those that did not. To enhance the information within each observation, we tested different masking methods to preprocess the data.

Results. We find average classification true skill statistics (TSS) scores of 0.53 for Mg II, 0.44 for Si IV, and 0.42 for C II. We speculate that Mg II h&k performs best because it samples the highest formation height range, and is sensitive to heating and density changes in the mid- to upper chromosphere. The flaring area relative to the field of view has a large effect on the model classification score and needs to be accounted for. Combining spectral lines has proven difficult, due to the difference in areas of high probability for an imminent flare between different lines.

Conclusions. Our models extract information from all three lines, independent of observational bias or GOES X-ray flux precursors, implying that the physics encoded in a combination of high resolution spectral data could be useful for flare forecasting.

Flare Expansion to a Magnetic Rope Accompanied by Rare Radio Bursts

Alena **Zemanová**, Marian Karlický, Jana Kašparová, and Jaroslav Dudík
2020 ApJ 905 111
https://doi.org/10.3847/1538-4357/abc424
We present multispectral analysis (radio, Hα, ultraviolet (UV)/extreme ultraviolet (EUV), and hard X-ray) of a confined flare from **2015 March 12**. This flare started within the active region NOAA 12 297 and then it expanded into a large preexisting magnetic rope embedded with a cold filament. The expansion started with several brightenings located along the rope. This process was accompanied by a group of slowly positively drifting bursts in the 0.8–2 GHz range. The frequency drift of these bursts was 45–100 MHz s−1. One of the bursts had an S-like form. During the brightening of the rope we observed a unique bright EUV structure transverse to the rope axis. The structure was observed in a broad range of temperatures and it moved along the rope with the velocity of about 240 km s−1. When the structure dissipated, we saw a plasma further following twisted threads in the rope. The observed slowly positively drifting bursts were interpreted considering particle beams and we show that one with the S-like form could be explained by the beam propagating through the helical structure of the magnetic rope. The bright structure transverse to the rope axis was interpreted considering line-of-sight effects and the dissipation-spreading process, which we found to be more likely.

Causal Attention Deep-learning Model for Solar Flare Forecasting

Xinze **Zhang**1,2, Long Xu3, Zihan Li1, and Xin Huang3
2024 ApJS 274 38
https://iopscience.iop.org/article/10.3847/1538-4365/ad7386/pdf
Solar flares originate from the sudden release of energy stored in the magnetic field of the active region on the Sun, but the trigger for flares is still uncertain. Currently, deep-learning-based solar flare prediction models have achieved good results and are widely recognized. However, these models focus more on data correlation rather than causality. An ideal flare prediction model should probe into the causes/triggers of solar flares, and diagnose the precursors of flares rather than just correlation analysis. To extract more informative precursors of flares from magnetograms, while suppressing the interference of confounding factors, a causal attention module is introduced to disentangle causal and confounder features from the input features. To address the problem of imbalanced positive and negative samples in the data set, an adaptive data set split mechanism is proposed. It divides the data set into several balanced subsets of positive and negative samples, and dynamically adjusts the subsets according to the model's prediction results during the training process. The experimental results demonstrate that our proposed model achieves 4.08%, 8.38%, and 2.19% higher accuracy, true skill score, and area under the receiver operating characteristic curve than the baseline model. Additionally, the class-specific heatmaps by using the gradient-weighted class activation mapping method reveal that our proposed model generally focuses on the polarity inverse line of active regions, well in line with theoretical study.

Transverse oscillation of prominence and filament induced by an EUV wave from the farside of the Sun

Yanjie **Zhang**, Qingmin Zhang, De-chao Song, Haisheng Ji
ApJ **2024**
https://arxiv.org/pdf/2401.15858.pdf
In this paper, we report our multi-angle observations of the transverse oscillation of a prominence and a filament induced by an EUV wave originating from the farside of the Sun on **2014 September 1**. The prominence oscillation was simultaneously observed by both Atmospheric Imaging Assembly (AIA) onboard the Solar Dynamics Observatory (SDO) spacecraft and Extreme-UltraViolet Imager (EUVI) onboard the Behind Solar Terrestrial Relations Observatory (STEREO) spacecraft. The speed of the shock travelling in the interplanetary space exceeds that of the EUV wave, and the coronal dimming area experiences minimal growth. This indicates that the shock wave is driven by the CME, while the EUV wave freely propagates after the lateral motion of the CME flanks has stopped. The observed oscillation direction of the prominence, determined through three-dimensional reconstruction, further supports this point. Moreover, The detailed investigation of the oscillations in the prominence and filament induced by the EUV wave reveals initial amplitudes of 16.08 and 2.15 Mm, periods of 1769 and 1863 s, damping time scales of 2640 and 1259 s, and damping ratios of 1.49 and 0.68, respectively. The radial component of magnetic field, as derived from the prominence and filament oscillation measurements, was estimated to be 5.4 G and 4.1 G, respectively. In turn, utilizing the onset times of both the prominence and filament oscillation, the average speeds of the EUV wave are determined to be 498 km s−1 and 451 km s−1, respectively.

Quasiperiodic Oscillations of Flare Loops and Slipping Motion of Ribbon Substructures during a C-class Flare

https://iopscience.iop.org/article/10.3847/1538-4357/ad5e69/pdf
Quasiperiodic oscillations in solar-flaring emission have been observed over the past few decades. To date, the underpinning processes resulting in the quasiperiodic oscillations remain unknown. In this paper, we report a unique event that exhibits both the long-duration quasiperiodic intensity oscillations of flare loops and the quasiperiodic slipping motion of ribbon substructures during a C9.1-class flare (SOL**2015-03-15**-T01:15), using the observations from the Solar Dynamics Observatory and Interface Region Imaging Spectrograph. The high-temperature flare loops rooted in the straight part of ribbons display a "bright–dim" intensity oscillation, with a period of about 4.5 minutes. The oscillation starts just after the flare onset and lasts over 3 hr. Meanwhile, the substructures within the ribbon tip display the quasiperiodic slipping motion along the ribbon at 1400 Å images, which has a similar periodicity to the stationary intensity oscillation of the flare loops in the straight part of the flare ribbons. We suggest that the quasiperiodic pattern is probably related to the loop-top dynamics caused by the reconnection outflow impinging on the flare loops.

Circular-ribbon flares and the related activities **Review**

Qingmin **Zhang**
Reviews of Modern Plasma Physics **2024**
https://arxiv.org/pdf/2401.16101.pdf
Solar flares are an impulsive increase of emissions as a result of impetuous release of magnetic free energy. In this paper, I will present the recent progress on circular-ribbon flares (CRFs) and their related activities, including coronal jets, filaments, coronal mass ejections (CMEs), radio bursts, coronal dimmings, and coronal loop oscillations. Owing to the prevalence of three-dimensional (3D) magnetic null points and the corresponding fan-spine topology in the solar atmosphere, CRFs are regularly observed in ultraviolet (UV), extreme-ultraviolet (EUV), and Hα passbands. Spine reconnection and fan reconnection around the null points are predominantly responsible for the energy release and subsequent particle acceleration. Slipping reconnection at quasi-separatrix layers (QSLs) may explain the sequential brightening or rapid degradation of the circular ribbons. Periodic or quasi-periodic acceleration and precipitation of nonthermal particles in the chromo- sphere produce observed quasi-periodic pulsations (QPPs) of CRFs in multiple altitudes as well as wavelengths. Like two-ribbon flares, the injected high-energy particles result in explosive evaporation in circular and inner ribbons, which is characterized by simultaneous blueshifts in the coronal emission lines and redshifts in the chromospheric emission lines. Homologous CRFs residing in the same active region present similar morphology, evolution, and energy partition. The peculiar topology of CRFs with closed outer spines facilitates remote brightenings and EUV late phases, which are uncommon in tworibbon flares. Besides, CRFs are often accompanied by coronal jets, type III radio bursts, CMEs, shock waves, coronal dimmings, and kink oscillations in coronal loops and filaments. Magnetohydrodynamics numerical simulations are very helpful to understand the key problems that are still unclear up to now. Multiwavelength and multipoint observations with state-of-the-art instruments are enormously desired to make a breakthrough. The findings in CRFs are important for a comprehensive understanding of solar flares and have implication for stellar flares. **2002-11-16, 2010-10-16, 2011-02-08, 6 Sep 2011, 7 Sep 2011, 23 Sep 2011, 2011-10-22, 2011-11-15, 2012 May 10 , 2012-07-14, 13 Jan 2013, 2013-03-02, 2013 November 5-6-7, 10 Nov 2013, 5 Mar 2014, 2014-04-16, 2014-08-24, 2014-12-17, 18 Dec 2014, 2015 March 10, 2015-04-20-21, 16 Oct 2015, 2016-01-09**

A Flare Observed in Coronal, Transition Region and Helium I 10830 ? Emissions

Zhicheng **Zeng**, Jiong Qiu, Wenda Cao, Philip G. Judge
2014 ApJ 793 87
http://arxiv.org/pdf/1408.0236v1.pdf
On **June 17, 2012**, we observed the evolution of a C-class flare associated with the eruption of a filament near a large sunspot in the active region NOAA 11504. We obtained high spatial resolution filtergrams using the 1.6 m New Solar Telescope at the Big Bear Solar Observatory in broad-band TiO at 706 nm (bandpass:10 ?) and He I 10830 ? narrow-band (bandpass: 0.5 ?, centered 0.25 ? to the blue). We analyze the spatio-temporal behavior of the He I 10830 ? data, which were obtained over a 90" X 90" field of view with a cadence of 10 sec. We also analyze simultaneous data from the Atmospheric Imaging Assembly and Extreme Ultraviolet Variability Experiment instruments on board the Solar Dynamics Observatory spacecraft, and data from Reuven Ramaty High Energy Solar Spectroscopic Imager and GOES spacecrafts. Non-thermal effects are ignored in this analysis. Several quantitative aspects of the data, as well as models derived using the "0D" Enthalpy-Based Thermal Evolution of Loops model (EBTEL: Klimchuk et al. 2008) code, indicate that the triplet states of the 10830 ? multiplet are populated by photoionization of chromospheric plasma followed by radiative recombination. Surprisingly, the He II 304 ? line is reasonably well matched by standard emission measure calculations, along with the C IV emission which dominates the AIA 1600 ? channel during flares. This work lends support to some of our previous work combining X-ray, EUV and UV data of flares to build models of energy transport from corona to chromosphere.

Quasi-periodic oscillations of flare loops and slipping motion of ribbon substructures during a C-class flare

Yining **Zhang**, Ting Li, Jing Ye

ApJ **2024**

https://arxiv.org/pdf/2407.03639

Quasi-periodic oscillations in solar flaring emission have been observed over the past few decades. To date, the underpinning processes resulting in the quasi-periodic oscillations remain unknown. In this paper, we report a unique event that exhibits both the long-duration quasi-periodic intensity oscillations of flare loops and the quasi-periodic slipping motion of ribbon substructures during a C9.1-class flare (SOL2015-03-15-T01:15), using the observations from Solar Dynamics Observatory and Interface Region Imaging Spectrograph. The high-temperature flare loops rooted in the straight part of ribbons display a "bright-dim" intensity oscillation, with a period of about 4.5 minutes. The oscillation starts just after the flare onset and lasts over 3 hours. Meanwhile, the substructures within the ribbon tip display the quasi-periodic slipping motion along the ribbon at 1400 Åimages which has a similar periodicity to the stationary intensity oscillation of the flare loops in the straight part of the flare ribbons. We suggest that the quasi-periodic pattern is probably related to the loop-top dynamics caused by the reconnection outflow impinging on the flare loops. **2015 March 15**

Plasma Dynamics and Nonthermal Particle Acceleration in 3D Nonrelativistic Magnetic Reconnection

Qile **Zhang**, Fan Guo, William Daughton, Xiaocan Li, Hui Li

ApJ **2024**

https://arxiv.org/pdf/2404.08807.pdf

Understanding plasma dynamics and nonthermal particle acceleration in 3D magnetic reconnection has been a long-standing challenge. In this paper, we explore these problems by performing large-scale fully kinetic simulations of multi-xline plasmoid reconnection with various parameters in both the weak and strong guide field regimes. In each regime, we have identified its unique 3D dynamics that leads to field-line chaos and efficient acceleration, and we have achieved nonthermal acceleration of both electrons and protons into power-law spectra. The spectral indices agree well with a simple Fermi acceleration theory that includes guide field dependence. In the low-guide-field regime, the flux-rope kink instability governs the 3D dynamics for efficient acceleration. The weak dependence of the spectra on the ion-to-electron mass ratio and β ($\ll 1$) implies that the particles are sufficiently magnetized for Fermi acceleration in our simulations. While both electrons and protons are injected at reconnection exhausts, protons are primarily injected by perpendicular electric fields through Fermi reflections and electrons are injected by a combination of perpendicular and parallel electric fields. The magnetic power spectra agree with in-situ magnetotail observations, and the spectral index may reflect a reconnection-driven size distribution of plasmoids instead of Goldreich-Sridhar vortex cascade. As the guide field becomes stronger, the oblique flux ropes of large sizes capture the main 3D dynamics for efficient acceleration. Intriguingly, the oblique flux ropes can also run into flux-rope kink instability to drive extra 3D dynamics. This work has broad implications for 3D reconnection dynamics and particle acceleration in heliophysics and astrophysics.

Energetics of a solar flare and a coronal mass ejection generated by a hot channel eruption

Qingmin **Zhang**, Weilin Teng, Dong Li, Jun Dai, Yanjie Zhang

ApJ **958** 85 **2023**

https://arxiv.org/pdf/2310.14010.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/ad05bc/pdf

Hot channels (HCs) are prevalent in the solar corona and play a critical role in driving flares and CMEs. In this paper, we estimate the energy contents of an X1.4 eruptive flare with a fast CME generated by a HC eruption on **2011 September 22**. Originating from NOAA AR11302, the HC is the most dramatic feature in 131 and 94 Å images observed by SDO/AIA. The flare is simultaneously observed by SDO/AIA, RHESSI, and STEREO-B/EUVI. The CME is simultaneously detected by the white-light coronagraphs of SOHO/LASCO and STEREO-B/COR1. Using multiwavelength and multiview observations of the eruption, various energy components of the HC, flare, and CME are calculated. The thermal and kinetic energies of the HC are (1.77±0.61)×1030 erg and (2.90±0.79)×1030 erg, respectively. The peak thermal energy of the flare and total radiative loss of SXR-emitting plasma are (1.63±0.04)×1031 erg and (1.03−1.31)×1031 erg, respectively. The ratio between the thermal energies of HC and flare is 0.11±0.03, suggesting that thermal energy of the HC is not negligible. The kinetic and potential energies of the CME are (3.43±0.94)×1031 erg and (2.66±0.49)×1030 erg, yielding a total energy of (3.69±0.98)×1031 erg for the CME. Continuous heating of the HC is required to balance the rapid cooling by heat conduction, which probably originate from intermittent magnetic reconnection at the flare current sheet. Our investigation may provide insight into the buildup, release, and conversion of energies in large-scale solar eruptions.

Observations of magnetic reconnection and particle acceleration locations in solar coronal jets

Yixian **Zhang**, Sophie Musset, Lindsay Glesener, Navdeep Panesar, Gregory Fleishman

ApJ **943** 180 **2023**

https://arxiv.org/pdf/2207.05668.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/aca654/pdf

We present a multi-wavelength analysis of two flare-related jets on **November 13, 2014**, using data from SDO/AIA, RHESSI, Hinode/XRT, and IRIS. Unlike most coronal jets where hard X-ray (HXR) emissions are usually observed near the jet base, in these events HXR emissions are found at several locations, including in the corona. We carry out the first differential emission measure (DEM) analysis that combines both AIA (and XRT when available) bandpass filter data and RHESSI HXR measurements for coronal jets, and obtain self-consistent results across a wide temperature range and into non-thermal energies. In both events, hot plasma first appeared at the jet base, but as the base plasma gradually cooled, hot plasma also appeared near the jet top. Moreover, non-thermal electrons, while only mildly energetic, are found in multiple HXR locations and contain a large amount of total energy. Particularly, the energetic electrons that produced the HXR sources at the jet top were accelerated near the top location, rather than traveling from a reconnection site at the jet base. This means that there was more than one particle acceleration site in each event. Jet velocities are consistent with previous studies, including upward and downward velocities around ~200 km/s and ~100 km/s respectively, and fast outflows of 400-700 km/s. We also examine the energy partition in the later event, and find that the non-thermal energy in accelerated electrons is most significant compared to other energy forms considered. We discuss the interpretations and provide constraints on mechanisms for coronal jet formation.

Multi-species Ion Acceleration in 3D Magnetic Reconnection

Qile **Zhang**, Fan Guo, William Daughton, Hui Li, Ari Le, Tai Phan, Mihir Desai

2022

https://arxiv.org/pdf/2210.04113.pdf

Magnetic reconnection drives explosive particle acceleration in a wide range of space and astrophysical applications. The energized particles often include multiple species (electrons, protons, heavy ions), but the underlying acceleration mechanism is poorly understood. In-situ observations of these minority heavy ions offer a more stringent test of acceleration mechanisms, but the multi-scale nature of reconnection hinders studies on heavy-ion acceleration. Here we employ hybrid simulations (fluid electron, kinetic ions) to capture 3D reconnection over an unprecedented range of scales. For the first time, our simulations demonstrate nonthermal acceleration of all available ion species into power-law spectra. The reconnection layers consist of fragmented kinking flux ropes as part of the reconnection-driven turbulence, which produces field-line chaos critical for accelerating all species. The upstream ion velocities influence the first Fermi reflection for injection. Then lower charge/mass species initiate Fermi acceleration at later times as they interact with growing flux ropes. The resulting spectra have similar power-law indices ($p \sim 4.5$), but different maximum energy/nucleon $\propto$(charge/mass)α, with $\alpha \sim 0.6$ for low plasma β, and with p and α increasing as β approaches unity. These findings are consistent with observations at heliospheric current sheets and the magnetotail, and provide strong evidence suggesting Fermi acceleration as the dominant ion-acceleration mechanism.

Solar Flare Index Prediction Using SDO/HMI Vector Magnetic Data Products with Statistical and Machine Learning Methods

ApJS **263** 28 **2022**

https://arxiv.org/pdf/2209.13779.pdf

https://iopscience.iop.org/article/10.3847/1538-4365/ac9b17/pdf

Solar flares, especially the M- and X-class flares, are often associated with coronal mass ejections (CMEs). They are the most important sources of space weather effects, that can severely impact the near-Earth environment. Thus it is essential to forecast flares (especially the M-and X-class ones) to mitigate their destructive and hazardous consequences. Here, we introduce several statistical and Machine Learning approaches to the prediction of the AR's Flare Index (FI) that quantifies the flare productivity of an AR by taking into account the numbers of different class flares within a certain time interval. Specifically, our sample includes 563 ARs appeared on solar disk from May 2010 to Dec 2017. The 25 magnetic parameters, provided by the Space-weather HMI Active Region Patches (SHARP) from Helioseismic and Magnetic Imager (HMI) on board the Solar Dynamics Observatory (SDO), characterize coronal magnetic energy stored in ARs by proxy and are used as the predictors. We investigate the relationship between these SHARP parameters and the FI of ARs with a machine-learning algorithm (spline regression) and the resampling method (Synthetic Minority Over-Sampling Technique for Regression with Gaussian Noise, short by SMOGN). Based on the established relationship, we are able to predict the value of FIs for a given AR within the next 1-day period. Compared with other 4 popular machine learning algorithms, our methods improve the accuracy of FI prediction, especially for large FI. In addition, we sort the importance of SHARP parameters by Borda Count method calculated from the ranks that are rendered by 9 different machine learning methods.

First detection of transverse vertical oscillation during the expansion of coronal loops

Qingmin **Zhang**, Chuan Li, Dong Li, Ye Qiu, Yanjie Zhang, Yiwei Ni

ApJL **2022**

https://arxiv.org/pdf/2209.00194.pdf

In this Letter, we perform a detailed analysis of the M5.5-class eruptive flare occurring in active region 12929 on **2022 January 20**. The eruption of a hot channel generates a fast coronal mass ejection (CME) and a dome-shaped extreme-ultraviolet (EUV) wave at speeds of 740−860 km s−1. The CME is associated with a type II radio burst, implying that the EUV wave is a fast-mode shock wave. During the impulsive phase, the flare shows quasi-periodic pulsations (QPPs) in EUV, hard X-ray, and radio wavelengths. The periods of QPPs range from 18 s to 113 s, indicating that flare energy is released and nonthermal electrons are accelerated intermittently with multiple time scales. The interaction between the EUV wave and low-lying adjacent coronal loops (ACLs) results in contraction, expansion, and transverse vertical oscillation of ACLs. The speed of contraction in 171, 193, and 211 Å is higher than that in 304 Å. The periods of oscillation are 253 s and 275 s in 304 Å and 171 Å, respectively. A new scenario is proposed to explain the interaction. The equation that interprets the contraction and oscillation of the overlying coronal loops above a flare core can also interpret the expansion and oscillation of ACLs, suggesting that the two phenomena are the same in essence.

Sunspot shearing and sudden retraction motion associated with the 2013 August 17 M3.3 Flare

Yanjie **Zhang**, Zhe Xu, Qingmin Zhang, Jun Dai, Haisheng Ji

ApJ **933** L20 **2022**

https://arxiv.org/pdf/2206.09156.pdf

https://iopscience.iop.org/article/10.3847/2041-8213/ac79b7/pdf

In this Letter, we give a detailed analysis to the M3.3 class flare that occurred on **August 17, 2013** (SOL2013-08-17T18:16). It presents a clear picture of mutual magnetic interaction initially from the photosphere to the corona via the abrupt rapid shearing motion of a small sunspot before the flare, and then suddenly from the corona back to the photosphere via the sudden retraction motion of the same sunspot during the flare impulsive phase. About 10 hours before the flare, a small sunspot in the active region NOAA 11818 started to move northeast along a magnetic polarity inversion line (PIL), creating a shearing motion that changed the quasi-static state of the active region. A filament right above the PIL was activated following the movement of the sunspot and then got partially erupted. The eruption eventually led to the M3.3 flare. The sunspot was then suddenly pulled back to the opposite direction upon the flare onset. During the backward motion, the Lorentz force underwent a simultaneous impulsive change both in magnitude and direction. Its directional change is found to be conformable with the retraction motion. The observation provides direct evidence for the role of the shearing motion of the sunspot in powering and triggering the flare. It especially confirms that the abrupt motion of a sunspot during a solar flare is the result of a back reaction caused by the reconfiguration of the coronal magnetic field.

Two-dimensional modeling of the tearing-mode-governed magnetic reconnection in the large-scale current sheet above the two-ribbon flare

Yining **Zhang**, Jing Ye, Zhixing Mei, Yan Li, Jun Lin

Research in Astronomy and Astrophysics **2022**

https://arxiv.org/pdf/2206.04484.pdf

We attempt to model magnetic reconnection during the two-ribbon flare in the gravitationally stratified solar atmosphere with the Lundquist number of S=106 using 2D simulations. We found that the tearing mode instability leads to the inhomogeneous turbulence inside the reconnecting current sheet (CS) and invokes the fast phase of reconnection. Fast reconnection brings an extra dissipation of magnetic field which enhances the reconnection rate in an apparent way. The energy spectrum in the CS shows the power-law pattern and the dynamics of plasmoids governs the associated spectral index. We noticed that the energy dissipation occurs at a scale lko of 100-200~km, and the associated CS thickness ranges from 1500 to 2500~km, which follows the Taylor scale lT=lkoS1/6. The termination shock(TS) appears in the turbulent region above flare loops, which is an important contributor to heating flare loops. Substantial magnetic energy is converted into both kinetic and thermal energies via TS, and the cumulative heating rate is greater than the rate of the kinetic energy transfer. In addition, the turbulence is somehow amplified by TS, of which the amplitude is related to the local geometry of the TS.

Implications for additional plasma heating driving the extreme-ultraviolet late phase of a solar flare with microwave imaging spectroscopy

Jiale **Zhang**, Bin Chen, Sijie Yu, Hui Tian, Yuqian Wei, Hechao Chen, Guangyu Tan, Yingjie Luo, Xingyao Chen

ApJ **2022**

https://arxiv.org/pdf/2205.03518.pdf **File**

Extreme-ultraviolet late phase (ELP) refers to the second extreme-ultraviolet (EUV) radiation enhancement observed in certain solar flares, which usually occurs tens of minutes to several hours after the peak of soft X-ray emission. The coronal loop system that hosts the ELP emission is often different from the main flaring arcade, and the enhanced EUV emission therein may imply an additional heating process. However, the origin of the ELP remains rather unclear. Here we present the analysis of a C1.4 flare that features such an ELP, which is also observed in microwave wavelengths by the Expanded Owens Valley Solar Array (EOVSA). Similar to the case of the ELP, we find a gradual microwave enhancement that occurs about three minutes after the main impulsive phase microwave peaks. Radio sources coincide with both footpoints of the ELP loops and spectral fits on the time-varying microwave spectra demonstrate a clear deviation of the electron distribution from the Maxwellian case, which could result from injected nonthermal electrons or nonuniform heating to the footpoint plasma. We further point out that the delayed microwave enhancement suggests the presence of an additional heating process, which could be responsible for the evaporation of heated plasma that fills the ELP loops, producing the prolonged ELP emission. **July 14th, 2017**

Statistical analysis of circular-ribbon flares

Yanjie **Zhang**, Qingmin Zhang, Dechao Song, Shuting Li, Jun Dai, Zhe Xu, Haisheng Ji
Astrophysical Journal Supplement Series **260** 19 **2022**
https://arxiv.org/pdf/2203.12819.pdf
https://iopscience.iop.org/article/10.3847/1538-4365/ac5f4c/pdf
Circular-ribbon flares (CFs) are a special type of solar flares owing to their particular magnetic topology. In this paper, we conducted a comprehensive statistical analysis of 134 CFs from 2011 September to 2017 June, including four B-class, 82 C-class, 40 M-class, and eight X-class flares, respectively. The flares were observed by the Atmospheric Imaging Assembly (AIA) on board the Solar Dynamics Observatory (SDO) spacecraft. The physical properties of CFs are derived, including the location, area (ACF), equivalent radius (rCF) assuming a semi-spherical fan dome, lifetime (τCF), and peak SXR flux in 1−8 Å. It is found that all CFs are located in active regions, with the latitudes between -30∘ and 30∘. The distributions of areas and lifetimes could be fitted with a log-normal function. There is a positive correlation between the lifetime and area. The peak SXR flux in 1−8 Å is well in accord with a power-law distribution with an index of −1.42. For the 134 CFs, 57\% of them are accompanied by remote brightenings or ribbons. A positive correlation exists between the total length (LRB) and average distance (DRB) of remote brightenings. About 47\% and 51\% of the 134 CFs are related to type III radio bursts and jets, respectively. The association rates are independent of flare energies. About 38\% of CFs are related to mini-filament eruptions, and the association rates increase with flare classes. Only 28\% of CFs are related to CMEs, meaning that a majority of them are confined rather than eruptive events. There is a positive correlation between the CME speed and peak SXR flux in 1−8 Å, and faster CMEs tend to be wider. **7 Sep 2011, 8 May 2012, 13 Jan 2013, 10 Nov 2013, 28 Dec 2013, 18 Apr 2014, 17 Dec 2014, 16 Oct 2015**

X-ray fine structure of a limb solar flare revealed by Insight-HXMT, RHESSI and Fermi

Ping **Zhang**, Wei Wang, Yang Su, Shuangnan Zhang, Liming Song, Fangjun Lu, Shu Zhang
Research in A&A Volume 22, Issue 5, id.055006, 9 pp **2022**
https://arxiv.org/pdf/2202.12600.pdf
We conduct a detailed analysis of an M1.3 limb flare occurring on **2017 July 3**, which have the X-ray observations recorded by multiple hard X-ray telescopes, including Hard X-ray Modulation Telescope (Insight-HXMT), Ramaty High Energy Solar Spectroscopic Imager (RHESSI), and The Fermi Gamma-ray Space Telescope (FERMI). Joint analysis has also used the EUV imaging data from the Atmospheric Imaging Assembly (AIA) aboard the Solar Dynamic Observatory. The hard X-ray spectral and imaging evolution suggest a lower corona source, and the non-thermal broken power law distribution has a rather low break energy ~ 15 keV. The EUV imaging shows a rather stable plasma configuration before the hard X-ray peak phase, and accompanied by a filament eruption during the hard X-ray flare peak phase. Hard X-ray image reconstruction from RHESSI data only shows one foot point source. We also determined the DEM for the peak phase by SDO/AIA data. The integrated EM beyond 10 MK at foot point onset after the peak phase, while the > 10 MK source around reconnection site began to fade. The evolution of EM and hard X-ray source supports lower corona plasma heating after non-thermal energy dissipation. The combination of hard X-ray spectra and images during the limb flare provides the understanding on the interchange of non-thermal and thermal energies, and relation between lower corona heating and the upper corona instability.

Non-thermal electron energization during the impulsive phase of an X9.3 flare revealed by Insight-HXMT

P. **Zhang**, W. Wang, Y. Su, L.M. Song, C.K. Li, D.K. Zhou, S.N. Zhang, H. Tian, S.M. Liu, H.S. Zhao, S. Zhang
ApJ **918** 42 **2021**
https://arxiv.org/pdf/2106.09506.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/ac0cfb/pdf
https://doi.org/10.3847/1538-4357/ac0cfb
The X9.3 flare SOL**20170906**T11:55 was observed by the CsI detector aboard the first Chinese X-ray observatory Hard X-ray Modulation telescope (Insight-HXMT). By using wavelets method, we report about 22 s quasiperiodic pulsations(QPPs) during the impulsive phase. And the spectra from 100 keV to 800 keV showed the evolution with the gamma-ray flux, of a power-law photon index from ∼1.8 before the peak, ∼2.0 around the flare peak, to ∼1.8 again. The gyrosynchrotron microwave spectral analysis reveals a $36.6 \pm 0.6 \arcsec$ radius gyrosynchrotron source with mean transverse magnetic field around 608.2 Gauss, and the penetrated ≥ 10 keV non-thermal electron density is about 106.7cm−3 at peak time. The magnetic field strength followed the evolution of high-frequency radio flux. Further gyrosynchrotron source modeling analysis implies that there exists a quite steady gyrosynchrotron source, the non-thermal electron density and transverse magnetic field evolution are similar to higher-frequency light curves. The temporally spectral analysis reveals that those non-thermal electrons are accelerated by repeated magnetic reconnection, likely from a lower corona source.

Efficient Nonthermal Ion and Electron Acceleration Enabled by the Flux-Rope Kink Instability in 3D Nonrelativistic Magnetic Reconnection

Qile **Zhang**, Fan Guo, William Daughton, Xiaocan Li, Hui Li
2021
https://arxiv.org/pdf/2105.04521.pdf
The relaxation of field-line tension during magnetic reconnection gives rise to a universal Fermi acceleration process involving the curvature drift of particles. However, the efficiency of this mechanism is limited by the trapping of energetic particles within flux ropes. Using 3D fully kinetic simulations, we demonstrate that the flux-rope kink instability leads to field-line chaos in weak-guide-field regimes where the Fermi mechanism is most efficient, thus allowing particles to transport out of flux ropes and undergo further acceleration. As a consequence, both ions and electrons develop clear power-law energy spectra which contain a significant fraction of the released energy. The low-energy bounds are determined by the injection physics, while the high-energy cutoffs are limited only by the system size. These results have strong relevance to observations of nonthermal particle acceleration in both the magnetotail and solar corona.

Energy partition in a confined flare with an extreme-ultraviolet late phase

Q. M. **Zhang**, J. X. Cheng, Y. Dai, K. V. Tam, A. A. Xu
A&A 650, A88 **2021**
https://arxiv.org/pdf/2104.03677.pdf
https://www.aanda.org/articles/aa/pdf/2021/06/aa38082-20.pdf
https://doi.org/10.1051/0004-6361/202038082
In this paper, we reanalyze the M1.2 confined flare with a large extreme-ultraviolet (EUV) late phase on **2011 September 9**, focusing on its energy partition. The radiation (∼5.4×1030 erg) in 1−70 Å is nearly eleven times larger than the radiation in 70−370 Å, and is nearly 180 times larger than the radiation in 1−8 Å. The peak thermal energy of the post-flare loops is estimated to be (1.7−1.8)×1030 erg based on a simplified schematic cartoon. Based on previous results of Enthalpy-Based Thermal Evolution of Loops (EBTEL) simulation, the energy inputs in the main flaring loops and late-phase loops are (1.5−3.8)×1029 erg and 7.7×1029 erg, respectively. The nonthermal energy ((1.7−2.2)×1030 erg) of the flare-accelerated electrons is comparable to the peak thermal energy and is sufficient to provide the energy input of the main flaring loops and late-phase loops. The magnetic free energy (9.1×1031 erg) before flare is large enough to provide the heating requirement and radiation, indicating that the magnetic free energy is adequate to power the flare.

Spectroscopic observations of a flare-related coronal jet

Q. M. **Zhang**, Z. H. Huang, Y. J. Hou, D. Li, Z. J. Ning, Z. Wu
A&A **2021**
https://arxiv.org/pdf/2101.06629.pdf
Coronal jets are ubiquitous in active regions (ARs) and coronal holes. In this paper, we study a coronal jet related to a C3.4 circular-ribbon flare in active region 12434 on **2015 October 16**. Two minifilaments were located under a 3D fan-spine structure before flare. The flare was generated by the eruption of one filament. The kinetic evolution of the jet was divided into two phases: a slow rise phase at a speed of ∼131 km s−1 and a fast rise phase at a speed of ∼363 km s−1 in the plane-of-sky. The slow rise phase may correspond to the impulsive reconnection at the breakout current sheet. The fast rise phase may correspond to magnetic reconnection at the flare current sheet. The transition between the two phases occurred at ∼09:00:40 UT. The blueshifted Doppler velocities of the jet in the Si {\sc iv} 1402.80 Å line range from -34 to -120 km s−1. The accelerated high-energy electrons are composed of three groups. Those propagating upward along open field generate type \textrm{III} radio bursts, while those propagating downward produce HXR emissions and drive chromospheric condensation observed in the Si {\sc iv} line. The electrons trapped in the rising filament generate a microwave burst lasting for ≤40 s. Bidirectional outflows at the base of jet are manifested by

significant line broadenings of the Si {\sc iv} line. The blueshifted Doppler velocities of outflows range from -13 to -101 km s−1. The redshifted Doppler velocities of outflows range from ∼17 to ∼170 km s−1. Our multiwavelength observations of the flare-related jet are in favor of the breakout jet model and are important for understanding the acceleration and transport of nonthermal electrons.

Simultaneous transverse oscillations of a coronal loop and a filament excited by a circular-ribbon flare

Q. M. **Zhang**
A&A 642, A159 **2020**
https://arxiv.org/pdf/2008.01451.pdf
https://doi.org/10.1051/0004-6361/202038557To investigate the excitation of kink oscillations in coronal loops and filaments, a C3.4 circular-ribbon flare (CRF) associated with a blowout jet in active region 12434 on **2015 October 16** is analyzed. The flare excited small-amplitude kink oscillation of a remote coronal loop. The oscillation lasted for ≥4 cycles without significant damping. The amplitude and period are 0.3±0.1 Mm and 207±12 s. Interestingly, the flare also excited transverse oscillation of a remote filament. The oscillation lasted for ∼3.5 cycles with decaying amplitudes. The initial amplitude is 1.7−2.2 Mm. The period and damping time are 437−475 s and 1142−1600 s. The starting times of simultaneous oscillations of coronal loop and filament were concurrent with the hard X-ray peak time. Though small in size and short in lifetime, the flare set off a chain reaction. It generated a bright secondary flare ribbon (SFR) in the chromosphere, remote brightening (RB) that was cospatial with the filament, and intermittent, jet-like flow propagating in the northeast direction. The loop oscillation is most probably excited by the flare-induced blast wave at a speed of ≥1300 km s−1. The excitation of the filament oscillation is more complicated. The blast wave triggers secondary magnetic reconnection far from the main flare, which not only heats the local plasma to higher temperatures (SFR and RB), but produces jet-like flow (i.e., reconnection outflow) as well. The filament is disturbed by the secondary magnetic reconnection and experiences transverse oscillation. The findings give new insight into the excitation of transverse oscillations of coronal loops and filaments.

Transverse coronal loop oscillations excited by homologous circular-ribbon flares

Q. M. **Zhang**, J. Dai, Z. Xu, D. Li, L. Lu, K. V. Tam, A. A. Xu
A&A 638, A32 **2020**
https://arxiv.org/pdf/2005.02067.pdf
https://www.aanda.org/articles/aa/pdf/2020/06/aa38233-20.pdf
We report our multiwavelength observations of two homologous circular-ribbon flares (CRFs) in active region 11991 on **2014 March 5**, focusing on the transverse oscillations of an extreme-ultraviolet (EUV) loop excited by the flares. The transverse oscillations are of fast standing kink-mode. The first-stage oscillation triggered by the C2.8 flare is decayless with lower amplitudes (310−510 km). The periods (115−118 s) in different wavelengths are nearly the same, indicating coherent oscillations. The magnetic field of the loop is estimated to be 65−78 G. The second-stage oscillation triggered by the M1.0 flare is decaying with larger amplitudes (1250−1280 km). The periods decreases from 117 s in 211 Å to 70 s in 171 Å, implying a decrease of loop length or an implosion after a gradual expansion. The damping time, being 147−315 s, increases with the period, so that the values of τ/P are close to each other in different wavelengths. The thickness of the inhomogeneous layer is estimated to be ∼0\farcs45 under the assumption of resonant absorption. This is the first observation of the excitation of two kink-mode loop oscillations by two sympathetic flares. The results are important for understanding of the excitation of kink oscillations of coronal loops and hence the energy balance in the solar corona. Our findings also validate the prevalence of significantly amplified amplitudes of oscillations by successive drivers.

Fast degradation of the circular flare ribbon on 2014 August 24

Q. M. **Zhang**, S. H. Yang, T. Li, Y. J. Hou, Y. Li
A&A L 636, L11 **2020**
https://arxiv.org/pdf/2004.06837.pdf
https://doi.org/10.1051/0004-6361/202038072
The separation and elongation motions of solar flare ribbons have extensively been investigated. The degradation and disappearance of ribbons have rarely been explored. In this paper, we report our multiwavelength observations of a C5.5 circular-ribbon flare associated with two jets (jet1 and jet2) on **2014 August 24**, focusing on the fast degradation of the outer circular ribbon (CR). The flare, consisting of a short inner ribbon (IR) and outer CR, was triggered by the eruption of a minifilament. The brightness of IR and outer CR reached their maxima simultaneously at ∼04:58 UT in all AIA wavelengths. Subsequently, the short eastern part of CR faded out quickly in 1600 Å but gradually in EUV wavelengths. The long western part of CR degraded in the counterclockwise direction and experienced a deceleration. The degradation was distinctly divided into two phases: phase I with faster apparent speeds (58−69 km s−1) and phase II with slower apparent speeds (29−35 km s−1). The second phase stopped at ∼05:10 UT when the western CR totally disappeared. Besides the outward propagation of jet1, the jet spire experienced untwisting motion in the counterclockwise direction during 04:55−05:00 UT. We conclude that the event can be explained by the breakout jet

model. The coherent brightenings of the IR and CR at ~04:58 UT may result from the impulsive interchange reconnection near the null point, whereas sub-Alfvénic slipping motion of the western CR in the counterclockwise direction indicates the occurrence of slipping magnetic reconnection. Another possible explanation of the quick disappearance of the hot loops connecting to the western CR is that they are simply reconnected sequentially without the need for significant slippage after the null point reconnection.

Longitudinal filament oscillations enhanced by two C-class flares

Q. M. **Zhang**, J. H. Guo, K. V. Tam, A. A. Xu

A&A 635, A132 **2020**

https://arxiv.org/pdf/2001.01250.pdf

https://doi.org/10.1051/0004-6361/201937291

Context. Large-amplitude, longitudinal filament oscillations triggered by solar flares have been well established in the literature. However, filament oscillations enhanced by flares have never been reported.

Aims. In this paper we report the multiwavelength observations of a very long filament in active region (AR) 11112 on **2010 October 18**. The filament was composed of two parts, the eastern part (EP) and the western part (WP). We focus on longitudinal oscillations of the EP, which were enhanced by two homologous C-class flares in the same AR.

Methods. The filament was observed in Hα wavelength by the Global Oscillation Network Group and in extreme ultraviolet wavelengths by the Atmospheric Imaging Assembly on board the Solar Dynamics Observatory (SDO). Line-of-sight magnetograms were provided by the Helioseismic and Magnetic Imager on board SDO. The global three-dimensional magnetic fields were obtained using the potential field source surface modeling. Soft X-ray light curves of the two flares were recorded by the GOES spacecraft. White light images of the corona were observed by the LASCO/C2 coronagraph on board SOHO. To reproduce part of the observations, we perform one-dimensional, hydrodynamic numerical simulations using the MPI-AMRVAC code.

Results. The C1.3 flare was confined without a coronal mass ejection (CME). Both EP and WP of the filament were slightly disturbed and survived the flare. After 5 h, eruption of the WP generated a C2.6 flare and a narrow jet-like CME. Three oscillating threads (thda, thdb, thdc) are obviously identified in the EP, and their oscillations are naturally divided into three phases by the two flares. The initial amplitude ranges from 1.6 to 30 Mm with a mean value of ~14 Mm. The period ranges from 34 to 73 min with a mean value of ~53 min. The curvature radii of the magnetic dips are estimated to be 29 to 133 Mm with a mean value of ~74 Mm. The damping times ranges from ~62 to ~96 min with a mean value of ~82 min. The value of τ/P is between 1.2 and 1.8. For thda in the EP, the amplitudes were enhanced by the two flares from 6.1 Mm to 6.8 Mm after the C1.3 flare, and further to 21.4 Mm after the C2.6 flare. The period variation as a result of perturbation from the flares was within 20%. The attenuation became faster after the C2.6 flare.

Conclusions. To the best of our knowledge, this is the first report of large-amplitude, longitudinal filament oscillations enhanced by flares. Numerical simulations reproduce the oscillations of thda very well. The simulated amplitudes and periods are close to the observed values, while the damping time in the last phase is longer, implying additional mechanisms should be taken into account apart from radiative loss.

Remote coronal dimmings related to a circular-ribbon flare

Q. M. **Zhang**, R. S. Zheng

A&A **2020**

https://arxiv.org/pdf/1912.09618.pdf

In this paper, multiwavelength observations of remote coronal dimmings related to an M1.1 circular-ribbon flare (CRF) in active region (AR) 12434 are reported. The confined flare without a CME was observed by AIA and HMI on board SDO on **2015 October 16**. Global three-dimensional (3D) magnetic fields before flare were obtained using the potential field source surface modeling. A few minutes before the flare hard X-ray peak time (06:13:48 UT), small-scale, weak dimming appeared ~240$\arcsec$ away from the flare site, which can be observed by AIA only in 131 and 171 Å. Afterwards, long and narrow dimmings became evident in all AIA EUV passbands except 304 Å, while localized core dimming was not clearly observed near the flare site. The large-area dimmings extended southeastward and the areas increased gradually. The total area of dimmings reaches (1.2±0.4)×104 Mm2 in 193 Å. The maximal relative intensity decreases in 171 and 193 Å reach 90\% and 80\%, respectively. Subsequently, the dimmings began to replenish and the area decreased slowly, lasting for ≥3 hr. The remote dimmings and AR 12434 were connected by large-scale coronal loops. The remote dimmings were associated with the southwest footpoints of coronal loops with weak negative polarities. Possible origins of remote dimmings are discussed.

A magnetic confinement nuclear fusion mechanism for solar flares

Ying-Zhi **Zhang**

Research in Astronomy and Astrophysics **2019**

https://arxiv.org/pdf/1912.00193.pdf

We propose a magnetic confinement nuclear fusion mechanism for the evolution of a solar flare in solar atmosphere. The mechanism agree with two observed characteristics of explosive flares and coronal mass ejections (CMEs) that

have proved to be very difficult to explain with previous mechanisms: the huge enrichments of 3He and the high energy gamma ray radiation. The twisted magnetic flux rope is a typical structure during the solar flares, which is closely related to the solar active region that magnetic fields have almost complete control over the plasma. Consequently, the plasma inside the flux rope is heated to more than 1.0×107 K by adiabatic compression process, and then the thermonuclear fusion can take place in the flux rope accompanied with high energy gamma rays. We utilize the time-dependent ideal 2.5-dimensional magnetohydrodynamic (MHD) simulation to demonstrate the physical mechanism for producing flares, which reveals three stages of flare development with process of magnetic energy conversion and intense release during the solar flares and CMEs in solar atmosphere. Furthermore, we discuss the relationship between magnetic reconnection and solar eruptions.

Energy partition in two M-class circular-ribbon flares

Q. M. **Zhang**, J. X. Cheng, L. Feng, Y. Su, L. Lu, Y. Huang, D. Li, T. H. Zhou, J. L. Chen
ApJ **883** 124 **2019**
https://arxiv.org/pdf/1908.02685.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ab3a52/pdf
In this paper, we investigate the energy partition of two homologous M1.1 circular-ribbon flares (CRFs) in active region (AR) 12434. They were observed by \textit{SDO}, \textit{GOES}, and \textit{RHESSI} on **2015 October 15 and 16**, respectively. The peak thermal energy, nonthermal energy of flare-accelerated electrons, total radiative loss of hot plasma, and radiant energies in 1−8 {\AA} and 1−70 {\AA} of the flares are calculated. The two flares have similar energetics. The peak thermal energies are (1.94±0.13)×1030 erg. The nonthermal energies in flare-accelerated electrons are (3.9±0.7)×1030 erg. The radiative outputs of the flare loops in 1−70 {\AA}, which are ∼200 times greater than the outputs in 1−8 {\AA}, account for ∼62.5\% of the peak thermal energies. The radiative losses of SXR-emitting plasma are one order of magnitude lower than the peak thermal energies. Therefore, the total heating requirements of flare loops including radiative loss are (2.1±0.1)×1030 erg, which could sufficiently be supplied by nonthermal electrons.

Imaging observations of chromospheric evaporation in a circular-ribbon flare

Q. M. **Zhang**, D. Li, Y. Huang
ApJ 870 109 **2019**
https://arxiv.org/pdf/1811.11363.pdf
http://iopscience.iop.org/article/10.3847/1538-4357/aaf4b7/pdf
In this paper, we report our multiwavelength imaging observations of chromospheric evaporation in a C5.5 circular-ribbon flare (CRF) on **2014 August 24**. The flare was observed by the Atmospheric Imaging Assembly (AIA) on board the \textit{Solar Dynamics Observatory} (\textit{SDO}), X-ray Telescope (XRT) on board the \textit{Hinode} spacecraft, and ground-based Nobeyama Radioheliograph (NoRH). The CRF consisted of a discrete circular ribbon with a diameter of ∼1$\arcmin$ and a short inner ribbon observed in ultraviolet (UV), extreme-ultraviolet (EUV), soft X-ray (SXR), and especially in 17 GHz. The peak time (∼04:58 UT) of the flare in 17 GHz coincided with that in UV 1600 Å and SXR derivative as a hard X-ray proxy, implying the peak time of impulsive energy deposition in the lower atmosphere. Shortly after the peak time, converging motion and filling process in the flare loop were revealed in AIA 131 Å and two XRT filters (Be_thin and Be_med), which are clear evidence for chromospheric evaporation upflows. The chromospheric evaporation lasted for ∼6 minutes until ∼05:04 UT. The temperature, density, and apparent velocities of the upflows are ∼107 K, ∼1.8×1010 cm−3, and 50−630 km s−1 with a mean value of ∼170 km s−1. By comparison with previous models, we are able to estimate that energies above 5×1010 erg cm−2 s−1 are likely needed to explain the observational results. Since heating by thermal conduction does not seem to provide enough energy, alternative mechanisms such as nonthermal electrons or Alfvénic waves might need to be invoked.

Impulsive radio and hard X-ray emission from an M-class flare

Ping **Zhang**1,2,4, Yang Guo3, Lu Wang1,2 and Siming Liu
A&A 615, A48 (**2018**)
https://www.aanda.org/articles/aa/pdf/2018/07/aa31274-17.pdf
Context. Impulsive radio and hard X-ray emission from large solar flares are usually attributed to a hard distribution of high-energy electrons accelerated in the energy dissipation process of magnetic reconnection.
Aims. We report the detection of impulsive radio and hard X-ray emissions produced by a population of energetic electrons with a very soft distribution in an M-class flare: SOL**2015-08-27**T05:45 .
Methods. The absence of impulsive emission at 34 GHz and hard X-ray emission above 50 keV and the presence of distinct impulsive emission at 17 GHz and lower frequencies and in the 25–50 keV X-ray band imply a very soft distribution of energetic electrons producing the impulsive radio emission via the gyro-synchrotron process, and impulsive X-rays via bremsstrahlung.
Results. The spectrum of the impulsive hard X-ray emission can be fitted equally well with a power-law model with an index of ∼6.5 or a super-hot thermal model with a temperature as high as 100 MK. Imaging observations in the extreme-UV and X-ray bands and extrapolation of the magnetic field structure using a nonlinear force-free model show that energetic electrons trapped in coronal loops are responsible for these impulsive emissions.

Conclusions. Since the index of the power-law model is nearly constant during the impulsive phase, the power-law distribution or the super-hot component should be produced by a bulk energization process such as the Fermi and betatron acceleration of collapsing magnetic loops.

Propagating wave in active region-loops, located over the solar disk observed by the Interface Region Imaging Spectrograph

B. **Zhang**, Y. J. Hou, J. Zhang
A&A **2018**
https://arxiv.org/pdf/1801.02880.pdf
We aim to ascertain the physical parameters of a propagating wave over the solar disk detected by the Interface Region Imaging Spectrograph (IRIS). Using imaging data from the IRIS and the Solar Dynamic Observatory (SDO), we tracked bright spots to determine the parameters of a propagating transverse wave in active region (AR) loops triggered by activation of a filament. Deriving the Doppler velocity of Si IV line from spectral observations of IRIS, we have determined the rotating directions of active region loops which are relevant to the wave. On **2015 December 19**, a filament was located on the polarity inversion line of the NOAA AR 12470. The filament was activated and then caused a C 1.1 two-ribbon flare. Between the flare ribbons, two rotation motions of a set of bright loops were observed to appear in turn with opposite directions. Following the end of the second rotation, a propagating wave and an associated transverse oscillation were detected in these bright loops. In 1400 A channel, there was bright material flowing along the loops in a wave-like manner, with a period of ~128 s and a mean amplitude of ~880 km. For the transverse oscillation, we tracked a given loop and determine the transverse positions of the tracking loop in a limited longitudinal range. In both of 1400 A and 171 A channels, approximately four periods are distinguished during the transverse oscillation. The mean period of the oscillation is estimated as ~143 s and the displacement amplitude as between ~1370 km and ~690 km. We interpret these oscillations as a propagating kink wave and obtain its speed of ~1400 km s-1. Our observations reveal that a flare associated with filament activation could trigger a kink propagating wave in active region loops over the solar disk.

Simultaneous transverse and longitudinal oscillations in a quiescent prominence triggered by a coronal jet

Qingmin **Zhang**, Dong Li, Zongjun Ning
ApJ **2017**
https://arxiv.org/pdf/1711.00670.pdf
In this paper, we report our multiwavelength observations of the simultaneous transverse and longitudinal oscillations in a quiescent prominence on **2015 June 29**. A C2.4 flare took place in active region 12373, which was associated with a pair of short ribbons and a remote ribbon. During the impulsive phase of the flare, a coronal jet spurted out of the primary flare site and propagated in the northwest direction at an apparent speed of ~224 km s−1. Part of the jet stopped near the remote ribbon. The remaining part continued moving forward before stopping to the east of prominence. Once the jet encountered the prominence, it pushed the prominence to oscillate periodically. The transverse oscillation of the eastern part (EP) of prominence can be divided into two phases. In phase I, the initial amplitude, velocity, period, and damping timescale are ~4.5 Mm, ~20 km s−1, ~25 minutes, and ~7.5 hr, respectively. In phase II, the initial amplitude increases to ~11.3 Mm while the initial velocity halves to ~10 km s−1. The period increases by a factor of ~3.5. The western part (WP) of prominence also experienced transverse oscillation. The initial amplitude is only ~2 Mm and the velocity is less than 10 km s−1. The period (~27 minutes) is slightly longer than that of EP in phase I. To the east of prominence, a handful of horizontal threads experienced longitudinal oscillation. The initial amplitude, velocity, period, and damping timescale are ~52 Mm, ~50 km s−1, ~99 minutes, and 2.5 hr, respectively. To our knowledge, this is the first report of simultaneous transverse and longitudinal prominence oscillations triggered by a coronal jet.

Are complex magnetic field structures responsible for the confined X-class flares in super active region 12192?

Jun **Zhang**, Ting Li, Huadong Chen
ApJ **845** 54 **2017**
https://arxiv.org/pdf/1707.03171.pdf
http://sci-hub.cc/10.3847/1538-4357/aa7e7d
From **2014 October 19 to 27**, six X-class flares occurred in super active region (AR) 12192. They were all confined flares and were not followed by coronal mass ejections (CMEs). To examine the structures of the four flares close to the solar disk center from October 22 to 26, we employ firstly composite triple-time images in each flare process to display {the stratified structure} of these flare loops. The loop structures of each flare in both lower (171 {\AA}) and higher (131 {\AA}) temperature channels are complex, e.g., the flare loops rooting at flare ribbons are sheared or twisted (enwound) together, and the complex structures have not been destroyed during the flares. For the first flare, although the flare loop system appears as a spindle shape, we can estimate their structure from observations, with lengths ranging

from 130 to 300 Mm, heights from 65 to 150 Mm, widths at the middle part of the spindle from 40 to 100 Mm, and shear angles from 16∘ to 90∘. Moreover, the flare ribbons display irregular movements, such as the left ribbon fragments of the flare on 22 swept a small region repeatedly, and the both ribbons of the flare on 26 moved along the same direction, instead of separating from each other. These irregular movements also imply that the corresponding flare loops are complex, e.g. several sets of flare loops are twisted together. Although previous studies suggest that the background magnetic fields prevent confined flares from erupting, we firstly suggest based on these observations that the complex flare loop structures may be responsible for these confined flares. **2014 September 10, October 22, 24, 25, 26 2014**

Photospheric Magnetic Free Energy Density of Solar Active Regions

Hongqi **Zhang**
Solar Phys. **2016**
We present the photospheric energy density of magnetic fields in two solar active regions (one of them recurrent) inferred from observational vector magnetograms, and compare it with other available differently defined energy parameters of magnetic fields in the photosphere. We analyze the magnetic fields in Active Regions NOAA 6580-6619-6659 and 11158. The quantity \(\frac{1}{4\pi}{\mathbf{B}}_{n}\cdot{\mathbf{B}}_{p}\) is an important energy parameter that reflects the contribution of magnetic shear to the difference between the potential (\(\mathbf{B}_{p}\)) and the non-potential magnetic field (\(\mathbf{B}_{n}\)), and also the contribution to the free magnetic energy near the magnetic neutral lines in the active regions. It is found that the photospheric mean magnetic energy density shows clear changes before the powerful solar flares in Active Region NOAA 11158, which is consistent with the change in magnetic fields in the flaring lower atmosphere. **April 14, 1991, May 11, 1991, June 9, 1991, 13-16 Feb 2011**

Pre-flare coronal dimmings

Q. M. **Zhang**, Y. N. Su, H. S. Ji
A&A 598, A3 (**2017**)
https://arxiv.org/pdf/1611.08371v1.pdf
In this paper, we focus on the pre-flare coronal dimmings. We report our multiwavelength observations of the GOES X1.6 solar flare and the accompanying halo CME produced by the eruption of a sigmoidal magnetic flux rope (MFR) in NOAA active region (AR) 12158 on **2014 September 10**. The eruption was observed by the Atmospheric Imaging Assembly (AIA) aboard the Solar Dynamic Observatory (SDO). The photospheric line-of-sight magnetograms were observed by the Helioseismic and Magnetic Imager (HMI) aboard SDO. The soft X-ray (SXR) fluxes were recorded by the GOES spacecraft. The halo CME was observed by the white light coronagraphs of the Large Angle Spectroscopic Coronagraph (LASCO) aboard SOHO.} {About 96 minutes before the onset of flare/CME, narrow pre-flare coronal dimmings appeared at the two ends of the twisted MFR. They extended very slowly with their intensities decreasing with time, while their apparent widths (8−9 Mm) nearly kept constant. During the impulsive and decay phases of flare, typical fanlike twin dimmings appeared and expanded with much larger extent and lower intensities than the pre-flare dimmings. The percentage of 171 {\AA} intensity decrease reaches 40\%. The pre-flare dimmings are most striking in 171, 193, and 211 {\AA} with formation temperatures of 0.6−2.5 MK. The northern part of the pre-flare dimmings could also be recognized in 131 and 335 {\AA}.} To our knowledge, this is the first detailed study of pre-flare coronal dimmings, which can be explained by the density depletion as a result of the gradual expansion of the coronal loop system surrounding the MFR during the slow rise of the MFR.

Chromospheric Condensation and Quasi-periodic Pulsations in a Circular-ribbon Flare

Q. M. **Zhang**, D. Li, Z. J. Ning
ApJ 832 65 **2016**
http://arxiv.org/pdf/1609.03165v1.pdf
In this paper, we report our multiwavelength observations of the C3.1 circular-ribbon flare SOL**2015-10-16**T10:20 in AR 12434. The flare consisted of a circular flare ribbon (CFR), an inner flare ribbon (IFR) inside, and a pair of short parallel flare ribbons (PFRs). During the impulsive phase of the flare, "two-step" raster observations of \textit{IRIS} with a cadence of 6 s and an exposure time of 2 s show plasma downflow at the CFR in the Si {\sc iv} λ 1402.77 line, suggesting chromospheric condensation. The downflow speeds first increased rapidly from a few km s−1 to the peak values of 45−52 kms−1, before decreasing gradually to the initial levels. The decay timescales of condensation were 3−4 minutes, indicating ongoing magnetic reconnection. Interestingly, the downflow speeds are positively correlated with logarithm of the Si {\sc iv} line intensity and time derivative of the \textit{GOES} soft X-ray (SXR) flux in 1−8 {\AA}. The radio dynamic spectra are characterized by a type \Rmnum{3} radio burst associated with the flare, which implies that the chromospheric condensation was most probably driven by nonthermal electrons. Using an analytical expression and the peak Doppler velocity, we derived the lower limit of energy flux of the precipitating electrons, i.e., 0.65×1010 erg cm−2 s−1. The Si {\sc iv} line intensity and SXR derivative show quasi-periodic pulsations with periods of 32−42 s.

Photospheric Magnetic Free Energy Density of Solar Active Regions

Hongqi **Zhang**
Solar Phys. Volume 291, Issue 12, pp 3501–3517 **2016**
http://arxiv.org/pdf/1608.07805v1.pdf
We present the photospheric energy density of magnetic fields in two solar active regions inferred from observational vector magnetograms, and compare it with the possible different defined energy parameters of magnetic fields in the photosphere. We analyze the magnetic fields in active region NOAA 6580-6619-6659 and 11158. It is noticed that the quantity 1/4pi Bn.Bp is an important energy parameter that reflects the contribution of magnetic shear on the difference between the potential magnetic field (Bp) and non-potential one (Bn), and also the contribution to the free magnetic energy near the magnetic neutral lines in the active regions. It is found that the photospheric mean magnetic energy density changes obviously before the powerful solar flares in the active region NOAA 11158, it is consistent with the change of magnetic fields in the lower atmosphere with flares. **1991 June, 2011 February 15**

Explosive Chromospheric Evaporation in a Circular-ribbon Flare

Q. M. **Zhang**, D. Li, Z. J. Ning, Y. N. Su, H. S. Ji, Y. Guo
ApJ **827** 27 **2016**
http://arxiv.org/pdf/1605.02823v1.pdf
In this paper, we report our multiwavelength observations of the C4.2 circular-ribbon flare in active region (AR) 12434 on **2015 October 16**. The short-lived flare was associated with positive magnetic polarities and a negative polarity inside, as revealed by the photospheric line-of-sight magnetograms. Such magnetic pattern is strongly indicative of a magnetic null point and spine-fan configuration in the corona. The flare was triggered by the eruption of a mini-filament residing in the AR, which produced the inner flare ribbon (IFR) and the southern part of a closed circular flare ribbon (CFR). When the eruptive filament reached the null point, it triggered null point magnetic reconnection with the ambient open field and generated the bright CFR and a blowout jet. Raster observations of the \textit{Interface Region Imaging Spectrograph} (\textit{IRIS}) show plasma upflow at speed of 35−120 km s−1 in the Fe {\sc xxi} 1354.09 {\AA} line (logT≈7.05) and downflow at speed of 10−60 km s−1 in the Si {\sc iv} 1393.77 {\AA} line (logT≈4.8) at certain locations of the CFR and IFR during the impulsive phase of flare, indicating explosive chromospheric evaporation. Coincidence of the single HXR source at 12−25 keV with the IFR and calculation based on the thick-target model suggest that the explosive evaporation was most probably driven by nonthermal electrons.

Secondary Flare Ribbons Observed by the Solar Dynamics Observatory

Jun **Zhang**, Ting Li, and Shuhong Yang
2014 ApJ 782 L27
Using the observations from the Atmospheric Imaging Assembly (AIA) and the Helioseismic and Magnetic Imager on board the Solar Dynamics Observatory, we statistically investigate the flare ribbons (FRs) of **19 X-class flares of the 24th solar cycle from 2010 June to 2013 August**. Of these 19 flares, the source regions of 16 can be observed by AIA and the FRs of each flare are well detected, and 11 of the 16 display multiple ribbons. Based on the ribbon brightness and the relationship between the ribbons and post-flare loops, we divide the multiple ribbons into two types: normal FRs, which are connected by post-flare loops and have been extensively investigated, and secondary flare ribbons (SFRs), which are weaker than the FRs, not connected by post-flare loops, and always have a short lifetime. Of the 11 SFRs, 10 appear simultaneously with the FRs, and none of them have post-flare loops. The last one, on the other hand, appears 80 minutes later than the FR, lasts almost two hours, and also has no post-flare loops detected. We suggest that the magnetic reconnection associated with this SFR is triggered by the blast wave that results from the main flare. These observations imply that in some flare processes, more than two sets of magnetic loops or more than twice the number of magnetic reconnections are involved.

Electron Acceleration in a Dynamically Evolved Current Sheet Under Solar Coronal Conditions

Shaohua **Zhang**, A. M. Du, Xueshang Feng, Xin Cao, Quanming Lu, Liping Yang, Gengxiong Chen, Ying Zhang
Solar Physics. May **2014**, Volume 289, Issue 5, pp 1607-1623
Electron acceleration in a drastically evolved current sheet under solar coronal conditions is investigated via the combined 2.5-dimensional (2.5D) resistive magnetohydrodynamics (MHD) and test-particle approaches. Having a high magnetic Reynolds number (105), the long, thin current sheet is torn into a chain of magnetic islands, which grow in size and coalesce with each other. The acceleration of electrons is explored in three typical evolution phases: when several large magnetic islands are formed (phase 1), two of these islands are approaching each other (phase 2), and almost merging into a “monster” magnetic island (phase 3). The results show that for all three phases electrons with an initial Maxwell distribution evolve into a heavy-tailed distribution and more than 20 % of the electrons can be accelerated higher than 200 keV within 0.1 second and some of them can even be energized up to MeV ranges. The lower-energy electrons are located away from the magnetic separatrices and the higher-energy electrons are inside the magnetic islands. The most energetic electrons have a tendency to be around the outer regions of the magnetic islands

or to appear in the small secondary magnetic islands. It is the trapping effect of the magnetic islands and the distributions of E p that determine the acceleration and spatial distributions of the energetic electrons.

A swirling flare-related EUV jet

Q. M. **Zhang** and H. S. Ji

E-print, Dec **2013**, A&A 561, A134 (**2014**)

We report our observations of a swirling flare-related EUV jet on **2011 October 15** at the edge of NOAA active region 11314.} {We utilised the multiwavelength observations in the extreme-ultraviolet (EUV) passbands from the Atmospheric Imaging Assembly (AIA) aboard the Solar Dynamics Observatory (SDO). We extracted a wide slit along the jet axis and 12 thin slits across its axis to investigate the longitudinal motion and transverse rotation. We also used data from the Extreme-Ultraviolet Imager (EUVI) aboard the Solar TErrestrial RElations Observatory (STEREO) spacecraft to investigate the three-dimensional (3D) structure of the jet. Gound-based Hα images from the El Teide as a member of the Global Oscillation Network Group (GONG) provide a good opportunity to explore the relationship between the cool surge and hot jet. Line-of-sight magnetograms from the Helioseismic and Magnetic Imager (HMI) aboard SDO enable us to study the magnetic evolution of the flare/jet event. We carried out potential-field extrapolation to figure out the magnetic configuration associated with the jet.} {The onset of jet eruption coincided with the start time of C1.6 flare impulsive phase. The initial velocity and acceleration of the longitudinal motion were 254pm10 km s-1 and -97pm5 m s-2, respectively. The jet presented helical structure and transverse swirling motion at the beginning of its eruption. The counter-clockwise rotation slowed down from an average velocity of ~122 km s-1 to ~80 km s-1. The interwinding thick threads of the jet untwisted into multiple thin threads during the rotation that lasted for 1 cycle with a period of ~7 min and an amplitude that increases from ~3.2 Mm at the bottom to ~11 Mm at the upper part. Afterwards, the curtain-like leading edge of the jet continued rising without rotation, leaving a dimming region behind before falling back to the solar surface. The appearance/disappearance of dimming corresponded to the longitudinal ascending/descending motions of jet. Cospatial Hα surge and EUV dimming imply that the dimming resulted from the absorption of hot EUV emission by cool surge. The flare/jet event was caused by continuous magnetic cancellation before the start of flare. The jet was associated with the open magnetic fields at the edge of AR 11314.

Magnetic Reconnection: From "Open" Extreme-ultraviolet Loops to Closed Post-flare Ones Observed by SDO

Jun **Zhang**1, Shuhong Yang1, Ting Li1, Yuzong Zhang1, Leping Li1, and Chaowei Jiang

E-print, Nov **2013; 2013** ApJ 776 57

We employ Solar Dynamics Observatory observations and select three well-observed events including two flares and one extreme-ultraviolet (EUV) brightening. During the three events, the EUV loops clearly changed. One event was related to a major solar flare that took place on **2012 July 12** in active region NOAA AR 11520. "Open" EUV loops rooted in a facula of the AR deflected to the post-flare loops and then merged with them while the flare ribbon approached the facula. Meanwhile, "open" EUV loops rooted in a pore disappeared from top to bottom as the flare ribbon swept over the pore. The loop evolution was similar in the low-temperature channels (e.g., 171 Å) and the high-temperature channels (e.g., 94 Å). The coronal magnetic fields extrapolated from the photospheric vector magnetograms also show that the fields apparently "open" prior to the flare become closed after it. The other two events were associated with a B1.1 flare on **2010 May 24** and an EUV brightening on **2013 January 03**, respectively. During both of these two events, some "open" loops either disappeared or darkened before the formation of new closed loops. We suggest that the observations reproduce the picture predicted by the standard magnetic reconnection model: "open" magnetic fields become closed due to reconnection, manifesting as a transformation from "open" EUV loops to closed post-flare ones.

EMERGING DIMMINGS OF ACTIVE REGIONS OBSERVED BY THE SOLAR DYNAMICS OBSERVATORY

Jun **Zhang**1, Shuhong Yang1, Yang Liu2, and Xudong Sun

2012 ApJ 760 L29

Using the observations from the Atmospheric Imaging Assembly and the Helioseismic and Magnetic Imager on board the Solar Dynamics Observatory, we statistically investigate the emerging dimmings (EDs) of 24 isolated active regions (IARs) from 2010 June to 2011 May. All the IARs show EDs in lower-temperature lines (e.g., 171 Å) at their early emerging stages. Meanwhile, in higher temperature lines (e.g., 211 Å), the ED regions brighten continuously. There are two types of EDs: fan-shaped and halo-shaped. There are 19 fan-shaped EDs and 5 halo-shaped ones. The EDs appear to be delayed by several to more than ten hours relative to the first emergence of the IARs. The shortest delay is 3.6 hr and the longest is 19.0 hr. The EDs last from 3.3 hr to 14.2 hr, with a mean duration of 8.3 hr. Before the appearance of the EDs, the emergence rate of the magnetic flux of the IARs is between 1.2 × 1019 Mx hr–1 to 1.4 × 1020 Mx hr–1. The larger the emergence rate is, the shorter the delay time is. While the dimmings appear, the magnetic flux of the IARs ranges from 8.8 × 1019 Mx to 1.3 × 1021 Mx. These observations imply that the reconfiguration of the coronal magnetic fields due to reconnection between the newly emerging flux and the surrounding existing fields results in a

new thermal distribution which leads to a dimming for the cooler channel (171 Å) and brightening in the warmer channels.

Statistical Studies on the Excess Peak Flux in Soft X-rays and EUV Bands from Solar Flares

D. H. **Zhang**, L. Cai, A. Ercha, Y. Q. Hao and Z. Xiao
Solar Physics, Volume 280, Number 1 (**2012**), 183-196
Based on the solar X-ray data in the band of 0.1 – 0.8 nm observed by Geostationary Operational Environmental Satellites (GOES), the XUV and EUV data in the bands of 26 – 34 nm and 0.1 – 50 nm observed by the Solar EUV Monitor (SEM) onboard the Solar and Heliospheric Observatory (SOHO), a statistical analysis on the excess peak flux (the pre-flare flux is subtracted) in two SEM bands during M- and X-class flares from 1998 to 2007 is given. The average ratio of the excess peak flux to the pre-flare flux for the M-class flares is 5.5 %±3.7 % and that for the X-class flares is 16 %±11 %. The excess peak fluxes in two SEM bands are positively correlated with the X-ray flare class; with the increase in the X-ray flare class, the excess peak flux in two SEM bands increases. However, a large dispersion in the excess peak flux in the SEM bands and their ratio is found for the same X-ray flare class. The relationship between the excess peak fluxes of the two SEM bands also shows large dispersion. It is considered that the diversity we found in the flare spectral irradiance is caused by many variable factors related to the structure and evolution of solar flares.

MAGNETIC HELICITY TRANSPORTED BY FLUX EMERGENCE AND SHUFFLING MOTIONS IN SOLAR ACTIVE REGION NOAA 10930

Y**. Zhang**1,2, R. Kitai2, and K. Takizawa
2012 ApJ 751 85
We present a new methodology which can determine magnetic helicity transport by the passage of helical magnetic field lines from the sub-photosphere and the shuffling motions of footpoints of preexisting coronal field lines separately. It is well known that only the velocity component, which is perpendicular to the magnetic field ($\upsilon \perp B$), has contributed to the helicity accumulation. Here, we demonstrate that $\upsilon \perp B$ can be deduced from a horizontal motion and vector magnetograms under a simple relation of $\upsilon t = \mu t + (\upsilon n / Bn) B t$, as suggested by Démoulin & Berger. Then after dividing $\upsilon \perp B$ into two components, as one is tangential and the other is normal to the solar surface, we can determine both terms of helicity transport. Active region (AR) NOAA 10930 is analyzed as an example during its solar disk center passage by using data obtained by the Spectropolarimeter and the Narrowband Filter Imager of Solar Optical Telescope on board Hinode. We find that in our calculation the helicity injection by flux emergence and shuffling motions have the same sign. During the period we studied, the main contribution of helicity accumulation comes from the flux emergence effect, while the dynamic transient evolution comes from the shuffling motions effect. Our observational results further indicate that for this AR the apparent rotational motion in the following sunspot is the real shuffling motions on the solar surface.

Statistical Properties of Solar Active Regions Obtained from an Automatic Detection System and the Computational Biases

Jie **Zhang**, Yuming Wang and Yang Liu
2010 ApJ 723 1006-1018, **File**
We have developed a computational software system to automate the process of identifying solar active regions (ARs) and quantifying their physical properties based on high-resolution synoptic magnetograms constructed from Michelson Doppler Imager (MDI; on board the SOHO spacecraft) images from 1996 to 2008. The system, based on morphological analysis and intensity thresholding, has four functional modules: (1) intensity segmentation to obtain kernel pixels, (2) a morphological opening operation to erase small kernels, which effectively remove ephemeral regions and magnetic fragments in decayed ARs, (3) region growing to extend kernels to full AR size, and (4) the morphological closing operation to merge/group regions with a small spatial gap. We calculate the basic physical parameters of the 1730 ARs identified by the auto system. The mean and maximum magnetic flux of individual ARs are 1.67 × 1022 Mx and 1.97 × 1023 Mx, while that per Carrington rotation are 1.83 × 1023 Mx and 6.96 × 1023 Mx, respectively. The frequency distributions of ARs with respect to both area size and magnetic flux follow a log-normal function. However, when we decrease the detection thresholds and thus increase the number of detected ARs, the frequency distribution largely follows a power-law function. We also find that the equatorward drifting motion of the AR bands with solar cycle can be described by a linear function superposed with intermittent reverse driftings. The average drifting speed over one solar cycle is or 0.708 ± 0.015 m s-1.

FINE MAGNETIC FEATURES AND CHIRALITY IN SOLAR ACTIVE REGION NOAA 10930

Hongqi **Zhang**
Astrophysical Journal, 716:1493–1502, **2010** June
In this paper, we present fine magnetic features near the magnetic inversion line in the solar active region NOAA

10930. The high-resolution vector magnetograms obtained by *Hinode* allow detailed analyses around magnetic fibrils in the active region. The analyses are based on the fact that the electric current density can be divided into two components: the shear component caused by the magnetic inhomogeneity and the twist component caused by the magnetic field twist. The relationships between magnetic field, electric current density, and its two components are examined. It is found that the individual magnetic fibrils are dominated by the current density component caused by the magnetic inhomogeneity, while the large-scale magnetic region is generally dominated by the electric current component associated with the magnetic twist. The microstructure of the magnetic field in the solar atmosphere is far from the force-free field. The current mainly flows around the magnetic flux fibrils in the active regions.

A Statistical Study on the Relationship between the Transport Rate of Magnetic Helicity and Solar Flares

Yin **Zhang**, Baolin Tan, Yihua Yan
E-print, Sept **2009;** Astrophysical Journal, 704:1622–1627, **2009** October
We present in this paper a statistical study of which is aimed at understanding the fact that some flares (type I flare) are associated with sharp variations of the transport rate of the magnetic helicity (dH/dt) and others not (type II flare). The sample consists of 49 M-class and X-class flares which produced by 9 isolated active regions. Used high temporal magnetograms obtained by the Michelson Doppler Imager (MDI) instrument on the Solar and Heliospheric Observatory (SOHO), we calculate the temporal variation of dH/dt during the flaring time, and compare its profile with the soft X-ray flux. We find that type I flares have longer duration and higher peak flux in soft X-ray than type II flares. Furthermore, the ratio of total unsigned magnetic flux of the host active region to that of the visible solar disk is also higher for type I flares, while the total flux itself is independent of the flare type. Our results show that whether the flare is associated with sharp variations of dH/dt depends on the properties of the flare and of its host active region. The relationship between dH/dt and microwave bursts is also discussed.

Relationship between Rotating Sunspots and Flares

Yin **Zhang** · Jihong Liu · Hongqi Zhang
Solar Phys (**2008**) 247: 39–52
http://www.springerlink.com/content/w54x26500vx51732/fulltext.pdf
Active Region (AR) NOAA 10486 was a super AR in the declining phase of solar cycle 23. Dominated by the rapidly rotating positive polarity of an extensive δ sunspot, it produced several powerful flare-CMEs. We study the evolution and properties of the rotational motion of the major poles of positive polarities and estimate the accumulated helicity injected by them.We also present two homologous flares that occurred in the immediate periphery of the rotating sunspots.
This suggests that the rotational motions of sunspots not only relate to the transport of magnetic energy and complexity from the low atmosphere to the corona but may also play a key role in the onset of the homologous flares.

Interaction between a Fast Rotating Sunspot and Ephemeral Regions as the Origin of the Major Solar Event on 2006 December 13

Jun **Zhang**, Leping Li, and Qiao Song
The Astrophysical Journal Letters, Volume 662, Number 1, Page L35-L38, **2007**
The major solar event on 2006 December 13 is characterized by the approximately simultaneous occurrence of a heap of hot ejecta, a great two-ribbon flare, and an extended Earth-directed coronal mass ejection. We examine the magnetic field and sunspot evolution in NOAA AR 10930, the source region of the event, while it transited the solar disk center from December 10 to 13. We find that the obvious changes in the active region associated with the event are the development of magnetic shear, the appearance of ephemeral regions, and fast rotation of a smaller sunspot. Around the area of the magnetic neutral line of the active region, interaction between the fast rotating sunspot and the ephemeral regions triggers continual brightening and finally the major flare. This indicates that only after the sunspot rotates up to 200° does the major event take place. The sunspot rotates at least 240° about its center, the largest sunspot rotation angle that has been reported.

Comprehensive Analysis of a Filament-embedding Solar Active Region at Different Stages of Evolution

Jie **Zhao**1, Fu Yu1, Sarah E. Gibson2, Yuhong Fan2, Yang Su1,3, Ying Li1,3, Jun Dai1, Hui Li1,3, Chuan Li4,5,6, Pengfei Chen4,5Show full author list

https://iopscience.iop.org/article/10.3847/2041-8213/ad3555/pdf
Active regions are the brightest structures seen in the solar corona, so their physical properties hold important clues to the physical mechanisms underlying coronal heating. In this work, we present a comprehensive study for a filament-embedding active region as determined from observations from multiple facilities including the Chinese Hα Solar Explorer. We find three types of dynamic features that correspond to different thermal and magnetic properties, i.e., the

overlying loops—1 MK cool loops, the moss region—2–3 MK hot loops' footprints, and the sigmoidal filament. The overlying cool loops, which have a potential field, always show Doppler blueshifts at the east footprint and Doppler redshifts at the west, indicating a pattern of "siphon flow." The moss-brightening regions, which sustain the hot loops that have a moderate sheared field, always show downward Doppler redshifts at the chromosphere, which could be a signature of plasma condensing into the inner region adjacent to the filament. The sigmoidal filament, which has strongly sheared field lines along the polarity inversion line, however, shows a different Doppler velocity pattern in its middle part, i.e., an upward Doppler blueshift at the double-J-shaped stage indicating tether-cutting reconnection during the filament channel formation and then a downward redshift showing the plasma condensation for the sigmoidal filament formation. The present work shows overall properties of the filament-embedding active region, constraining the heating mechanisms of different parts of the active region and providing hints regarding the mass loading of the embedded filament. **2022 February 14–17**

SDO/HMI Captured Another Limb Flare in Continuum Intensity → 2022 May 3

Junwei **Zhao**, Wei Liu, Jean-Claude Vial
HMI Science Nuggets #179 May **2022** http://hmi.stanford.edu/hminuggets/?p=3900

A Survey and Statistical Study of Off-Limb Events Observed in SDO/HMI Continuum Intensity.

Zhao, J.S., Liu, Y.
Sol Phys 298, 148 (**2023**).
https://doi.org/10.1007/s11207-023-02240-4
Several strong eruptive events that occurred near the solar limb were reported generating off-limb features detectable in the SDO/HMI's continuum intensity. These observations offer new insights into the emission mechanisms of off-limb flaring loops, magnetic strength in the loops, and electron density distributions, among others. However, only a limited number of such events were reported, and it is unclear whether off-limb white-light features are popular or only associated with specific eruptions. In this study, we surveyed all the flaring events that occurred between May 2010 and August 2023 with a magnitude stronger than M2.0 and a heliographic longitude larger than 65◦. We found that among the 189 flares that met our selection criteria, 78 (41.3%) had off-limb features associated with them. Further statistical analysis showed, unsurprisingly, that the stronger the flare, the more likely it has an off-limb white-light feature, and the closer the flare is to the limb, the more likely an off-limb feature is detectable. We then categorized these off-limb white-light events into four types, closed-loop eruptions, open-loop eruptions, fast ejection, and flare arcades, and identified the events with visible flare ribbons. Coupling two examples of the white-light observations with simultaneous UV/EUV observations, we demonstrate the usefulness of the former in studying the flare dynamics and emission mechanisms. Our catalogue provides a rather complete list of the off-limb white-light events, which will benefit the community interested in studying such events.

White-light Continuum Observation of the Off-limb Loops of the SOL2017-09-10 X8.2 Flare: Temporal and Spatial Variations

Junwei **Zhao**, Wei Liu, Jean-Claude Vial
ApJ Letters **921** L26 **2021**
https://arxiv.org/pdf/2110.14130.pdf
https://iopscience.iop.org/article/10.3847/2041-8213/ac3339/pdf
https://doi.org/10.3847/2041-8213/ac3339
Observations of the Sun's off-limb white-light (WL) flares offer rare opportunities to study the energy release and transport mechanisms in flare loops. One of the best such events was SOL2017-09-10, an X8.2 flare that occurred near the Sun's west limb on **2017 September 10** and produced a WL loop system lasting more than 60 minutes and reaching an altitude higher than 30 Mm. The event was well observed by a suite of ground- and space-based instruments, including the Solar Dynamics Observatory/Helioseismic and Magnetic Imager (SDO/HMI) that captured its off-limb loops in WL continuum near Fe I 6173 A, and the Atmospheric Imager Assembly (SDO/AIA) that observed its ultraviolet (UV) and extreme-ultraviolet (EUV) counterparts. We found quasi-periodic pulsations in the WL and UV emissions at the flare loop-top with a period around 8.0 min. Each pulsation appears to have an EUV counterpart that occurs earlier in time and higher in altitude. Despite many similarities in the WL and UV images and light curves, the WL flux at the loop-top continues to grow for about 16 minutes while the UV fluxes gradually decay. We discuss the implication of these unprecedented observations on the understanding of the enigmatic off-limb WL flare emission mechanisms.
HMI Science Nuggets #167 Oct **2021** http://hmi.stanford.edu/hminuggets/?p=3713

Waves of Magnetic-field Variations Observed in a Flare-excited Sunquake Event

Junwei **Zhao**1 and Ruizhu Chen1,2
2018 ApJL 860 L29 DOI 10.3847/2041-8213/aacbd6

We report on the detection of waves of magnetic-field variations that were associated with flare-excited sunquake waves. An X-9.3 flare that occurred on **2017 September 6** excited strong sunquakes, and the sunquake waves were observed sweeping across the flare's host active region. This rare event gives us an unprecedented opportunity to study responses of magnetic field to passing sunquake waves. A wave of magnetic-field variations was observed in each of the two sunspots that the sunquake waves swept through, and the time–distance relations for the waves observed in magnetic field and Doppler velocity are similar. The phase relations measured between, as well as the oscillatory power distributions calculated from, the Doppler velocity variations and magnetic-field variations associated with the sunquake waves are compared with those obtained from the background waves in the same areas of the sunspot umbra and penumbra separately. The phase relations seem to favor the theory that the waves of magnetic variations are owing to opacity changes associated with the passing sunquake waves. The comparisons of phases and power distributions indicate that the background magnetic variations observed in sunspots are a combination of various wave modes, and fast magnetoacoustic waves only account for a fraction of those magnetic variations.
HMI Science Nuggets #105 **2018** http://hmi.stanford.edu/hminuggets/?p=2579

Hooked flare ribbons and flux-rope related QSL footprints

Jie **Zhao**, Stuart A. Gilchrist, Guillaume Aulanier, Brigitte Schmieder, Etienne Pariat, Hui Li
ApJ **823** 62 **2014**
http://arxiv.org/pdf/1603.07563v1.pdf
We studied the magnetic topology of active region 12158 on **2014 September 10** and compared it with the observations before and early in the flare which begins at 17:21 UT (SOL2014-09-10T17:45:00). Our results show that the sigmoidal structure and flare ribbons of this active region observed by SDO/AIA can be well reproduced from a Grad-Rubin non linear force free field extrapolation method. Various inverse-S and -J shaped magnetic field lines, that surround a coronal flux rope, coincide with the sigmoid as observed in different extreme ultraviolet wavelengths, including its multi-threaded curved ends. Also, the observed distribution of surface currents in the magnetic polarity where it was not prescribed is well reproduced. This validates our numerical implementation and set-up of the Grad-Rubin method. The modeled double inverse-J shaped Quasi-Separatrix Layer (QSL) footprints match the observed flare ribbons during the rising phase of the flare, including their hooked parts. The spiral-like shape of the latter may be related to a complex pre-eruptive flux rope with more than one turn of twist, as obtained in the model. These ribbon-associated flux-rope QSL-footprints are consistent with the new standard flare model in 3D, with the presence of a hyperbolic flux tube located below an inverse tear drop shaped coronal QSL. This is a new step forward forecasting the locations of reconnection and ribbons in solar flares, and the geometrical properties of eruptive flux ropes.
See **ERRATUM** **2016** ***ApJ*** 825 **80**

Temporal Evolution of the Magnetic Topology of the NOAA Active Region 11158

Jie **Zhao**, Hui Li, Etienne Pariat, Brigitte Schmieder, Yang Guo, Thomas Wiegelmann
2014, ApJ
http://arxiv.org/pdf/1404.5004v1.pdf
We studied the temporal evolution of the magnetic topology of the active region (AR) 11158 based on the reconstructed three-dimensional magnetic elds in the corona. The non-linear force-free eld (NLFFF) extrapolation method was applied to the 12 minutes cadence data obtained with the Helioseismic and Magnetic Imager (HMI) onboard the Solar Dynamics Observatory (SDO) during ve days. By calculating the squashing degree factor Q in the volume, the derived quasi-separatrix layers (QSLs) show that this AR has an overall topology, resulting from a magnetic quadrupole, including an hyperbolic ux tube (HFT) con guration which is relatively stable at the time scale of the are (1 □ 2 hours). A strong QSL, which corresponds to some highly sheared arcades that might be related to the formation of a ux rope, is prominent just before the **M6.6 and X2.2** ares, respectively. These facts indicate the close relationship between the strong QSL and the high are productivity of AR 11158. In addition, with a close inspection of the topology, we found a small-scale HFT which has an inverse teardrop structure above the aforementioned QSL before the X2.2 are. It indicates the existence of magnetic ux rope at this place. Even though a global con guration (HFT) is recognized in this AR, it turns out that the large-scale HFT only plays a secondary role during the eruption. In nal, we dismiss a trigger based on the breakout model and highlight the central role of the ux rope in the related eruption.

Statistical Study of Emerging Flux Regions and the Upper Atmosphere Response

Zhao, Jie; Li, Hui
E-print, July **2012**, RAA
We statistically study the property of emerging flux regions (EFRs) and the upper solar atmosphere response to the flux emergence by using data from the Helioseismic and Magnetic Imager (HMI) and the Atmospheric Imaging Assembly (AIA) on board the Solar Dynamics Observatory (SDO). Parameters including the total emerged flux, the flux growth rate, the maximum area, the duration of the emergence and the separation speed of the opposite polarities are adopted to delineate the property of the EFRs. The response of the upper atmosphere is addressed by the response of the

atmosphere at different wavelengths (and thus at different temperatures). According to our results, the total emerged fluxes are in the range of (0.44 -- 11.2)x1019 Mx while the maximum area ranges from 17 to 182 arcsec^2. The durations of the emergence are between 1 and 12 hours, which are positively correlated to both the total emerged flux and the maximum area. The maximum distances between the opposite polarities are 7 -- 25 arcsec and are also correlated to the duration positively. The separation speeds are from 0.05 to 1.08 km s-1, negatively correlated to the duration. The derived flux growth rates are (0.1 -- 1.3)x1019 Mx hr-1, which are positively correlated to the total emerging flux. The upper atmosphere responds to the flux emergence in the 1600AA chromospheric line first, and then tens and hundreds of seconds later, in coronal lines, such as the 171AA (T=105.8 K) and 211AA (T=106.3 K) lines almost simultaneously, suggesting the successively heating of atmosphere from the chromosphere to the corona.

Determination of the Topology Skeleton of Magnetic Fields in a Solar Active Region *

Hui **Zhao**, Jing-Xiu Wang1, Jun Zhang1, Chi-Jie Xiao1 and Hai-Min Wang2
Chin. J. Astron. Astrophys. Vol. 8 (**2008**), No. 2, 133–145
http://www.chjaa.org

Magnetic topology has been a key to the understanding of magnetic energy release mechanism. Based on observed vector magnetograms, we have determined the threedimensional (3D) topology skeleton of the magnetic fields in the active region **NOAA 10720 (15 January 2005)**. The skeleton consists of six 3D magnetic nulls and a network of corresponding spines, fans, and null-null lines. For the first time, we have identified a spiral magnetic null in Sun's corona. The magnetic lines of force twisted around the spine of the null, forming a 'magnetic wreath' with excess of free magnetic energy and resembling observed brightening structures at extraultraviolet (EUV) wavebands. We found clear evidence of topology eruptions which are referred to as catastrophic changes of topology skeleton associated with a coronal mass ejection (CME) and an explosive X-ray flare. These results shed new lights on the structural complexity and its role in explosive magnetic activity. The concept of flux rope has been widely used in modelling explosive magnetic activity, although their observational identity is rather obscure or, at least, lacking of necessary details up to date.We suggest that the magnetic wreath associated with the 3D spiral null is likely an important class of the physical entity of flux ropes.

Plasma turbulence generated in 3D current sheet with magnetic islands

Zharkova V. and Xia, Q
Frontiers in Space Physics Volume 8 | Article 665998 **2021**
https://solargsm.com/wp-content/uploads/2021/10/frontiers_cs_turb.pdf
https://www.frontiersin.org/articles/10.3389/fspas.2021.665998/pdf
https://doi.org/10.3389/fspas.2021.665998

In this paper we aim to investigate the kinetic turbulence in a reconnecting current sheet (RCS) with X- and O-nullpoints and to explore its link to the features of accelerated particles. We carry out simulations of magnetic reconnection in a thin current sheet with 3D magnetic field topology affected by tearing instability until the formation of two large magnetic islands using particle-in-cell (PIC) approach. The model utilises a strong guiding field that leads to separation of the particles of opposite charges, generation of a strong polarisation electric field across the RCS and suppression of kink instability in the 'out-of-plane' direction. The accelerated particles of the same charge entering an RCS from the opposite edges are shown accelerated to different energies forming the `bump-in-tail' velocity distributions that, in turn, can generates plasma turbulence in different locations. The turbulence-generated waves produced by either electron or proton beams can be identified from the energy spectra of electromagnetic field fluctuations in the phase and frequency domains. From the phase space analysis we gather that the kinetic turbulence may be generated by accelerated particle beams, which are later found to evolve into a phase-space hole indicating the beam breakage. This happens at some distance from the particle entrance into an RCS, e.g. about 7di (ion inertial depth) for the electron beam and 12di for the proton beam. In a wavenumber space the spectral index of the power spectrum of the turbulent magnetic field near the ion inertial length is found to be -2.7 that is consistent with other estimations. The collective turbulence power spectra are consistent with the high-frequency fluctuations of perpendicular electric field, or upper hybrid waves, to occur in a vicinity of X-nullpoints, where the Langmuir (LW) can be generated by accelerated electrons with high growth rates, while further from X-nullponts or on the edges of magnetic islands, where electrons become ejected and start moving across the magnetic field lines, Bernstein waves can be generated. The frequency spectra of high and low-frequency waves are explored in the kinetic turbulence in parallel and perpendicular directions to the local magnetic field showing noticeable lower hybrid turbulence occurring between the electron's gyro- and plasma frequencies seen also in the wavelet spectra. Fluctuation of the perpendicular electric field component of turbulence can be consistent with the oblique whistler waves generated on the ambient density fluctuations by intense electron beams. This study brings attention to a key role of particle acceleration in generation kinetic turbulence inside current sheets.

Sunquake with a second bounce, other sunquakes, and emission associated with the X9.3 flare of 6 September 2017. I. Observations

Sergei **Zharkov**1, Sarah Matthews2, Valentina Zharkova3, Malcolm Druett4, Satoshi Inoue5, Ingolf E. Dammasch6 and Connor Macrae1

A&A 639, A78 (**2020**)
https://www.aanda.org/articles/aa/pdf/2020/07/aa36755-19.pdf
https://www.aanda.org/articles/aa/pdf/forth/aa36755-19.pdf

Aims. The 6 September 2017 X9.3 solar flare produced very unique observations of magnetic field transients and a few seismic responses, or sunquakes, detected by the Helioseismic and Magnetic Imager (HMI) instrument aboard Solar Dynamic Observatory (SDO) spacecraft, including the strongest sunquake ever reported. This flare was one of a few flares occurring within a few days or hours in the same active region. Despite numerous reports of the fast variations of magnetic field, and seismic and white light emission, no attempts were made to interpret the flare features using multi-wavelength observations. In this study, we attempt to produce the summary of available observations of the most powerful flare of the 6 September 2017 obtained using instruments with different spatial resolutions (this paper) and to provide possible interpretation of the flaring events, which occurred in the locations of some seismic sources (a companion Paper II).
Methods. We employed non-linear force-free field extrapolations followed by magnetohydrodynamic simulations in order to identify the presence of several magnetic flux ropes prior to the initiation of this X9.3 flare. Sunquakes were observed using the directional holography and time–distance diagram detection techniques. The high-resolution method to detect the Hα line kernels in the CRISP instrument at the diffraction level limit was also applied.
Results. We explore the available γ-ray (GR), hard X-ray (HXR), Lyman-α, and extreme ultra-violet (EUV) emission for this flare comprising two flaring events observed by space- and ground-based instruments with different spatial resolutions. For each flaring event we detect a few seismic sources, or sunquakes, using Dopplergrams from the HMI/SDO instrument coinciding with the kernels of Hα line emission with strong redshifts and white light sources. The properties of sunquakes were explored simultaneously with the observations of HXR (with KONUS/WIND and the Reuven Ramaty High Energy Solar Spectroscopic Imager payload), EUV (with the Atmospheric Imaging Assembly (AIA/SDO and the EUV Imaging Spectrometer aboard Hinode payload), Hα line emission (with the CRisp Imaging Spectro-Polarimeter (CRISP) in the Swedish Solar Telescope), and white light emission (with HMI/SDO). The locations of sunquake and Hα kernels are associated with the footpoints of magnetic flux ropes formed immediately before the X9.3 flare onset.
Conclusions. For the first time we present the detection of the largest sunquake ever recorded with the first and second bounces of acoustic waves generated in the solar interior, the ripples of which appear at a short distance of 5–8 Mm from the initial flare location. Four other sunquakes were also detected, one of which is likely to have occurred 10 min later in the same location as the largest sunquake. Possible parameters of flaring atmospheres in the locations with sunquakes are discussed using available temporal and spatial coverage of hard X-ray, GR, EUV, hydrogen Hα-line, and white light emission in preparation for their use in an interpretation to be given in Paper II.

Properties of the 15 February 2011 Flare Seismic Sources

S. **Zharkov**, L. M. Green, S. A. Matthews, V. V. Zharkova

Solar Physics, June **2013**, Volume 284, Issue 2, pp 315-327

The first near-side X-class flare of Solar Cycle 24 occurred in February 2011 (SOL2011-02-05T01:55) and produced a very strong seismic response in the photosphere. One sunquake was reported by Kosovichev (Astrophys. J. Lett. 734, L15, 2011), followed by the discovery of a second sunquake by Zharkov, Green, Matthews et al. (Astrophys. J. Lett. 741, L35, 2011). The flare had a two-ribbon structure and was associated with a flux-rope eruption and a halo coronal mass ejection (CME) as reported in the CACTus catalogue. Following the discovery of the second sunquake and the spatial association of both sources with the locations of the feet of the erupting flux rope (Zharkov, Green, Matthews et al., Astrophys. J. Lett. 741, L35, 2011), we present here a more detailed analysis of the observed photospheric changes in and around the seismic sources. These sunquakes are quite unusual, taking place early in the impulsive stage of the flare, with the seismic sources showing little hard X-ray (HXR) emission, and strongest X-ray emission sources located in the flare ribbons. We present a directional time–distance diagram computed for the second source, which clearly shows a ridge corresponding to the travelling acoustic-wave packet and find that the sunquake at the second source happened about 45 seconds to one minute earlier than the first source. Using acoustic holography we report different frequency responses of the two sources. We find strong downflows at both seismic locations and a supersonic horizontal motion at the second site of acoustic-wave excitation.

COMPARISON OF SEISMIC SIGNATURES OF FLARES OBTAINED BY SOHO/MICHELSON DOPPLER IMAGER AND GONG INSTRUMENTS

S. **Zharkov**1, V. V. Zharkova2 and S. A. Matthews

2011 ApJ 739 70

The first observations of seismic responses to solar flares were carried out using time-distance (TD) and holography techniques applied to SOHO/Michelson Doppler Imager (MDI) Dopplergrams obtained from space and unaffected by terrestrial atmospheric disturbances. However, the ground-based network GONG is potentially a very valuable source of sunquake observations, especially in cases where space observations are unavailable. In this paper, we present an updated technique for pre-processing of GONG observations for the application of subjacent vantage holography. Using this method and TD diagrams, we investigate several sunquakes observed in association with M- and X-class solar flares and compare the outcomes with those reported earlier using MDI data. In both GONG and MDI data sets, for the first time, we also detect the TD ridge associated with the **2001 September 9** flare. Our results show reassuringly positive identification of sunquakes from GONG data that can provide further information about the physics of seismic processes associated with solar flares.

Statistical properties of H -alpha flares in relation to sunspots and active regions in the cycle 23

Zharkov S.I. and Zharkova V.V.
E-print, Nov **2009**, JASTP
The statistical properties of H flare occurrences compared with those of sunspot and active region areas in the cycle 23. The flare numbers in the cycle 23 of all significances and locations are obtained from the Solar Geophysical Data (SGD) and the other data was taken from the automated Solar Feature Catalogs (SFC, http://solar.inf.brad.ac.uk). The average monthly flare occurrences during the whole cycle correlate closely with the total and cumulative areas of active regions and sunspots. The cumulative distribution of solar flare occurrences at different latitudes in the northern and southern hemispheres versus the time reveal a strong asymmetry with a domination of one or other hemispheres similar to the cumulative distributions of sunspots and active regions. Although the sunspot area asymmetry lags the flare occurrence asymmetry by about time of a few months at the ascending phase of the cycle and up to 12 months in the descending one. The latitudinal distribution of flare occurrences in the whole period reveal a well defined maximum at 18◦ in the northern and two maxima at 14◦ and 20◦ in the southern hemisphere. The longitudinal distributions of flare occurrence residuals of the running values and those averaged with a one year filter reveal a set of persistent longitudes in the opposite hemispheres lasting for about 1.0-1.5 years and changing quickly a few times over the cycle phases.

Pitch-angle distribution of accelerated electrons in 3D current sheets with magnetic islands

V. **Zharkova** and Q. Xia
A&A **2021**
https://solargsm.com/wp-content/uploads/2021/02/zharkova_xia_PADs_aa21.pdf
This research aims to explore variations of electron pitch-angle distribution (PAD) during spacecraft cross reconnecting current sheets (RCSs) with magnetic islands. The results can benchmark the sampled characteristic features with realistic PADs derived from in-situ observations. Particle motion is simulated in 2.5D Harris-type RCSs using particle-in-cell (PIC) method considering the plasma feedback to electromagnetic fields. We evaluate particle energy gains and PADs in different locations and under the different directions of passing the current sheet by a virtual spacecraft. The RCS parameters are comparable to heliosphere and solar wind conditions. The energy gains and the PADs of particles would change depending on the specific topology of magnetic fields. Besides, the observed PADs also depend on the crossing paths of the spacecraft. When the guiding field is weak, the bi-directional electron beams (strahls) are mainly present inside the islands and located closely above/below the X-nullpoints in the inflow regions. The magnetic field relaxation near X-nullpoint converts the PADs towards 90 degrees. As the guiding field becomes larger, the regions with bi-directional strahls are compressed towards small areas in the exhausts of RCSs. Mono-directional strahls are quasi-parallel to the magnetic field lines near the X-nullpoint due to the dominant Fermi-type magnetic curvature drift acceleration. Meanwhile, the high-energy electrons confined inside magnetic islands create PADs about 90 degrees. Our results link the electron PADs to local magnetic structures and directions of spacecraft crossings. This can help explain a variety of the PAD features reported in the recent observations in the solar wind and the Earth's magnetosphere.

Sunquake with a second bounce, other sunquakes, and emission associated with the X9.3 flare of 6 September 2017. II. Proposed interpretation

https://www.aanda.org/articles/aa/pdf/2020/07/aa37885-20.pdf
https://solargsm.com/wp-content/uploads/2020/05/Zharkova_et-al_6sept17_aa20.pdf
In this paper we present the interpretation of the observations of the flare from **6 September 2017** reported in Paper 1. These include gamma-ray (GR), hard X-ray (HXR), soft X-rays (SXR), Lyα line, extreme ultraviolet (EUV), Hα, and white light (WL) emission, which were recorded during the two flaring events 1 (FE1) and 2 (FE2) that occurred at 11:55:37 UT (FE1) and 12:06:40 UT (FE2). Paper 1 also reported the first detection of the sunquake with first and second bounces of seismic waves combined with four other sunquakes in different locations supported with the

observations of HXR, GR, EUV, Hα, and WL emission with strongly varying spatial resolution and temporal coverage. In the current Paper 2, we propose some likely scenarios for heating of flaring atmospheres in the footpoints with sunquakes which were supported with EUV and Hα emission. We used a range of parameters derived from the HXR, EUV, and Hα line observations to generate hydrodynamic models, which can account for the blueshifts derived from the EUV emission and the redshifts observed with the EUV Imaging Spectrometer (EIS) in the He II line and by the CRisp Imaging Spectro-Polarimeter (CRISP) in the Swedish Solar Telescope (SST) in Hα line emission. The parameters of hydrodynamic shocks produced by different beams in flaring atmospheres were used as the initial conditions for another type of hydrodynamic models that were developed for acoustic wave propagation in the solar interior. These models simulate the sets of acoustic waves produced in the interior by the hydrodynamic shocks from atmospheres above deposited in different footpoints of magnetic loops. The Hα line profiles with large redshifts in three kernels (two in FE1 and one in FE2) were interpreted with the full non-local thermodynamic equilibrium (NLTE) radiative simulations in all optically thick transitions (Lyman lines and continuum Hα, Hβ, and Pα) applied for flaring atmospheres with fast downward motions while considering thermal and non-thermal excitation and ionisation of hydrogen atoms by energetic power-law electron beams. The observed Hα line profiles in three kernels were fit with the simulate blue wing emission of the Hα line profiles shifted significantly (by 4-6 Å) towards the line red wings, because of strong downward motions with velocities about 300 km s-1 by the shocks generated in flaring atmospheres by powerful beams. The flaring atmosphere associated with the largest sunquake (seismic source 2 in FE1) is found consistent with being induced by a strong hydrodynamic shock produced by a mixed beam deposited at an angle of -30◦ from the local vertical. We explain the occurrence of a second bounce in the largest sunquake by a stronger momentum delivered by the shock generated in the flaring atmosphere by a mixed beam and deeper depths of the interior where this shock was deposited. Indeed, the shock with mixed beam parameters is found deposited deeply into the interior beneath the flaring atmosphere under the angle to the local vertical that would allow the acoustic waves generated in the direction closer to the surface to conserve enough energy for the second bounces from the interior layers and from the photosphere. The wave characteristics of seismic sources 1 and 3 (in FE1) were consistent with those produced by the shocks generated by similar mixed beams deposited at the angles -(0 - 10)◦ (seismic source 1) and +30◦ (seismic source 3) to the local vertical. The differences of seismic signatures produced in the flares of **6 September 2011** and 2017 are also discussed.

Beam electrons as sources of Hα ribbons in a C-class flare

Valentina **Zharkova**, Malcolm Druett and Eamon Scullion (Northumbria)
UK Solar Physics (UKSP) – Nuggets #83. **2017** www.uksolphys.org/?p=13393
New flare simulations explain a decades-old redshift mystery.
Observations of solar flare onsets show a rapid increase of hard and soft X-rays, ultra-violet emission with large Doppler blue-shifts associated with plasma upflows, and Hα emission with red-shifts up to 1–4 Å [1, 2, 3]. Modern radiative hydrodynamic models account well for blue-shifted emission, but struggle to reproduce closely the red-shifted Hα lines observed at the flare onset. Here we present a joint hydrodynamic and radiative model showing that during the first seconds of beam injection the effects caused by beam electrons can reproduce Hα line profiles with large red-shifts closely matching those observed in a C1.5 flare by the Swedish Solar Telescope. The model also accounts for the timing and magnitude of upward plasma motion to the corona observed 29 s after the event onset in 171 Å by the Atmospheric Imaging Assembly/Solar Dynamics Observatory. **30th June 2013**

Analytical solutions of continuity equation for joint collisional and Ohmic energy losses and their effects on hard X-ray emission. II. Mixed energy losses

Zharkova V.V. and Dobranskis R.R.
MNRAS **2016**
http://mnras.oxfordjournals.org/content/early/2016/03/07/mnras.stw500.full.pdf?keytype=ref&ijkey=zcVKoDhBj8zNW7o
In this paper we consider simultaneous analytical solutions of continuity equations for electron beam precipitation a) in collisional losses and b) in Ohmic losses, or mixed energy losses (MEL), by applying the iterative method to calculate the resulting differential densities at given precipitation depth. The differential densities of precipitating electrons derived from the analytical solutions for mixed energy losses reveal increased flattening at energies below 10-30 keV compared to a pure collisional case. This flattening becomes stronger with an increasing precipitation depth turning into a positive slope at greater precipitation depths in the chromosphere resulting in a differential density distribution with maximum that shifts towards higher energies with increase of a column depth. While the differential densities combining precipitating and returning electrons are higher at lower energies than those for a pure collisional case. The resulting hard X-ray (HXR) emission produced by the beams with different initial energy fluxes and spectral indices is calculated using the MEL approach for different ratios between the differential densities of precipitating and returning electrons. The number of returning electrons can be even further enhanced by a magnetic mirroring, not considered in the present model, while dominating at lower atmospheric depths where the magnetic convergence and magnitude are the highest. The proposed MEL approach provides an opportunity to account simultaneously for both collisional and ohmic losses in flaring events, which can be used for a quick spectral fitting of HXR spectra and evaluation of a fraction of returning electrons versus precipitating ones. The semi-analytical MEL approach is used for spectral fitting to

RHESSI observations of nine C, M and X class flares revealing a close fit to the observations and good resemblance to numerical FP solutions. **01 Oct 2012, 23 Oct 2012, 25 Oct 2013, 19 Dec 2013, 08 Jan 2014, 13 Jan 2014, 17 Jan 2014,**

On the Generation of Hydrodynamic Shocks by Mixed Beams and Occurrence of Sunquakes in Flares

Valentina **Zharkova** , Sergei Zharkov

Solar Physics November **2015**, Volume 290, Issue 11, pp 3163-3188

Observations of solar flares with sunquakes by space- and ground-based instruments reveal essentially different dynamics of seismic events in different flares. Some sunquakes are found to be closely associated with the locations of hard X-ray (HXR) and white-light (WL) emission, while others are located outside either of them. In this article we investigate possible sources causing a seismic response in a form of hydrodynamic shocks produced by the injection of mixed (electron plus proton) beams, discuss the velocities of these shocks, and the depths where they deposit the bulk of their energy and momentum. The simulation of hydrodynamic shocks in flaring atmospheres induced by electron-rich and proton-rich beams reveals that the linear depth of the shock termination is shifted beneath the level of the quiet solar photosphere on a distance from 200 to 5000 km. The parameters of these atmospheric hydrodynamic shocks are used as initial condition for another hydrodynamic model developed for acoustic-wave propagation in the solar interior (Zharkov, Mon. Not. Roy. Astron. Soc. 431, 3414, 2013). The model reveals that the depth of energy and momentum deposition by the atmospheric shocks strongly affects the propagation velocity of the acoustic-wave packet in the interior. The locations of the first bounces from the photosphere of acoustic waves generated in the vicinity of a flare are seen as ripples on the solar surface, or sunquakes. Mixed proton-dominated beams are found to produce a strong supersonic shock at depths 200 – 300 km under the level of the quiet-Sun photosphere and in this way produce well-observable acoustic waves, while electron-dominated beams create a slightly supersonic shock propagating down to 5000 km under the photosphere. This shock can only generate acoustic waves at the top layers beneath the photosphere since the shock velocity very quickly drops below the local sound speed. The distance Δ of the first bounce of the generated acoustic waves is discussed in relation to the minimal phase velocities of wave packets defined by the acoustic cutoff frequency and the parameters of atmospheric shock termination beneath the photosphere.

Particle acceleration in 3D single current sheets formed in the solar corona and heliosphere: PIC approach

Zharkova V.V. and Siversky T

Journal of Physics, Conference Series (JPCS), **2015**, 642, 012032

http://computing.unn.ac.uk/staff/slmv5/kinetics/zharkova_aiac15_v3.pdf

Acceleration of protons and electrons in a reconnecting current sheet (RCS) is investigated with the test particle and particle-in-cell (PIC) approaches in a 3D magnetic topology. PIC simulations confirm a spatial separation of electrons and protons with respect to the midplane depending on the guiding field. Simulation reveals that the separation occurs in magnetic topologies with strong guiding fields and lasts as long as the particles are kept dragged into a current sheet. This separation produces a polarisation electric field induced by the plasma feedback to a presence of accelerated particles, which shape can change from symmetric towards the midplane (for weak guiding field) to fully asymmetric (for strong guiding field). Particles are found accelerated at a midplane of any current sheets present in the heliosphere to the energies up to hundred keV for electrons and hundred MeV for protons. The maximum energy gained by particles during their motion inside the current sheet is defined by its magnetic field topology (the ratio of magnetic field components), the side and location from the X-nullpoint, where the particles enter a current sheet. In strong magnetic fields of the solar corona with weaker guiding fields, electrons are found circulating about the midplane to large distances where proton are getting accelerated, creating about the current sheet midplane clouds of high energy electrons, which can be the source of hard X-ray emission in the coronal sources of flares. These electrons are ejected into the same footpoint as protons after the latter reach the energy sufficient to break from a current sheet. In a weaker magnetic field of the heliosphere the bounced electrons with lower energies cannot reach the midplane turning instead at some distance D before the current sheet midplane by 180 degrees from their initial motion. Also the beams of accelerated transit and bounced particles are found to generate turbulent electric fields in a form of Langmuir waves (electrons) or ion-acoustic waves (protons).

Recent Advances in Understanding Particle Acceleration Processes in Solar Flares **Review**

Space Sci Rev (**2011**) 159:357–420, **File**

We **review** basic theoretical concepts in particle acceleration, with particular emphasis on processes likely to occur in regions of magnetic reconnection. Several new developments are discussed, including detailed studies of reconnection in three-dimensional magnetic field configurations (e.g., current sheets, collapsing traps, separatrix regions) and stochastic acceleration in a turbulent environment. Fluid, test-particle, and particle-in-cell approaches are used and results compared. While these studies show considerable promise in accounting for the various observational manifestations of solar flares, they are limited by a number of factors, mostly relating to available computational power. Not the least of these issues is the need to explicitly incorporate the electrodynamic feedback of the accelerated particles themselves on the environment in which they are accelerated. A brief prognosis for future advancement is offered.

Diagnostics of electron beam properties from the simultaneous hard X-ray and microwave emission in the 2001 March 10 flare

V. V. **Zharkova**, N. S. Meshalkina, L. K. Kashapova, A. A. Kuznetsov and A. T. Altyntsev
E-print May, **2011,** A&A 532, A17 (**2011**)

Context. Microwave (MW) and hard X-ray (HXR) data are thought to be powerful means of investigating the mechanisms of particle acceleration and precipitation in solar flares, reflecting different aspects of electron interaction with ambient particles in the presence of a magnetic field. Simultaneous simulation of HXR and MW emission with the same populations of electrons is still a big challenge for interpreting observations of real events. Recent progress in simulations of particle kinetics with the time-dependent Fokker-Planck (FP) approach offers an opportunity to produce this interpretation.
Aims. In this paper we apply the FP kinetic model of precipitation of electron beam with energy range from 12 keV to 1.2 MeV to the interpretation of X-ray and MW emissions observed in the flare of **2001 March 10**.
Methods. The theoretical HXR and MW emissions were calculated by using the distribution functions of electron beams found by solving time-dependent approach in a converging magnetic field for anisotropic scattering of beam electrons on the ambient particles in Coloumb collisions and Ohmic losses.
Results. The simultaneously observed HXR photon spectra and frequency distribution of MW emission and polarization were fit by those simulated from FP models that include the effects of electric field induced by beam electrons and precipitation onto a converging magnetic loop. Magnetic field strengths in the footpoints on the photosphere were updated with newly calibrated SOHO/MDI data. The observed HXR energy spectrum above 10 keV is shown to be a double power law that was precisely fit by the photon HXR spectrum simulated for the model including the self-induced electric field but without magnetic convergence. The MW emission simulated for different models of electron precipitation revealed a better fit (above 90% confidence level) to the observed distribution at higher frequencies for the models combining collisions and electric field effects with a moderate magnetic field convergence of two. The MW simulations were able to reproduce closely the main features of the MW emission observed at higher frequencies: the spectral index, the frequency of peak intensity and the frequency of the MW polarization reversal, while at lower frequencies the simulated MW intensities are lower than the observed ones.

THE EFFECTS OF ELECTRON-BEAM-INDUCED ELECTRIC FIELD ON THE GENERATION OF LANGMUIR TURBULENCE IN FLARING ATMOSPHERES

Valentina V. **Zharkova** and Taras V. Siversky
2011 ApJ 733 33

The precipitation of an electron beam injected into the solar atmosphere is studied for the generation of Langmuir wave turbulence in the presence of collisional and Ohmic losses. The system of quasi-linear time-dependent kinetic equations describing the evolution of beams and Langmuir waves is solved by using the summary approximation method. It is found that at upper atmospheric levels the self-induced electric field suppresses the generation of Langmuir turbulence to very small regions below injection. With further precipitation into deeper atmosphere the initial single power-law distributions of beam electrons are transformed into energy distributions with maxima at lower energies formed by collisional and Ohmic energy depletion. The electrons with lower energies (<20 keV) generate on large spatial scales intense low-hybrid and high-hybrid Langmuir waves with well-defined patterns in the corona while higher energy electrons generate moderate low-hybrid waves in the chromosphere. The maximum wave density appears at the maximum of the ambient density. The self-induced electric field reduces the level and makes the regions with low-hybrid Langmuir turbulence narrower in the corona and upper chromosphere. The higher the beam energy flux or its self-induced electric field, the narrower the regions with Langmuir turbulence. High-hybrid Langmuir waves in the form of multiple patterns in space (in the corona) and energy (below 20 keV) are found to be generated only by a very intense electron beam. The number of patterns in both dimensions is also shown to be significantly reduced by the self-induced electric field.

The effect of energetic particle beams on the chromospheric emission of the 25th July 2004 flare

Zharkova V.V., Kashapova L.K., Chornogor S.N. and Andrienko O,V.
E-print Oct **2010**, MNRAS

In this paper a role of particle beams for generation of a close spatial and temporal correlation between hard H-ray (HXR) energy and Hα line emission bursts in the solar flare of **25 July 2004** is discussed. The light curves in HXR emission and Hα line revealed the pre-flare and main flare events correlated with the variations of a line-of-sight (LOS) magnetic flux. HXR emission shows the three main bursts during the main flare phase which are accompanied by Hα intensity increases. The latter appear in 10 locations (kernels) at different times in succession; the kernel locations are associated with strong magnetic sources situated on the opposite sides from the magnetic neutral line (MNL). The appearance of Hα kernels in the pre-flare event and those at the start of the main event are correlated very closely (within a few seconds) with the HXR emission observed by RHESSI (HXR+Hα kernels), while the appearance of some other ones, not associated with HXR emission, was delayed by ten of seconds. Electron beam parameters were derived from the RHESSI spectra in where the observed HXR photon flux was corrected for the self-induced electric field effect. Possible implications of this electric field on production of the transient magnetic fields observed during the flare are discussed. The Hα emission observed during the first burst was simulated in hydrodynamic atmospheres for 5 level plus continuum hydrogen atom with the full non-LTE approach combining radiative, thermal and non-thermal excitation and ionization by an electron beam with the derived parameters. The simulated temporal profiles of Hα emission produced by non-thermal hydrogen excitation revealed a very good fit to the observed ones in the HXR+Hα kernels and 10-20 s delays in the other kernels. This allows to speculate that Hα emission in these kernels is caused mainly by electrons in the HXR+Hα kernels and mainly by protons in the other ones.

Diagnostics of energetic electrons with anisotropic distributions in solar flares I. Hard X-rays bremsstrahlung emission

Zharkova V.V., Kuznetsov A.A. and Siversky T.V.
E-print, Nov 2009, A&A, 512, A8 (**2010**)
http://www.aanda.org/10.1051/0004-6361/200811486

Aims. The paper aims are to simulate steady-state distributions of electrons beams precipitating in collisional and Ohmic losses with pitch angle anisotropy into a flaring atmosphere with converging magnetic field and to apply these to the interpretation of HXR photon spectra, directivity and polarization observed for different photon energies and positions of flares.
Methods. Summary approximation method is applied to time-dependent Fokker-Planck equation splitting a temporal derivative equally between the derivatives in depth, energy and pitch angles and finding the solutions in forward and backward directions for each variable.
Results. For softer beams there is a noticeable flattening of the photon spectra at lower energies caused by the self-induced electric field which increases for larger viewing angles. For the models with electric field the HXR emission with lower energies (30 keV) becomes directed mainly upwards at upper atmospheric levels owing to the increased number of particles moving upwards, while at the deeper layers it becomes again directed downwards. The polarization maximum shifts to higher energies with every precipitation depth approaching 25 keV for the models with pure collisions and 100 keV for the models with return currents. At deeper layers the polarization decreases because of the izotropization of electrons by collisions. The maximum polarization is observed at the viewing angle of 90◦ becoming shifted to lower angles for softer beams. The integrated polarization and directivity shows dependence on a magnetic field convergence for harder beams while for softer beam the directivity is strongly affected by the self-induced electric field changing from downward to upward one at upper atmospheric depths.
Conclusions. The proposed precipitation model for an electron beam with wider pitch angle dispersion of 0.2 taking into account collisional and Ohmic losses allowed us to fit the double power law HXR photon spectra with a spectrum flattening at lower energies observed in the flares of **20 and 23 July 2002**. The observed directivity of HXR photons of 20 keV derived for a large number of flares located from the disk center to limb is also well reproduced by the theoretical directivity calculated for an electron beam with a very narrow pitch angle dispersion of 0.02. The simulated polarization of such the narrowly-directed electron beam fits up to 90% of all the available polarimetric observations carried out at various locations on the solar disk.

Energy Dissipation in Magnetohydrodynamic Turbulence: Coherent Structures or "Nanoflares"?

Vladimir **Zhdankin**, Stanislav Boldyrev, Jean Carlos Perez, Steven M. Tobias

ApJ, 795 127 **2014**

http://arxiv.org/pdf/1409.3285v1.pdf

We investigate the intermittency of energy dissipation in magnetohydrodynamic (MHD) turbulence by identifying dissipative structures and measuring their characteristic scales. We find that the probability distribution of energy dissipation rates exhibits a power law tail with index very close to the critical value of -2.0, which indicates that structures of all intensities contribute equally to energy dissipation. We find that energy dissipation is uniformly spread among coherent structures with lengths and widths in the inertial range. At the same time, these structures have thicknesses deep within the dissipative regime. As the Reynolds number is increased, structures become thinner and more numerous, while the energy dissipation continues to occur mainly in large-scale coherent structures. This implies that in the limit of high Reynolds number, energy dissipation occurs in thin, tightly packed current sheets which nevertheless span a continuum of scales up to the system size, exhibiting features of both coherent structures and nanoflares previously conjectured as a coronal heating mechanism.

Kelvin--Helmholtz Instability in Solar Atmosphere Jets

I. **Zhelyazkov**

2014 J. Astrophys. Astr.

http://arxiv.org/pdf/1411.6472v1.pdf

In this article I have discussed the recent approaches in studying the Kelvin--Helmholtz (KH) instability of magnetohydrodynamic (MHD) waves propagating in solar atmosphere jets. The main focus is on the modeling the KH instability developing in coronal mass ejections in view of its (instability) contribution to triggering a wave turbulence subsequently leading to an effective coronal heating. KH instability of MHD waves in coronal active regions recently observed and imaged in unprecedented detail in EUV thanks to the high cadence, high-resolution observations by \emph{SDO}/AIA instrument, and spectroscopic observations by \emph{Hinode}/EIS instrument is a challenge for modeling this event. It is shown that considering the solar mass flows of coronal mass ejections as moving cylindrical twisted magnetic flux tubes the imaged instability can be explained in terms of unstable m=−3 MHD mode. Obtained critical jet speeds for the instability onset as well as the linear wave growth rates are in good agreement with observational data.

Kelvin--Helmholtz instability of magnetohydrodynamic waves propagating on solar surges

I. **Zhelyazkov**, R. Chandra, A. K. Srivastava, T. Mishonov

2014

http://arxiv.org/pdf/1411.6481v1.pdf

In the present paper, we study the evolutionary conditions for Kelvin--Helmholtz (KH) instability in a high-temperature solar surge observed in NOAA AR11271 using the Solar Dynamics Observatory data on 2011 August 25. We study the propagation of normal MHD modes in a flux tube considering the two cases, notably of untwisted magnetic flux tube and the twisted one. The numerical solution to the dispersion relation shows that the kink (m=1) wave traveling in an untwisted flux tube becomes unstable if the jet speed exceeds 1060 km\,s−1 -- a speed which is inaccessible for solar surges. A weak twist (the ratio of azimuthal to longitudinal magnetic field component) of the internal magnetic field in the range of 0.025--0.2 does not change substantially the critical flow velocity. Thus, one implies that, in general, the kink mode is stable against the KH instability. It turns out, however, that the m=−2 and m=−3 MHD modes can become unstable when the twist parameter has values between 0.2 and 0.4. Therefore, the corresponding critical jet speed for instability onset lies in the range of 93.5--99.3 km\,s1. The instability wave growth rate, depending on the value of the wavelength, is of the order of several dozen inverse milliseconds. It remains to be seen whether these predictions will be observationally validated in future in the coronal jet-like structures in abundant measure.

Multiclass solar flare forecasting models with different deep learning algorithms

Yanfang **Zheng** and others

Monthly Notices of the Royal Astronomical Society, Volume 521, Issue 4, June **2023**, Pages 5384–5399,

https://doi.org/10.1093/mnras/stad839

https://watermark.silverchair.com/stad839.pdf

We develop a Hybrid Bidirectional Long and Short-Term Memory based on attention mechanism (HBiLSTM-Attention) model and a BiLSTM-Attention model for multiclass flare forecasting within 24 h. We construct a new data base containing 10 separate data sets with magnetogram images and magnetic field parameters. Based on the same data base, for the first time we compare the multiclass forecasting performance of our proposed HBiLSTM-Attention model, BiLSTM-Attention model, and three other deep-learning models based on Convolutional Neural Network (CNN-based) from two aspects of categorical performance with the true skill statistic (TSS) and probabilistic performance with the Brier skill score (BSS). The major results are as follows. (1) The TSS values of our proposed model are 0.692 ± 0.042,

0.475 ± 0.038, 0.642 ± 0.043, 0.754 ± 0.062, 0.692 ± 0.042, and 0.708 ± 0.052 for No-flare, C, M, X, ≥C, and ≥M class, respectively, which are better than those of the BiLSTM-Attention model, and much better than those of the three other CNN-based models. (2) Our proposed model achieves the scores of BSS = 0.498 ± 0.061, 0.202 ± 0.037, 0.209 ± 0.050, −0.271 ± 0.180, 0.498 ± 0.061, 0.268 ± 0.056 for No-flare, C, M, X, ≥C, and ≥M class, respectively, outperforming the other four models in every class except for X class. (3) To our knowledge, HBiLSTM-Attention is the first multiclass flare forecasting model based on magnetic field parameters and deep learning, and achieves promising prediction performance. Moreover, this is the first attempt to investigate the reliability of probabilistic prediction for multiclass flares.

Solar Flare Prediction with the Hybrid Deep Convolutional Neural Network

Yanfang **Zheng1**, Xuebao Li1, and Xinshuo Wang
2019 ApJ 885 73
https://iopscience.iop.org/article/10.3847/1538-4357/ab46bd/pdf
We propose a hybrid Convolutional Neural Network (CNN) model (Model 2) and modify a popular CNN model (Model 1) to predict multiclass solar flare occurrence within 24 hr. We collect samples of solar active regions provided by the Space-weather Helioseismic and Magnetic Imager Active Region Patches data from 2010 May to 2018 September. These samples are categorized into four classes (No-flare, C, M, and X), containing 10 separate data sets. Then after training, validating, and testing our models, we compare the results with previous studies in forecast verification metrics with an emphasis on the true skill statistic (TSS). The main results are summarized as follows. (1) This is the first time that the CNN models are used to make multiclass predictions of solar flare. (2) Model 2 has better values of all statistical scores than Model 1 in every class. (3) Model 2 achieves relatively high average scores of TSS = 0.768 for No-flare class, 0.538 for C class, 0.534 for M class, and 0.552 for X class, which are the best results from the existing literatures. (4) Model 2 also can be used to make binary class flare predictions for ≥M-class major flares, and the performance yields a TSS with 0.749 ± 0.079. (5) Model 2 obtains fairly good scores in other metrics for both multiclass flare predictions and ≥M-class major flare predictions. We surmise that some crucial features extracted automatically by our models may have not been excavated before and could provide important clues for studying the mechanism of flare.

Sunspots rotation and magnetic transients associated with flares in NOAA AR 11429

Jianchuan **Zheng**, Zhiliang Yang, Jianpeng Guo, Kaiming Guo, Hui Huang, Xuan Song, Weixing Wan
Research in Astronomy and Astrophysics (RAA) **2017**
https://arxiv.org/pdf/1704.08018.pdf
We analyze sunspots rotation and magnetic transients in NOAA AR 11429 during two X-class (X5.4 and X1.3) flares using the data from the Helioseismic and Magnetic Imager on board the \emph{Solar Dynamics Observatory}. A large leading sunspot with positive magnetic polarity rotated counterclockwise. As expected, the rotation was significantly affected by the two flares. The magnetic transients induced by the flares were clearly evident in the sunspots with negative polarity. They were moving across the sunspots with speed of order 3−7 km s−1. Furthermore, the trend of magnetic flux evolution of these sunspots exhibited changes associated with the flares. These results may shed light on the understanding of the evolution of sunspots. **5-7 March 2012**

Slipping magnetic reconnections with multiple flare ribbons during an X-class solar flare

Ruisheng **Zheng**, Yao Chen, Bing Wang
ApJ 823 136 **2016**
http://arxiv.org/pdf/1604.04982v1.pdf
https://iopscience.iop.org/article/10.3847/0004-637X/823/2/136/pdf
With the observations of the Solar Dynamics Observatory, we present the slipping magnetic reconnections with multiple flare ribbons (FRs) during an X1.2 eruptive flare on **2014 January 7**. A center negative polarity was surrounded by several positive ones, and there appeared three FRs. The three FRs showed apparent slipping motions, and hook structures formed at their ends. Due to the moving footpoints of the erupting structures, one tight semi-circular hook disappeared after the slippage along its inner and outer edge, and coronal dimmings formed within the hook. The east hook also faded as a result of the magnetic reconnection between the arcades of a remote filament and a hot loop that was impulsively heated by the under flare loops. Our results are accordant with the slipping magnetic reconnection regime in 3D standard model for eruptive flares. We suggest that complex structures of the flare is likely a consequence of the more complex flux distribution in the photosphere, and the eruption involves at least two magnetic reconnections.

Semicircular-like Secondary Flare Ribbons Associated with a Failed Eruption

R. **Zheng**1, M. B. Korsós1,2, and R. Erdélyi

2015 ApJ 809 45
Flare ribbons (FRs) are one of the most apparent signatures of solar flares and have been treated as an indicator of magnetic reconnection. Drawing upon the observations from the Solar Dynamics Observatory, we present semicircular-like secondary FRs (SFRs) of a C2.3 flare on **2013 June 19**. Before the flare eruption, two bipoles in this core region subsequently emerged. Due to the interaction between the two bipoles, a tether-cutting eruption took place in the core region. The SFRs, surrounding the core region nearly simultaneously with the flare onset, were much weaker than the two normal FRs. Two ends of the SFRs experienced a separation and extension movement, but the middle part of the SFRs hardly expanded outward. We find SFRs are closely associated with the footpoint brightenings of some small loops around the core region. The eruption was confined by transequatorial loops (TLs), which resulted in the plasma material falling in the north end of the TLs and remote brightenings showing up in the south end of the TLs. The disappearance of the faint (filament) material during the emergence of the SFRs could indicate another eruption. We conclude that two or more magnetic reconnections are involved in this event and propose that SFRs consisting of a small part of true FRs resulted from the second magnetic reconnection and bright footpoints of loop clusters likely heated by the main flare.

Solar Flares and the Axion Quark Nugget Dark Matter Model

Ariel **Zhitnitsky**
JCAP **2018**
https://arxiv.org/pdf/1801.01509.pdf
We advocate the idea that the nanoflares conjectured by Parker long ago to resolve the corona heating problem, may also trigger the larger solar flares. The arguments are based on the model where emission of extreme ultra violet (EUV) radiation and soft x-rays from the Sun are powered externally by incident dark matter particles within the Axion Quark Nugget (AQN) Dark Matter Model. The corresponding annihilation events of the AQNs with the solar material are identified with nanoflares. This model gives a very reasonable intensity of EUV radiation without adjustments of any parameters in the model. When the same nuggets enter the regions with high magnetic field they serve as the triggers igniting the magnetic reconnections which eventually may lead to much larger flares. Technically, the magnetic reconnection is ignited due to the shock wave which inevitably develops when the dark matter nuggets enter the solar atmosphere with velocity $v\sim 10^{-3}c$ which is much higher than the speed of sound cs, such that the Mach number $M=v/cs\gg 1$. These shock waves generate very strong and very short impulses expressed in terms of pressure $\Delta p/p\sim M2$ and temperature $\Delta T/T\sim M2$ in vicinity of (would be) magnetic reconnection area. We find that this mechanism is consistent with x -ray observations as well as with observed jet like morphology of the initial stage of the flares. The mechanism is also consistent with the observed scaling of the flare distribution $dN\sim W^{-\alpha}dW$ as a function of the flare's energy W. We also speculate that the same nuggets may trigger the sunquakes which are known to be correlated with large flares.

Extreme-ultraviolet Late Phase in Homologous Solar Flares from a Complex Active Region

Y. **Zhong**, Y. Dai, M. D. Ding
ApJ **916** 37 **2021**
https://doi.org/10.3847/1538-4357/ac0430
https://arxiv.org/pdf/2105.10069.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ac0430/pdf
Recent observations in extreme-ultraviolet (EUV) wavelengths reveal a new late phase in some solar flares, which is seen as a second peak in warm coronal emissions (~3 MK) several tens of minutes to a few hours after the soft X-ray (SXR) peak. The origin of the EUV late phase (ELP) is explained by either a long-lasting cooling process in the long ELP loops, or a delayed energy ejection into the ELP loops well after the main flare heating. Using the observations with the \emph{Solar Dynamics Observatory} (\emph{SDO}), we investigate the production of the ELP in six homologous flares (F1--F6) originating from a complex active region (AR) NOAA 11283, with an emphasis on the emission characteristics of the flares. It is found that the main production mechanism of the ELP changes from additional heating in flare F1 to long-lasting cooling in flares F3--F6, with both mechanisms playing a role in flare F2. The transition is evidenced by an abrupt decrease of the time lag of the ELP peak, and the long-lasting cooling process in the majority of the flares is validated by a positive correlation between the flare ribbon fluence and the ELP peak intensity. We attribute the change in ELP production mechanism to an enhancement of the envelope magnetic field above the AR, which facilitates a more prompt and energetic heating of the ELP loops. In addition, the last and the only confined flare F6 exhibits an extremely large ELP. The different emission pattern revealed in this flare may reflect a different energy partitioning inside the ELP loops, which is due to a different magnetic reconnection process. **2011: August 31 to September 11, September 6, 7, 8, 9.**

Transition from circular-ribbon to parallel-ribbon flares associated with a bifurcated magnetic flux rope

Z. **Zhong**, Y. Guo, M. D. Ding, C. Fang, Q. Hao
ApJ **871** 105 **2019**

https://arxiv.org/pdf/1812.10223.pdf
Magnetic flux ropes play a key role in triggering solar flares in the solar atmosphere. In this paper, we investigate the evolution of active region NOAA 12268 within 36 hours from **2015 January 29 to 30**, during which a flux rope was formed and three M-class and three C-class flares were triggered without coronal mass ejections. During the evolution of the active region, the flare emission seen in the Hα and ultraviolet wavebands changed from a circular shape (plus an adjacent conjugated ribbon and a remote ribbon) to three relatively straight and parallel ribbons. Based on a series of reconstructed nonlinear force-free fields, we find sheared or twisted magnetic field lines and a large-scale quasi-separatrix layer (QSL) associated with 3D null points in a quadrupolar magnetic field. These features always existed and constantly evolved during the two days. The twist of the flux rope was gradually accumulated that eventually led to its instability. Around the flux rope, there were some topological structures, including a bald patch, a hyperbolic flux tube and a torus QSL. We discuss how the particular magnetic structure and its evolution produce the flare emission. In particular, the bifurcation of the flux rope can explain the transition of the flares from circular to parallel ribbons. We propose a two-stage evolution of the magnetic structure and its associated flares. In the first stage, sheared arcades under the dome-like large-scale QSL were gradually transformed into a flux rope through magnetic reconnection, which produced the circular ribbon flare. In the second stage, the flux rope bifurcated to form the three relatively straight and parallel flare ribbons.

On the origin of a broad QFP wave train: unwinding jet as the driver

Xinping **Zhou**, Zehao Tang, Zhining Qu, Ke Yu, Chengrui Zhou, Yuqi Xiang, Ahmed Ahmed Ibrahim, Yuandeng Shen
ApJ **2024**
https://arxiv.org/pdf/2409.17741
Large-scale extreme-ultraviolet (EUV) waves commonly exhibit as single wavefront and are believed to be caused by coronal mass ejections (CMEs). Utilizing high spatiotemporal resolution imaging observations from the Solar Dynamics Observatory, we present two sequentially generated wave trains originating from the same active region: a narrow quasiperiodic fast-propagating (QFP) wave train that propagates along the coronal loop system above the jet and a broad QFP wave train that travels along the solar surface beneath the jet. The measurements indicate that the narrow QFP wave train and the accompanying flare's quasiperiodic pulsations (QPPs) have nearly identical onsets and periods. This result suggests that the accompanying flare process excites the observed narrow QFP wave train. However, the broad QFP wave train starts approximately 2 minutes before the QPPs of the flare, but consistent with the interaction between the unwinding jet and the solar surface. Moreover, we find that the \zx{period of the broad QFP wave train, approximately 130\,s, closely matches that of the unwinding jet}. This period is significantly longer than the 30\,s period of the accompanying flare's QPPs. Based on these findings, we propose that the intermittent energy release of the accompanying flare excited the narrow QFP wave train confined propagating in the coronal loop system. The unwinding jet, rather than the intermittent energy release in the accompanying flare, triggered the broad QFP wave train propagating along the solar surface. **2011 January 27**

Resolved magnetohydrodynamic wave lensing in the solar corona

Xinping **Zhou**, Yuandeng Shen, Ding Yuan, Rony Keppens, Xiaozhou Zhao, Libo Fu, Zehao Tang, Jiaoyang Wang, Chengrui Zhou
Nature Communications 15, 3281 (**2024**)
https://arxiv.org/pdf/2404.12044.pdf
Electromagnetic wave lensing, a common physical phenomenon recognized in visible light for centuries, finds extensive applications in manipulating light in optical systems such as telescopes and cameras. Magnetohydrodynamic wave is a common perturbation phenomenon in the corona. By using high spatio-temporal resolution observations from the Solar Dynamics Observatory, here, we report the observation of a magnetohydrodynamic wave lensing in the highly ionized and magnetized coronal plasma, where quasi-periodic wavefronts emanated from a flare converged at a specific point after traversing a coronal hole. The entire process resembles an electromagnetic wave lensing from the source to the focus. Meanwhile, the magnetohydrodynamic wave lensing is well reproduced through a magnetohydrodynamic numerical simulation with full spatio-temporal resolution. We further investigate potential applications for coronal seismology, as the lensing process encodes information on the Alfvén speed, in conjunction with favorable geometric and density variations. **2011 February 24**

Consecutive Narrow and Broad Quasi-periodic Fast-propagating Wave Trains Associated with a Flare

Xinping **Zhou**, Yuandeng Shen, Chengrui Zhou, Zehao Tang, Ahmed Ahmed Ibrahim
ScChG **2024**
https://arxiv.org/pdf/2401.06661.pdf
The excitation mechanism of coronal quasi-period fast-propagating (QFP) wave trains remains unresolved. Using Atmospheric Imaging Assembly onboard the Solar Dynamics Observatory observations, we study a narrow and a broad QFP wave train excited one after another during the successive eruptions of filaments hosted within a fan-spine

magnetic system on **2013 October 20**. The consecutive occurrence of these two types of QFP wave trains in the same event provides an excellent opportunity to explore their excitation mechanisms and compare their physical parameters. Our observational results reveal that narrow and broad QFP wave trains exhibit distinct speeds, periods, energy fluxes, and relative intensity amplitudes, although originating from the same active region and being associated with the same {\em GOES} C2.9 flare. Using wavelet analysis, we find that the narrow QFP wave train shares a similar period with the flare itself, suggesting its possible excitation through the pulsed energy release in the magnetic reconnection process that generated the accompanying flare. On the other hand, the broad QFP wave train appears to be associated with the energy pulses released by the successive expansion and unwinding of filament threads. Additionally, it is plausible that the broad QFP wave train was also excited by the sequential stretching of closed magnetic field lines driven by the erupting filament. These findings shed light on the different excitation mechanisms and origins of the QFP wave trains.

Recurrent narrow quasi-periodic fast-propagating wave trains excited by the intermittent energy release in the accompanying solar flare

Xinping **Zhou**, Yuandeng Shen, Hongfei Liang, Zhining Qu, Yadan Duan, Zehao Tang, Chengrui Zhou, Song Tan

ApJ **941** 59 **2022**

https://arxiv.org/pdf/2211.14488.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/aca1b6/pdf

About the driven mechanisms of the quasi-periodic fast-propagating (QFP) wave trains, there exist two dominant competing physical explanations: associated with the flaring energy release or attributed to the waveguide dispersion. Employing Solar Dynamics Observatory (SDO) Atmospheric Imaging Assembly (AIA) 171 A images, we investigated a series of QFP wave trains composed of multiple wavefronts propagating along a loop system during the accompanying flare on **2011 November 11**. The wave trains showed a high correlation in start time with the energy release of the accompanying flare. Measurements show that the wave trains phase speed is almost consistent with its group speed with a value of about 1000 km s-1, indicating that the wave trains should not be dispersed waves. The period of the wave trains was the same as that of the oscillatory signal in X ray emissions released by the flare. Thus we propose that the QFP wave trains were most likely triggered by the flare rather than by dispersion. We investigated the seismological application with the QFP waves and then obtained that the magnetic field strength of the waveguide was about 10 Gauss. Meanwhile, we also estimated that the energy flux of the wave trains was about 1.2X105 erg cm-2 s-1.

Observations of a Flare-ignited broad Quasi-periodic Fast-propagating wave train

Xinping **Zhou**, Yuandeng Shen, Ying D. Liu, Huidong Hu, Jiangtao Su, Zehao Tang, Chengrui Zhou, Yadan Duan, Song Tan

ApJL **930** L5 **2022**

https://arxiv.org/pdf/2204.05603.pdf

https://iopscience.iop.org/article/10.3847/2041-8213/ac651e/pdf

Large-scale Extreme-ultraviolet (EUV) waves are frequently observed as an accompanying phenomenon of flares and coronal mass ejections (CMEs). Previous studies mainly focus on EUV waves with single wavefronts that are generally thought to be driven by the lateral expansion of CMEs. Using high spatio-temporal resolution multi-angle imaging observations taken by the Solar Dynamic Observatory and the Solar Terrestrial Relations Observatory, we present the observation of a broad quasi-periodic fast propagating (QFP) wave train composed of multiple wavefronts along the solar surface during the rising phase of a GOES M3.5 flare on **2011 February 24**. The wave train transmitted through a lunate coronal hole (CH) with a speed of 840 +/-67 km/s, and the wavefronts showed an intriguing refraction effect when they passed through the boundaries of the CH. Due to the lunate shape of the CH, the transmitted wavefronts from the north and south arms of the CH started to approach each other and finally collided, leading to the significant intensity enhancement at the collision site. This enhancement might hint the occurrence of interference between the two transmitted wave trains. The estimated magnetosonic Mach number of the wave train is about 1.13, which indicates that the observed wave train was a weak shock. Period analysis reveals that the period of wave train was ~90 seconds, in good agreement with that of the accompanying flare. Based on our analysis results, we conclude that the broad QFP wave train was a large-amplitude fast-mode magnetosonic wave or a weak shock driven by some non-linear energy release processes in the accompanying flare.

Diagnosing the Optically Thick/Thin Features Using the Intensity Ratio of Si IV Resonance Lines in Solar Flares

Yi-an **Zhou**, Jie Hong, Y. LI, M.D. Ding

ApJ **2022**

https://arxiv.org/pdf/2201.05305.pdf

In the optically thin regime, the intensity ratio of the two Si IV resonance lines (1394 and 1403 Å) are theoretically the same as the ratio of their oscillator strengths, which is exactly 2. Here, we study the ratio of the integrated intensity of the Si IV lines ($R=\int I1394(\lambda)d\lambda/\int I1403(\lambda)d\lambda$) and the ratio of intensity at each wavelength point

(r(Δλ)=I1394(Δλ)/I1403(Δλ)) in two solar flares observed by the Interface Region Imaging Spectrograph. We find that at flare ribbons, the ratio R ranges from 1.8 to 2.3 and would generally decrease when the ribbons sweep across the slit position. Besides, the distribution of r(Δλ) shows a descending trend from the blue wing to the red wing. In loop cases, the Si IV line presents a wide profile with a central reversal. The ratio R deviates little from 2, but the ratio r(Δλ) can vary from 1.3 near the line center to greater than 2 in the line wings. Hence we conclude that in flare conditions, the ratio r(Δλ) varies across the line, due to the variation of the opacity at the line center and line wings. We notice that, although the ratio r(Δλ) could present a value which deviates from 2 as a result of the opacity effect near the line center, the ratio R is still close to 2. Therefore, caution should be taken when using the ratio of the integrated intensity of the Si IV lines to diagnose the opacity effect. **2014 April 18, 2017 September 9**

Resolving Two Distinct Thermal X-ray Components in a compound Solar Flare

Zhenjun **Zhou**, Rui Liu, Jianqing Sun, Jie Zhang, Mingde Ding, Yuming Wang, Xiaoyu Yu, Lijuan Liu, Jun Cui

ApJ **925** 132 **2022**

https://arxiv.org/pdf/2112.04652.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/ac3bbe/pdf **File**

X-ray emission provides the most direct diagnostics of the energy-release process in solar flares. Occasionally, a superhot X-ray source is found to be above hot flare loops of ~10 MK temperature. While the origin of the superhot plasma is still elusive, it has conjured up an intriguing image of in-situ plasma heating near the reconnection site high above the flare loops, in contrast to the conventional picture of chromospheric evaporation. Here we investigate an extremely long-duration solar flare, in which EUV images show two distinct flare loop systems that appear successively along a Gamma-shaped polarity inversion line (PIL). When both flare loop systems are present, the HXR spectrum is found to be well fitted by combining a hot component (Te ~12 MK) and a superhot component (Te ~30 MK). Associated with a fast CME, the superhot X-ray source is located at top of the flare arcade that appears earlier, straddling and extending along the long "arm" of the Gamma-shaped PIL. Associated with a slow CME, the hot X-ray source is located at the top of the flare arcade that appears later and sits astride the short "arm" of the Gamma-shaped PIL. Aided by observations from a different viewing angle, we are able to verify that the superhot X-ray source is above the hot one in projection, but the two sources belong to different flare loop systems. Thus, this case study provides a stereoscopic observation explaining the co-existence of superhot and hot X-ray emitting plasmas in solar flares. **2012 July 17**

https://doi.org/10.3847/1538-4357/abb77c

In this paper, we analyze the high-resolution UV spectra for a C1.7 solar flare (SOL**2017-09-09**T06:51) observed by the \textit{Interface Region Imaging Spectrograph} (\textit{IRIS}). {We focus on the spectroscopic observations at the locations where the cool lines of \ion{Si}{4} 1402.8 Å (~104.8 K) and \ion{C}{2} 1334.5/1335.7 Å (~104.4 K) reveal significant redshifts with Doppler velocities up to ~150 km s−1.} These redshifts appear in the rise phase of the flare, then increase rapidly, reach the maximum in a few minutes, and proceed into the decay phase. Combining the images from \textit{IRIS} and Atmospheric Imaging Assembly (AIA) on board the {\em Solar Dynamics Observatory} ({\em SDO}), we propose that the redshifts in the cool lines are caused by the downflows in the transition region and upper chromospheric layers, which likely result from a magnetic reconnection leading to the flare. In addition, the cool \ion{Si}{4} and \ion{C}{2} lines show gentle redshifts (a few tens of km s−1) at some other locations, which manifest some distinct features from the above locations. This is supposed to originate from a different physical process.

Extreme-ultraviolet Late Phase Caused by Magnetic Reconnection over Quadrupolar Magnetic Configuration in a Solar Flare

Zhenjun **Zhou**, Xin Cheng, Lijuan Liu, Yu Dai, Yuming Wang, Jun Cui

2019 *ApJ* **878** 46

https://arxiv.org/pdf/1905.00549.pdf

sci-hub.se/10.3847/1538-4357/ab1d5c

A second emission enhancement in warm coronal extreme-ultraviolet (EUV) lines (about 2-7 MK) during some solar flares is known as the EUV late phase. Imaging observations confirm that the late phase emission originates from a set of longer or higher loops than the main flare loops. Nevertheless, some questions remain controversial: What is the relationship between these two loop systems? What is the heating source of late phase emission, a heating accompany the main phase heating or occuring quite later? In this paper, we present clear evidence for heating source in a late-

phase solar flare: magnetic reconnection of overlying field in a quadrupolar magnetic configuration. The event is triggered by an erupted core structure that eventually leads to a coronal mass ejection (CME). Cusp feature and its shrinkage motion high in the late-phase emission region are the manifestation of the later phase reconnection following the main flare reconnection. Using the enthalpy-based thermal evolution of loops (EBTEL) model, we reasonably reproduce the late-phase emissions in some EUV lines. We suggest that a continuous additional heating is responsible for the appearance of the elongated EUV late phase. **2014 April 25**

Toward Understanding the 3D Structure and Evolution of Magnetic Flux Ropes in an Extremely Long Duration Eruptive Flare

Zhenjun **Zhou** , Jie Zhang4, Yuming Wang1,3, Rui Liu1,5, and Georgios Chintzoglou
2017 ApJ 851 133 **File**
http://iopscience.iop.org.sci-hub.tw/0004-637X/851/2/133/
In this work, we analyze the initial eruptive process of an extremely long duration C7.7-class flare that occurred on **2011 June 21**. The flare had a 2 hr long rise time in soft X-ray emission, which is much longer than the rise time of most solar flares, including both impulsive and gradual ones. Combining the facts that the flare occurred near the disk center as seen by the Solar Dynamic Observatory (SDO) but near the limb as seen by two Solar Terrestrial Relations Observatory(STEREO) spacecraft, we are able to track the evolution of the eruption in 3D in a rare slow-motion manner. The time sequence of the observed large-scale EUV hot channel structure in the Atmospheric Imaging Assembly (AIA) high-temperature passbands of 94 and 131 Å clearly shows the process of how the sigmoid structure prior to the eruption was transformed into a near-potential post-eruption loop arcade. We believe that the observed sigmoid represents the structure of a twisted magnetic flux rope (MFR), which has reached a height of about 60 Mm at the onset of the eruption. We argue that the onset of the flare precursor phase is likely triggered by the loss of the magnetohydrodynamic equilibrium of a preexisting MFR, which leads to the slow rise of the flux rope. The rising motion of the flux rope leads to the formation of a vertical current sheet underneath, triggering the fast magnetic reconnection that in turn leads to the main phase of the flare and fast acceleration of the flux rope.

ELECTRON ACCELERATION BY CASCADING RECONNECTION IN THE SOLAR CORONA. II. RESISTIVE ELECTRIC FIELD EFFECTS

X. **Zhou**1,2, J. Büchner2, M. Bárta2,3, W. Gan1, and S. Liu
2016 ApJ 827 94
We investigate electron acceleration by electric fields induced by cascading reconnections in current sheets trailing coronal mass ejections via a test particle approach in the framework of the guiding-center approximation. Although the resistive electric field is much weaker than the inductive electric field, the electron acceleration is still dominated by the former. Anomalous resistivity η is switched on only in regions where the current carrier's drift velocity is large enough. As a consequence, electron acceleration is very sensitive to the spatial distribution of the resistive electric fields, and electrons accelerated in different segments of the current sheet have different characteristics. Due to the geometry of the 2.5-dimensional electromagnetic fields and strong resistive electric field accelerations, accelerated high-energy electrons can be trapped in the corona, precipitating into the chromosphere or escaping into interplanetary space. The trapped and precipitating electrons can reach a few MeV within 1 s and have a very hard energy distribution. Spatial structure of the acceleration sites may also introduce breaks in the electron energy distribution. Most of the interplanetary electrons reach hundreds of keV with a softer distribution. To compare with observations of solar flares and electrons in solar energetic particle events, we derive hard X-ray spectra produced by the trapped and precipitating electrons, fluxes of the precipitating and interplanetary electrons, and electron spatial distributions.

Electron acceleration by cascading reconnection in the solar corona I Magnetic gradient and curvature effects

X. **Zhou**, J. Büchner, M. Barta, W. Gan, S. Liu
A&A **2015**
http://arxiv.org/pdf/1504.06486v1.pdf
Aims: We investigate the electron acceleration in convective electric fields of cascading magnetic reconnection in a flaring solar corona and show the resulting hard X-ray (HXR) radiation spectra caused by Bremsstrahlung for the coronal source. Methods: We perform test particle calculation of electron motions in the framework of a guiding center approximation. The electromagnetic fields and their derivatives along electron trajectories are obtained by linearly interpolating the results of high-resolution adaptive mesh refinement (AMR) MHD simulations of cascading magnetic reconnection. Hard X-ray (HXR) spectra are calculated using an optically thin Bremsstrahlung model. Results: Magnetic gradients and curvatures in cascading reconnection current sheet accelerate electrons: trapped in magnetic islands, precipitating to the chromosphere and ejected into the interplanetary space. The final location of an electron is determined by its initial position, pitch angle and velocity. These initial conditions also influence electron acceleration efficiency. Most of electrons have enhanced perpendicular energy. Trapped electrons are considered to cause the observed bright spots along coronal mass ejection CME-trailing current sheets as well as the flare loop-top HXR emissions.

Converging motion of conjugate flaring kernels during two large solar flares

Tuanhui **Zhou**, Haisheng Ji and Guangli Huang

Advances in Space Research , Volume 41, Issue 8, **2008**, Pages 1195-1201

In this paper, we analyze the footpoint motion of two large solar flares using observations made by the Transition Region and Coronal Explorer (TRACE) and Reuven Ramaty High Energy Solar Spectroscopic Imager (*RHESSI*). The two flares are the **M5.7 flare of March 14, 2002 and the X10 flare of October 29, 2003.** They are both classical two-ribbon flares as observed in TRACE 1600 or 171 Å images and have long-duration conjugate hard X-ray (HXR) footpoint emission. We use the 'center-of-mass' method to locate the centroids of the UV/EUV flare ribbons. The results are: (1) The conjugate UV/EUV ribbons and HXR footpoints of the two flares show a converging (inward) motion during the impulsive phase. For the two flares, the converging motion lasts about 3 and 10 min, respectively. The usual separation (outward) motion for the flare ribbons and footpoints take place only after the converging motion. (2) During the inward and the outward motion, the conjugate ribbons and footpoints of the two events exhibit a strong unshear motion. In obtaining above results, TRACE UV/EUV and *RHESSI* HXR data show an overall agreement. The two events demonstrate that the magnetic reconnection for the flares occurs in highly sheared magnetic field. Furthermore, the results support the magnetic model constructed by Ji et al. [Ji, H., Huang, G., Wang, H. Astrophys. J. 660, 893–900, 2007], who proposed that the contracting motion of flaring loops is the signature of the relaxation of sheared magnetic fields.

Quasi-Simultaneous Flux Emergence in the Events of October – November 2003

Guiping **Zhou** · Jingxiu Wang · Yuming Wang · Yuzong Zhang

Solar Phys (**2007**) 244: 13–24; **File**

From late October to the beginning of November 2003, a series of intense solar eruptive events took place on the Sun. More than six active regions (ARs), including three large ARs (NOAA numbers AR 10484, AR 10486, and AR 10488), were involved in the activity. Among the six ARs, four of them bear obviously quasi-simultaneous emergence of magnetic flux. Based on the global Hα and SOHO/EIT EUV observations, we found that a very long filament channel went through the six ARs. This implies that there is a magnetic connection among these ARs. The idea of large-scale magnetic connectivity among the Ars is supported by the consistency of the same chirality in the three major ARs and in their associated magnetic clouds. Although the detailed mechanisms for the quasi-simultaneous flux emergence and the large-scale flux system formation need to be extensively investigated, the observations provide new clues in studying the global solar activity.

Modeling Mg II h, k and Triplet Lines at Solar Flare Ribbons

Yingjie **Zhu**, Adam F. Kowalski, Hui Tian, Han Uitenbroek, Mats Carlsson, Joel C. Allred

2019 *ApJ* **879** 19

https://arxiv.org/pdf/1904.12285.pdf

sci-hub.se/10.3847/1538-4357/ab2238

Observations from the \textit{Interface Region Imaging Spectrograph} (\textsl{IRIS}) often reveal significantly broadened and non-reversed profiles of the Mg II h, k and triplet lines at flare ribbons. To understand the formation of these optically thick Mg II lines, we perform plane parallel radiative hydrodynamics modeling with the RADYN code, and then recalculate the Mg II line profiles from RADYN atmosphere snapshots using the radiative transfer code RH. We find that the current RH code significantly underestimates the Mg II h \& k Stark widths. By implementing semi-classical perturbation approximation results of quadratic Stark broadening from the STARK-B database in the RH code, the Stark broadenings are found to be one order of magnitude larger than those calculated from the current RH code. However, the improved Stark widths are still too small, and another factor of 30 has to be multiplied to reproduce the significantly broadened lines and adjacent continuum seen in observations. Non-thermal electrons, magnetic fields, three-dimensional effects or electron density effect may account for this factor. Without modifying the RADYN atmosphere, we have also reproduced non-reversed Mg II h \& k profiles, which appear when the electron beam energy flux is decreasing. These profiles are formed at an electron density of ∼8×1014 cm−3 and a temperature of ∼1.4×104 K, where the source function slightly deviates from the Planck function. Our investigation also demonstrates that at flare ribbons the triplet lines are formed in the upper chromosphere, close to the formation heights of the h \& k lines. **2014 March 29**

Two-Phase Heating in Flaring Loops

Chunming **Zhu**, Jiong Qiu, Dana W. Longcope

ApJ **856** 27 **2018**

https://arxiv.org/pdf/1802.00871.pdf

We analyze and model a C5.7 two-ribbon solar flare observed by SDO, Hinode and GOES on **2011 December 26**. The flare is made of many loops formed and heated successively over one and half hours, and their footpoints are brightened in the UV 1600 A before enhanced soft X-ray and EUV missions are observed in flare loops. Assuming that anchored at each brightened UV pixel is a half flaring loop, we identify more than 6,700 half flaring loops, and infer the heating rate of each loop from the UV light curve at the foot-point. In each half loop, the heating rate consists of two phases, an intense impulsive heating followed by a low-rate heating persistent for more than 20 minutes. Using these heating rates, we simulate the evolution of their coronal temperatures and densities with the model of "enthalpy-based thermal evolution of loops" (EBTEL). In the model, suppression of thermal conduction is also considered. This model successfully reproduces total soft X-ray and EUV light curves observed in fifteen pass-bands by four instruments GOES, AIA, XRT, and EVE. In this flare, a total energy of 4.9x10^30 ergs is required to heat the corona, around 40% of this energy is in the slow heating phase. About two fifth of the total energy used to heat the corona is radiated by the coronal plasmas, and the other three fifth transported to the lower atmosphere by thermal conduction.

Evolution of a Current Sheet in a Solar Flare

Chunming **Zhu**, Rui Liu, David Alexander, R.T. James McAteer
2016 *ApJ* **821** L29
http://arxiv.org/pdf/1603.07062v1.pdf
We report multi-wavelength and multi-viewpoint observations of a solar eruptive event which involves loop-loop interactions. During a C2.0 flare, motions associated with inflowing and outflowing plasma provide evidence for ongoing magnetic reconnection. The flare loop top and a rising "concave-up" feature are connected by a current-sheet-like structure (CSLS). The physical properties (thickness, length, temperature, and density) of the CSLS are evaluated. In regions adjacent to the CSLS, the EUV emission (characteristic temperature at 1.6 MK) begins to increase more than ten minutes prior to the onset of the flare, and steeply decreases during the decay phase. The reduction of the emission resembles that expected from coronal dimming. The dynamics of this event imply a magnetic reconnection rate in the range 0.01 -- 0.05. **2013 December 10**

Complex Flare Dynamics Initiated by a Filament-Filament Interaction

Chunming **Zhu**, Rui Liu, David Alexander, Xudong Sun, James McAteer
2015 ApJ 813 60
http://arxiv.org/pdf/1507.05889v1.pdf
We report on an eruption involving a relatively rare filament-filament interaction on **2013 June 21**, observed by SDO and STEREO-B. The two filaments were separated in height within AR 11777. The onset of the eruption of the lower filament was accompanied simultaneously by the apparent descent of the upper filament resulting in a convergence and direct interaction of the two filaments. The interaction was accompanied by the heating of plasmas surrounding the upper filament and the subsequent coalescence of the filaments into a magnetically complex structure, whose eruption was associated with an M2.9 class solar flare. Magnetic loop shrinkage and descending dark voids were observed at different locations as part of the large flare energy release giving us a unique insight into these dynamic flare phenomena.

Successive Coronal Mass Ejections Associated with Weak Solar Energetic Particle Events

Bin **Zhuang**, Noé Lugaz, Tingyu Gou, Liuguan Ding
ApJ **921** 6 **2021**
https://arxiv.org/pdf/2109.02225.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ac17e9/pdf
https://doi.org/10.3847/1538-4357/ac17e9
The scenario of twin coronal mass ejections (CMEs), i.e., a fast and wide primary CME (priCME) preceded by previous CMEs (preCMEs), has been found to be favorable to a more efficient particle acceleration in large solar energetic particle (SEP) events. Here, we study 19 events during 2007--2014 associated with twin-CME eruptions but without large SEP observations at L1 point. We combine remote-sensing and in situ observations from multiple spacecraft to investigate the role of magnetic connectivity in SEP detection and the CME information in 3-dimensional (3D) space. We study one-on-one correlations of the priCME 3D speed, flare intensity, suprathermal backgrounds, and height of CME-CME interaction with the SEP intensity. Among these, the priCME speed is found to correlate with the SEP peak intensity at the highest level. We use the projection correlation method to analyze the correlations between combinations of these multiple independent factors and the SEP peak intensity. We find that the only combination of two or more parameters that has higher correlation with the SEP peak intensity than the CME speed is the CME speed combined with the propagation direction. This further supports the dominant role of the priCME in controlling the SEP enhancements, and emphasizes the consideration of the latitudinal effect. Overall, the magnetic connectivity in longitude as well as latitude and the relatively lower priCME speed may explain the existence of the twin-CME SEP-poor events. The role of the barrier effect of preCME(s) is discussed for an event on **2013 October 28.**
Table 1:: Twin-CME (L1-point) SEP-poor events during 2007– 2014
Table 2:: Twin-CME (L1-point) large SEP events in solar cycle 24

Topological Quantification of the "Anemone" (Branching) Solar Flares

Evgeny V. **Zhuzhoma**, Vladislav S. Medvedev, Yurii V. Dumin, Boris V. Somov
Physica D **2021**
https://arxiv.org/pdf/2111.06730.pdf
Here, using the methods of dynamical systems and Morse-Smale theory, we derive a few universal topological relations between the numbers of the null points and sources of various kinds with arbitrary arrangement in the above-mentioned structures. Such relations can be a valuable tool both for a quantification of the already-observed anemone flares and for a prediction of the new ones in complex magnetic configurations.

Cylindrical and Spherical Pistons as Drivers of MHD Shocks

Tomislav **Žic** · Bojan Vršnak · Manuela Temmer · Carla Jacobs
Solar Phys (**2008**) 253: 237–247
We consider an expanding three-dimensional (3-D) piston as a driver of an MHD shock wave. It is assumed that the source-region surface accelerates over a certain time interval to achieve a particular maximum velocity. Such an expansion creates a large-amplitude wave in the ambient plasma. Owing to the nonlinear evolution of the wave front, its profile steepens and after a certain time and distance a discontinuity forms, marking the onset of the shock formation. We investigate how the formation time and distance depend on the acceleration phase duration, the maximum expansion velocity (defining also acceleration), the Alfvén velocity (defining also Mach number), and the initial size of the piston. The model differs from the 1-D case, since in the 3-D evolution, a decrease of the wave amplitude with distance must be taken into account. We present basic results, focusing on the timing of the shock formation in the low- and high-plasma-beta environment. We find that the shockformation time and the shock-formation distance are (1) approximately proportional to the acceleration phase duration; (2) shorter for a higher expansion velocity; (3) larger in a higher Alfvén speed environment; (4) only weakly dependent on the initial source size; (5) shorter for a stronger acceleration; and (6) shorter for a larger Alfvén Mach number of the source surface expansion. To create a shock causing a high-frequency type II burst and the Moreton wave, the source region expansion should, according to our results, achieve a velocity on the order of 1000 km s^{-1} within a few minutes, in a low Alfvén velocity environment.

Quasi-Periodic Energy Release in a Three-Ribbon Solar Flare

Ivan **Zimovets**, Ivan Sharykin & Ivan Myshyakov
Solar Physics volume 296, Article number: 188 (**2021**)
https://link.springer.com/content/pdf/10.1007/s11207-021-01936-9.pdf
https://doi.org/10.1007/s11207-021-01936-9
Quasi-periodic pulsations (QPPs) are found in solar flares of various magnetic morphologies, e.g. in two-ribbon or circular-ribbon flares, and the mechanisms of their generation are not yet clear. Here we present the first detailed analysis of QPPs (with a period P=54±13 seconds) found in the Ramaty High Energy Solar Spectroscopic Imager (RHESSI) observations of a relatively rare three-ribbon M1.1 class flare that occurred on **5 July 2012** (SOL**2012-07-05T06:49**). QPPs are manifested in the temporal profiles of temperature [TT] and emission measure [EMEM] of "super-hot" ($T_s \approx 30 - 50$ MK) plasma but are almost invisible in the profiles of "hot" ($T_h \approx 15 - 20$ MK) plasma parameters when approximating X-ray spectra of the flare with the bremsstrahlung spectrum of a two-temperature thermal (Maxwellian) plasma. In addition, QPPs with a similar period are found in the temporal profiles of the flux and spectral index of nonthermal electrons if the observed X-ray spectra are approximated by a combination of the bremsstrahlung spectra of a single-temperature plasma and nonthermal electrons with a power-law energy distribution. QPPs are not well expressed in the X-ray flux according to RHESSI and GOES data, or in radio data. The QPPs are accompanied by apparent systematic movement of a single X-ray source at a low speed of 34±21 km s^{-1} along the central flare ribbon over a narrow (<5 Mm) "tongue" of negative magnetic polarity, elongated (≈20 Mm) between two areas of positive polarity. The results of magnetic extrapolation in the nonlinear force-free field (NLFFF) approximation show that the X-ray source could move along curved and twisted field lines between two sheared flare arcades. It is worth noting that in the homologous three-ribbon M6.1 flare (SOL**2012-07-05T11:39**), which occurred in the same region about five hours later, the X-ray sources moved much less systematically and did not produce similar QPPs. We interpret the observed QPPs as a result of successive episodes of energy release in different spatial locations. In each pulsation, $\approx(1 - 4)\times 10^{29}$ erg is released in the form of thermal energy of hot and super-hot plasmas (or accelerated electrons), which is comparable with the energy of a microflare. The total kinetic energy released during all QPPs is $\approx(0.7 - 3.5)\times 10^{30}$ erg, which is about an order of magnitude less than the free magnetic energy $\approx 1.56\times 10^{31}$ erg released in the flare region. We discuss possible propagating triggers of the quasi-periodic energy release (slow magnetoacoustic waves, asymmetric rise of curved/twisted field lines, flapping

oscillations, and thermal instability in a reconnecting current sheet) and argue that the current state of available mechanisms and observations does not allow us to reach an unambiguous conclusion.

Quasi-Periodic Pulsations in Solar and Stellar Flares: A Review of Underpinning Physical Mechanisms and Their Predicted Observational Signatures

I. V. **Zimovets**, J. A. McLaughlin, A. K. Srivastava, D. Y. Kolotkov, A. A. Kuznetsov, E. G. Kupriyanova, I.-H. Cho, A. R. Inglis, F. Reale, D. J. Pascoe, H. Tian, D. Yuan, D. Li & Q. M. Zhang
Space Science Reviews volume 217, Article number: 66 (**2021**)
https://link.springer.com/content/pdf/10.1007/s11214-021-00840-9.pdf
https://doi.org/10.1007/s11214-021-00840-9

The phenomenon of quasi-periodic pulsations (QPPs) in solar and stellar flares has been known for over 50 years and significant progress has been made in this research area. It has become clear that QPPs are not rare—they are found in many flares and, therefore, robust flare models should reproduce their properties in a natural way. At least fifteen mechanisms/models have been developed to explain QPPs in solar flares, which mainly assume the presence of magnetohydrodynamic (MHD) oscillations in coronal structures (magnetic loops and current sheets) or quasi-periodic regimes of magnetic reconnection. We review the most important and interesting results on flare QPPs, with an emphasis on the results of recent years, and we present the predicted and prominent observational signatures of each of the fifteen mechanisms. However, it is not yet possible to draw an unambiguous conclusion as to the correct underlying QPP mechanism because of the qualitative, rather than quantitative, nature of most of the models and also due to insufficient observational information on the physical properties of the flare region, in particular the spatial structure of the QPP source. We also review QPPs in stellar flares, where progress is largely based on solar-stellar analogies, suggesting similarities in the physical processes in flare regions on the Sun and magnetoactive stars. The presence of QPPs with similar properties in solar and stellar flares is, in itself, a strong additional argument in favor of the likelihood of solar-stellar analogies. Hence, advancing our understanding of QPPs in solar flares provides an important additional channel of information about stellar flares. However, further work in both theory/simulations and in observations is needed. **1972 May 16, 1998 May 8, 29 May 2003, February 15, 2011, 2012-07-19, 26 Oct 2014, 09 November 2014, 2014 December 17, 2015 March 12, 5 May 2015, 2015 November 04, September 10, 2017**

Relationships between Photospheric Vertical Electric Currents and Hard X-Ray Sources in Solar Flares: Statistical Study

I.V. **Zimovets**, I.N. Sharykin, W.Q. Gan
ApJ **891** 138 **2020**
https://arxiv.org/pdf/2002.06646.pdf
https://doi.org/10.3847/1538-4357/ab75be

There are still debates whether particle acceleration in solar flares may occur due to interruption of electric currents flowing along magnetic loops. To contribute to this problem, we performed the first statistical study of relationships between flare hard X-ray (HXR; 50−100 keV) sources observed by the \textit{Ramaty High-Energy Solar Spectroscopic Imager} (RHESSI) and photospheric vertical electric currents (PVECs, jr) calculated using vector magnetograms obtained with the Helioseismic and Magnetic Imager (HMI) on-board the \textit{Solar Dynamics Observatory} (SDO). A sample of 48 flares, from C3.0 to X3.1 class, observed in central part of the solar disk by both instruments in 2010--2015 was analyzed. We found that ≈70\% of all HXR sources overlapped with islands or ribbons of enhanced (|jr|≳104 statampere~cm−2) PVECs. However, less than ≈40\% of the HXR sources overlapped with PVEC maxima, with an accuracy of ±3″. More than in half of the flares there were HXR sources outside regions of enhanced PVECs. We found no correlation between intensity of the HXR sources and PVEC density or total PVEC under them. No systematic dissipation of PVECs under the HXR sources was found during the flares. Collectively, the results do not support the current-interruption flare models. However, the results indicate the importance of the presence of longitudinal currents in flare regions. Understanding of their specific role in the processes of energy release, plasma heating, and acceleration of particles requires further investigation. **2010-10-16, 2011-09-26, 2011-12-25, 2012-06-03, 2012-07-06,**

2019
https://arxiv.org/pdf/1908.09016.pdf

Solar active regions contain electric currents. Information on the distribution of currents is important for understanding the processes of energy release on the surface of the Sun and in the overlying layers. The paper presents an analysis of the probability density function (PDF) of the absolute value of the photospheric vertical electric current density (|jz|) in 48 active regions before and after flares in 2010--2017. Calculation of |jz| is performed by applying the differential form of Ampere's circuital law to photospheric vector magnetograms obtained from observations of the Helioseismic and Magnetic Imager (HMI) instrument onboard the Solar Dynamics Observatory (SDO). It has been established that for the

studied active regions PDF(|jz|) is described by the Gauss function in the low-|jz| region (|jz|<10110±1321 statampere/cm2) and the decaying power-law function in the region of higher |jz| values. Also, for some active regions PDF(|jz|) can be described by the special kappa-function. The distributions of the parameters of the approximating functions are obtained using the least squares method. The average absolute value of the power-law function index is 3.69±0.51, and 3.99±0.51 of the kappa-function. No systematic changes in parameters during the flares are detected. An explicit connection between the parameters and the flare X-ray class, as well as with the Hale magnetic class of the active regions, is not found. Arguments are presented in favor of the suggestion that the Gaussian distribution in the low-value region of PDF(|jz|) represents noise in the data, while the power-law "tail" reflects the nature of electric currents in the solar active regions. **03.08.2011, 29.09.2014**

Magnetic Structure of Solar Flare Regions Producing Hard X-Ray Pulsations

I.V. **Zimovets**, R. Wang, Y.D. Liu, C.C. Wang, S.A. Kuznetsov, I.N. Sharykin, A.B. Struminsky, V.M. Nakariakov

JASTP Volume 174, September **2018**, Pages 17-27

https://reader.elsevier.com/reader/sd/57C406616EBCC7F3D96944EB109BA6D4F5D66AE6550663538F70F573EDBECEA44C3F56C5ECD99D9123B1BAFD853872E3

We present analysis of the magnetic field in seven solar flare regions accompanied by the pulsations of hard X-ray (HXR) emission. These flares were studied by Kuznetsov et al. (2016) (Paper I), and chosen here because of the availability of the vector magnetograms for their parent active regions (ARs) obtained with the SDO/HMI data. In Paper I, based on the observations only, it was suggested that a magnetic flux rope (MFR) might play an important role in the process of generation of the HXR pulsations. The goal of the present paper is to test this hypothesis by using the extrapolation of magnetic field with the non-linear force-free field (NLFFF) method. Having done this, we found that before each flare indeed there was an MFR elongated along and above a magnetic polarity inversion line (MPIL) on the photosphere. In two flare regions the sources of the HXR pulsations were located at the footpoints of different magnetic field lines wrapping around the central axis, and constituting an MFR by themselves. In five other flares the parent field lines of the HXR pulsations were not a part of an MFR, but surrounded it in the form of an arcade of magnetic loops. These results show that, at least in the analyzed cases, the “single flare loop” models do not satisfy the observations and magnetic field modeling, while are consistent with the concept that the HXR pulsations are a consequence of successive episodes of energy release and electron acceleration in different magnetic flux tubes (loops) of a complex AR. An MFR could generate HXR pulsations by triggering episodes of magnetic reconnection in different loops in the course of its non-uniform evolution along an MPIL. However, since three events studied here were confined flares, actual eruptions may not be required to trigger sequential particle acceleration episodes in the magnetic systems containing an MFR.

https://reader.elsevier.com/reader/sd/D943F3EDFFA19652E63E628B39C4696C309935683003CD5FBC75683B316096AEE20F06928C0501F3965BF0549093FDB1

We present analysis of magnetic field and vertical electric currents (VECs) in seven solar flare regions accompanied by pulsations of hard X-ray (HXR) emission. These flares were studied by Kuznetsov et al. (2016) and chosen here because of the availability of the vector magnetograms for their parent active regions (ARs) obtained with the SDO/HMI data. By extrapolation of magnetic field with the non-linear force-free field (NLFFF) method we found that before each flare there was a magnetic flux rope (MFR) elongated along and above a magnetic polarity inversion line (MPIL) on the photosphere. In two flare regions the sources of the HXR pulsations were located at footpoints of different magnetic field lines wrapping around the central axis, and constituting an MFR by themselves. In five other flares the parent field lines of the HXR pulsations were not a part of an MFR, but surrounded it in the form of an arcade of magnetic loops. Also, we found that in three out of seven events the sources of the HXR pulsations were located in vicinity of enhanced ($\gtrsim$104~statampere~cm^{-2}) regions of VECs on the photosphere, having the form of extended ribbons elongated ($\gtrsim$10~Mm) mainly along an MPIL. In four remaining events VECs are concentrated in multiple tiny ($\lesssim$5~Mm) islands scattered around the MPIL. In general, the HXR sources are found to locate close but out of the sites of the highest VECs on the photosphere. There are no significant correlations between intensity of the HXR sources and characteristics of VECs and magnetic field components (as well as of their evolution in time) on the photosphere beneath the HXR sources. All these observational results are in favor of the concept that the HXR pulsations are a consequence of successive episodes of energy release in different magnetic flux tubes of a complex AR triggered by

non-uniform eruption of an MFR. **15-Feb-2011, 07-Jun-2011, 06-Sep-2011, 18-Apr-2014, 22- Oct-2014, 24-Oct-2014, and 09-Nov-2014**

Spatio-Temporal Dynamics of Flare Hard X-ray Pulsations

I. V. **Zimovets**, S. A. Kuznetsov & A. B. Struminsky
RHESSI Science Nuggets #285 Oct **2016**
http://sprg.ssl.berkeley.edu/~tohban/wiki/index.php/Spatio-Temporal_Dynamics_of_Flare_Hard_X-ray_Pulsations
The goal of the present work is to perform systematic analysis of spatio-temporal evolution of sources of the HXR pulsations in a large set of flares observed with RHESSI between 2002 and 2015. We emphasize that our study is not accented on the finding and analysis of the quasi-periodicities. Our approach is more general. We are interested in all flares which are accompanied by multiple HRX pulsations/peaks seen in the RHESSI data, no matter whether they are quasi-periodic (in the above sense) or not.
Two main results of our systematic analysis of large set of solar flares with HXR pulsations are:
1) The sources of HXR pulsations in all studied flares were not persistent: the spatial locations of the HXR sources changed in time from one pulsation peak to another;
2) The majority of flares (83%) were associated with CMEs and, thus, were eruptive events, i.e. were accompanied by eruptive processes - sudden ejections of filaments and/or magnetic structures such as magnetic flux ropes and arcades of magnetic loops.
In our view, the crucial role in generation of pulsations, as well as in excitation of coronal loops oscillations (see, e.g., Ref. [3]), is played by unstable eruptive magnetic structures. **2002-11-09, 2002-08-20**

Excitation of kink oscillations of coronal loops: statistical study

Zimovets, I.V., Nakariakov, V.M.
A&A, 577, A4 **2015**
E-print, Dec **2014**
Context. Solar flares are often accompanied by kink (transverse) oscillations of coronal loops. Despite intensive study of these oscillations in recent years mechanisms for their excitation remain unrevealed.
Aims. To clarify the excitation mechanisms for kink oscillations of coronal loops.
Methods. We analyse 58 kink oscillation events observed by the Atmospheric Imaging Assembly (AIA) onboard the Solar Dynamics Observatory (SDO) during its first four years (2010-2014) with the use of the JHelioviewer. Association of these oscillation events with flares, lower coronal eruptions and plasma ejections, coronal mass ejections (CMEs) and coronal type II radio bursts is studied.
Results. It is found that 44 out of these 58 oscillation events (76%) were associated with CMEs observed in the white light emission. Moreover, 57 events (98%) were accompanied by lower coronal eruptions/ejections (LCEs) observed in the EUV band in the parental active regions. An LCE was not clearly seen only in one event but it was definitely associated with a CME. The main observational finding is that the kink oscillations were excited by the deviation of loops from their equilibria by a nearby LCEs in 55 events (95%). In 3 remaining events it was difficult to reliably determine the cause of the oscillations because of limitations of the observational data. We also found that 53 events (91%) were associated with flares. In five remaining events the parental active regions were behind the limb and we could not directly see flare sites. It indicates that there is a close relationship between these two kinds of the solar activity. However, the estimated speeds of a hypothetical driver of kink oscillations by flares were found to be low than 500 km/s in 80% of cases. Such low speeds are not in favour of the association of the oscillation excitation with a shock wave, as it has usually been assumed. The fact that only 23 (40%) of the oscillation events were found to be associated with coronal type II radio bursts is also against the shock wave mechanism for the excitation of kink oscillations.
Conclusions. The performed statistical analysis shows that the most probable mechanism for the excitation of kink oscillations of coronal loops is the deviation of loops from their equilibrium by nearby eruptions or plasma ejections rather than a blast shock wave ignited by a flare.

Fine structure of the sources of quasi-periodic pulsations in “single-loop” solar flares

I. V. **Zimovets**, S. A. Kuznetsov & A. B. Struminsky
Astronomy Letters, April **2013**, Volume 39, Issue 4, pp 267-278
Pis’ma v Astronomicheskiĭ Zhurnal, **2013**, Vol. 39, No. 4, pp. 297–309.
Analysis of the observational data obtained with a high angular resolution in the ranges of vacuum ultraviolet (1″, TRACE) and hard X-ray (4″, RHESSI) emissions in some solar flares previously considered “single-loop” ones shows that they are not such flares. The thick single loops with a diameter of 13″–21″ observed in these flares in the microwave range with an angular resolution of 5″–10″ (NoRH) are actually arcades of thinner loops with a diameter of less than 3″. In this case, the observed quasi-periodic pulsations of microwave emission are not a consequence of the oscillations of an isolated thick loop, as is usually assumed, but a result of the successive involvement of many relatively thinner loops in the process of flare energy release. The established facts impose significant constraints on the generation models of pulsations in flares. **March 14, 2002, JULY 22, 2004**

Non-thermal “Burst-on-Tail” of Long-Duration Solar Event on 26 October 2003

I. **Zimovets**, A. Struminsky

Solar Physics, December **2012**, Volume 281, Issue 2, pp 749-763

Observations of a rare long-duration solar event of GOES class X1.2 from **26 October 2003** are presented. This event showed a pronounced burst of hard X-ray and microwave emission, which was extremely delayed (> 60 min) with respect to the main impulsive phase and did not have any significant response visible in soft X-ray emission. We refer to this phenomenon as a “burst-on-tail”. Based on TRACE observations of the growing flare arcade and some simplified estimation, we explain why a reaction of active region plasma to accelerated electrons may change drastically over time. We suggest that, during the “burst-on-tail”, non-thermal electrons were injected into magnetic loops of larger spatial scale than during the impulsive phase bursts, thus resulting in much smaller values of plasma temperature and emission measure in their coronal volume, and hence little soft X-ray flux. The nature of the long gap between the main impulsive phase and the “burst-on-tail” is, however, still an open question.

Observations of Double-Periodic X-Ray Emission in Interacting Systems of Solar Flare Loops

I.V. **Zimovets** · A.B. Struminsky

Solar Phys (**2010**) 263: 163–174

We investigate the M1.8 solar flare of **20 October 2002**. The flare was accompanied by quasi-periodic pulsations (QPP) of both thermal and nonthermal hard X-ray emissions (HXR) observed by RHESSI in the 3 – 50 keV energy range. Analysis of the HXR time profiles in different energy channels made with the Lomb periodogram has indicated two statistically significant time periods of about 16 and 36 s. The 36 s QPP were observed only in the nonthermal HXR emission in the impulsive phase of the flare. The 16 s QPP were found in thermal and nonthermal HXR emission both in the impulsive and in the decay phases of the flare. Imaging analysis of the flare region, the determined time periods of the QPP, and the estimated physical parameters of the flare loops allowed us to interpret the observed QPP in terms of MHD oscillations excited in two spatially separated, but interacting systems of flaring loops.

Imaging Observations of Quasi-Periodic Pulsatory Nonthermal Emission in Two-Ribbon Solar Flares

I.V. **Zimovets** · A.B. Struminsky

Solar Phys (**2009**) 258: 69–88

Using RHESSI and some auxiliary observations we examine possible connections between the spatial and temporal structure of nonthermal hard X-ray (HXR) emission sources from the two-ribbon flares of **29 May 2003** and **19 January 2005**. In each of these events quasi-periodic pulsations (QPP) with time period of 1 – 3 minutes are evident in both hard X rays and microwaves. The sources of nonthermal HXR emission are situated mainly at the footpoints of the flare arcade loops observed by TRACE and the SOHO/EIT instrument in the EUV range. At least one of the sources moves systematically during and after the QPP phase in each flare. The sources move predominantly parallel to the magnetic inversion line during the 29 May flare and along flare ribbons during the QPP phase of both flares. By contrast, the sources start to show movement perpendicular to the flare ribbons with velocity comparable to that along the ribbons’ movement after the QPP phase. The sources of each pulse are localized in distinct parts of the ribbon during the QPP phase. The measured velocity of the sources and the estimated energy release rate do not correlate well with the flux of the HXR emission calculated from these sources. The sources of microwaves and thermal HXRs are situated near the apex of the flare loop arcade and are not stationary either. Almost all of the QPP as well as some pulses of nonthermal HXR emission during the post-QPP phase reveal soft – hard – soft spectral behavior, indicating separate acts of electron acceleration and injection. In our opinion at least two different flare scenarios based on the Nakariakov *et al.* (2006, *Astron. Astrophys.* **452**, 343) model and on the idea of current-carrying loop coalescence are suitable for interpreting the observations. However, it is currently not possible to choose between them owing to observational limitations.

Continuous Null-Point Magnetic Reconnection Builds Up a Torus Unstable Magnetic Flux Rope Triggering the X9.3 Flare in Solar Active Region~12673

Peng **Zou**, Chaowei Jiang, Fengsi Wei, Xueshang Feng, Pingbing Zuo, Yi Wang

ApJ **890** 10 **2020**

https://arxiv.org/pdf/2001.04633.pdf

https://doi.org/10.3847/1538-4357/ab6aa8

Two X-class solar flares occurred on **2017 September 6** from active region NOAA 12673: the first one is a confined X2.2 flare, and it is followed only ~3 hours later by the second one, which is the strongest flare in solar cycle 24, reaching X9.3 class and accompanied with a coronal mass ejection. Why these two X-class flares occurred in the same position with similar magnetic configurations, but one is eruptive while the other is not? Here we track the coronal magnetic field evolution via nonlinear force-free field extrapolations from a time sequence of vector magnetograms with high cadence. A detailed analysis of the magnetic field shows that a magnetic flux rope (MFR) forms and grows gradually before the first flare, and shortly afterwards, the MFR's growth is significantly enhanced with a much faster rise in height, from far below the threshold of torus instability to above it, while the magnetic twist only increases mildly. Combining EUV observations and the magnetic field extrapolation, we found that overlying the MFR is a null-point magnetic topology, where recurrent brightening is seen after the first flare. We thus suggest a scenario to interpret the occurrence of the two flares. The first flare occurred since the MFR reached a high enough height to activate the null point, and its continuous expansion forces the null-point reconnection recurrently. Such reconnection weakens the overlying field, allowing the MFR to rise faster, which eventually crosses the threshold of torus instability and triggers the second, eruptive flare.

A Two-Step Magnetic Reconnection in a Confined X-class Flare in Solar Active Region 12673

Peng **Zou**, Chaowei Jiang, Xueshang Feng, Pingbing Zuo, Yi Wang, Fengsi Wei

2019 ApJ 870 97

sci-hub.tw/10.3847/1538-4357/aaf3b7

https://arxiv.org/pdf/1811.09005.pdf

Solar flares are often associated with coronal eruptions, but there are confined ones without eruption, even for some X-class flares. How such large flares occurred and why they are confined are still not well understood. Here we studied a confined X2.2 flare in NOAA 12673 on **2017 September 6**. It exhibits two episodes of flare brightening with rather complex, atypical ribbons. Based on topology analysis of extrapolated coronal magnetic field, we revealed that there is a two-step magnetic reconnection process during the flare. Prior to the flare, there is a magnetic flux rope (MFR) with one leg rooted in a rotating sunspot. Neighboring to the leg is a magnetic null-point structure. The sunspot drives the MFR to expand, pushing magnetic flux to the null point, and reconnection is first triggered there. The disturbance from the null-point reconnection triggers the second reconnection, i.e., a tether-cutting reconnection below the rope. However, these two reconnections failed to produce an eruption, because the rope is firmly held by its strapping flux. Furthermore, we compared this flare with an eruptive X9.3 flare in the same region with 2 hours later, which has a similar MFR configuration. The key difference between them is that, for the confined flare, the MFR is fully below the threshold of torus instability, while for the eruptive one, the MFR reaches entirely above the threshold. This study provides a good evidence supporting that reconnection alone may not be able to trigger eruption, rather, MHD instability plays a more important role.

Continuum enhancements, line profiles and magnetic field evolution during consecutive flares

Francesca **Zuccarello**, Salvo L. Guglielmino, Vincenzo Capparelli, Mihalis Mathioudakis, Peter H. Keys, Serena Criscuoli, Mariachiara Falco, Mariarita Murabito

ApJ **889** 65 **2020**

https://arxiv.org/pdf/1912.00859.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/ab621f/pdf

During solar flares, magnetic energy can be converted into electromagnetic radiation from radio waves to γ rays. Enhancements in the continuum at visible wavelengths give rise to white-light flares, as well as continuum enhancements in the FUV and NUV passbands. In addition, the strong energy release in these events can lead to the rearrangement of the magnetic field at the photospheric level, causing morphological changes in large and stable magnetic structures like sunspots. In this context, we describe observations acquired by satellite instruments (IRIS, SDO/HMI, Hinode/SOT) and ground-based telescopes (ROSA/DST) during two consecutive C7.0 and X1.6 flares occurred in active region NOAA 12205 on **2014 November 7**. The flare was accompanied by an eruption. The results of the analysis show the presence of continuum enhancements during the evolution of the events, observed both in ROSA images and in \textit{IRIS} spectra. In the latter, a prominent blue-shifted component is observed at the onset of the eruption. We investigate the role played by the evolution of the δ sunspots of the active region in the flare triggering, and finally we discuss the changes in the penumbrae surrounding these sunspots as a further consequence of these flares.

Continuum emission enhancements and penumbral changes observed during flares by IRIS, ROSA, and Hinode

F. **Zuccarello**, S.L. Guglielmino, V. Capparelli, M. Mathioudakis, P. Keys, L. Fletcher, S. Criscuoli, M. Falco, M. Murabito

Nuovo Cimento C as proceeding of the Third Meeting of the Italian Solar and Heliospheric Community **2019**

https://arxiv.org/pdf/1901.01732.pdf
In this paper we describe observations acquired by satellite instruments (Hinode/SOT and IRIS) and ground-based telescopes (ROSA@DST) during two consecutive C7.0 and X1.6 flares occurred in active region NOAA 12205 on **2014 November 7**. The analysis of these data show the presence of continuum enhancements during the evolution of the events, observed both in ROSA images and in IRIS spectra. Moreover, we analyze the role played by the evolution of the δ sunspots of the active region in the flare triggering, indicating the disappearance of a large portion of penumbra around these sunspots.

Vortex and Sink Flows in Eruptive Flares as a Model for Coronal Implosions

F. P. **Zuccarello**1,2,5, G. Aulanier2, J. Dudík3, P. Démoulin2, B. Schmieder2, and S. A. Gilchrist4
2017 ApJ 837 115
http://iopscience.iop.org.sci-hub.cc/0004-637X/837/2/115/
Eruptive flares are sudden releases of magnetic energy that involve many phenomena, several of which can be explained by the standard 2D flare model and its realizations in 3D. We analyze a 3D magnetohydrodynamics simulation, in the framework of this model, that naturally explains the contraction of coronal loops in the proximity of the flare sites, as well as the inflow toward the region above the cusp-shaped loops. We find that two vorticity arcs located along the flanks of the erupting magnetic flux rope are generated as soon as the eruption begins. The magnetic arcades above the flux rope legs are then subjected to expansion, rotation, or contraction depending on which part of the vortex flow advects them. In addition to the vortices, an inward-directed magnetic pressure gradient exists in the current sheet below the magnetic flux rope. It results in the formation of a sink that is maintained by reconnection. We conclude that coronal loop apparent implosions observed during eruptive flares are the result of hydromagnetic effects related to the generation of vortex and sink flows when a flux rope moves in a magnetized environment.

The transition from eruptive to confined flares in the same active region

F. P. **Zuccarello**, R. Chandra, B. Schmieder, G. Aulanier, R. Joshi
A&A 601, A26 **2017**
https://arxiv.org/pdf/1702.02477.pdf **File**
Solar flares are sudden and violent releases of magnetic energy in the solar atmosphere that can be divided in eruptive flares, when plasma is ejected from the solar atmosphere, resulting in a coronal mass ejection (CME), and confined flares when no CME is associated with the flare. We present a case-study showing the evolution of key topological structures, such as spines and fans which may determine the eruptive versus non-eruptive behavior of the series of eruptive flares, followed by confined flares, which are all originating from the same site. To study the connectivity of the different flux domains and their evolution, we compute a potential magnetic field model of the active region. Quasi-separatrix layers are retrieved from the magnetic field extrapolation. The change of behavior of the flares from one day to the next -eruptive to confined- can be attributed to the change of orientation of the magnetic field below the fan with respect to the orientation of the overlaying spine, rather than an overall change in the stability of the large scale field. Flares tend to be more-and-more confined when the field that supports the filament and the overlying field gradually become less-and-less anti-parallel, as a direct result of changes in the photospheric flux distribution, being themselves driven by continuous shearing motions of the different magnetic flux concentrations. **2014 April 15**
See **Introduction**

Vortex and sink flows in eruptive flares as a model for coronal implosions

Francesco P. **Zuccarello**, Guillaume Aulanier, Jaroslav Dudík, Pascal Démoulin, Brigitte Schmieder, Stuart A. Gilchrist
ApJ **2017**
https://arxiv.org/pdf/1702.00199v1.pdf
Eruptive flares are sudden releases of magnetic energy that involve many phenomena, several of which can be explained by the standard 2D flare model and its realizations in three-dimensions. We analyze a three-dimensional magnetohydrodynamics simulation in the framework of this model that naturally explains the contraction of coronal loops in the proximity of the flare sites, as well as the inflow towards the region above the cusp-shaped loops.
We find that two vorticity arcs located along the flanks of the erupting magnetic flux rope are generated as soon as the eruption begins. The magnetic arcades above the flux-rope legs are then subjected to expansion, rotation or contraction depending on which part of the vortex-flow advects them. In addition to the vortices, an inward-directed magnetic pressure gradient exists in the current sheet below the magnetic flux rope. It results in the formation of a sink that is maintained by reconnection.
We conclude that coronal loop apparent implosions observed during eruptive flares are the result of hydro-magnetic effects related to the generation of vortex- and sink-flows when a flux rope moves in a magnetized environment.

The X17.2 flare occurred in NOAA 10486: an example of filament destabilization caused by a domino effect:

F. **Zuccarello**, P. Romano, F. Farnik, M. Karlicky, L. Contarino, V. Battiato, S.═L. Guglielmino, M. Comparato and I. Ugarte-Urra
A&A 493 (2009) 629-637

Context. It is now possible to distinguish between two main models describing the mechanisms responsible for eruptive flares : the standard model, which assumes that most of the energy is released, by magnetic reconnection, in the region hosting the core of a sheared magnetic field, and the breakout model, which assumes reconnection occurs at first in a magnetic arcade overlaying the eruptive features.
Aims. We analyze the phenomena observed in NOAA 10486 before and during an X17.2 flare that occurred on 2003 October 28, to study the relationship between the pre-flare and flare phases and determine which model is the most suitable for interpreting this event.
Methods. We performed an analysis of multiwavelength data set available for the event using radio data (0.8–4.5 GHz), images in the visible range (WL and H^{α}), EUV images (1600 and 195 Å), and X-ray data, as well as MDI longitudinal magnetograms. We determined the temporal sequence of events occurring before and during the X17.2 flare and the magnetic field configuration in the linear force-free field approximation.
Results. The active region was characterized by a multiple arcade configuration and the X17.2 flare was preceded, by ~2 h, by the partial eruption of one filament. This eruption caused reconnection at null points located in the low atmosphere and a decrease in magnetic tension in the coronal field lines overlaying other filaments present in the active region. As a consequence, these filaments were destabilized and the X17.2 flare occurred.
Conclusions. The phenomena observed in NOAA 10486 before and during the X17.2 flare cannot be explained by a simple scenario such as the standard or breakout model, but instead in terms of a so-called domino effect, involving a sequence of destabilizing processes that triggered the flare.

Дифференциальная мера эмиссии солнечных нановспышек, определенная с помощью алгоритма SITES.

Белов С.А., Леденцов Л.С., Завершинский Д.И., Богачёв С.А.
СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том 10 № 2 , **2024** С. 4–14.
https://naukaru.ru/ru/storage/viewWindow/159165

В работе представлены результаты исследования возможностей алгоритма SITES (Solar Iterative Temperature Emission Solver) [Morgan, Pickering, 2019] для восстановления дифференциальной меры эмиссии (ДМЭ) источника по его излучению в нескольких участках электромагнитного спектра в контексте наблюдения солнечных нановспышек прибором AIA/SDO. Метод SITES был реализован на языке программирования Python и впервые был применен для построения ДМЭ нановспышек. С этой целью мы проверили эффективность работы алгоритма на модельных одно- и двухпиковых ДМЭ при температурах, характерных для солнечных нановспышек. Результаты тестирования говорят о том, что алгоритм SITES может быть ограниченно применим для исследования ДМЭ нановспышек в однопиковом приближении. Алгоритм обладает сочетанием хорошей точности и высокой скорости счета в исследуемой области температур от 1 до 3 МК. Особенности ДМЭ нановспышек, восстановленных методом SITES, были изучены на основе найденной нами ранее выборки из 58855 событий, наблюдавшихся в 2019 г. с помощью AIA/SDO. Полученные результаты подтверждают, что характерная температура плазмы в нановспышках составляет 1–2 МК. Восстановленные ДМЭ нановспышек, как правило, имеют один максимум внутри этого диапазона, однако полученное нами для всех вспышек распределение по температуре формирует два кластера с максимумами при 1.2 и 1.7 МК. Мы интерпретируем это как возможное свидетельство существования двух типов солнечных нановспышек, но данный результат требует дополнительного подтверждения.

ТЕМП ФОРМИРОВАНИЯ СОЛНЕЧНЫХ НАНОВСПЫШЕК В РАЗЛИЧНЫХ СПЕКТРАЛЬНЫХ ДИАПАЗОНАХ

Белов С.А., Завершинский Д.И., Богачев С.А., Леденцов Л.С.
АЖ Том: 100Номер: 12 Год: 2023 Страницы: 1322-1331
DOI: 10.31857/S0004629923120010

Частота и темп формирования солнечных нановспышек (НВ) измерены в 6 корональных спектральных диапазонах (094, 131, 171, 193, 211, 335 Å) и одном, относящимся к переходному слою (304 Å). Были использованы данные SDO/AIA, полученные в минимуме солнечной активности в мае 2019 г. Мы проанализировали одну и ту же область Солнца размером 360\textquotedblleft×720\textquotedblleft во всех каналах на протяжении интервала времени 1 ч. Для поиска НВ во всех спектральных диапазонах мы применили одинаковый алгоритм, основанный на анализе амплитуды быстрых уярчений на изображениях. Частота и темп НВ, как можно ожидать, существенно различаются в различных диапазонах. Для порога 5σ наибольшая частота НВ, 207 $с^{-1}$, измерена в канале 171 Å. Далее следуют спектральные диапазоны 193 Å (85% от канала 171 Å), 211 Å (74%) и 131 Å (63%). Мы не смогли достоверно измерить частоту в каналах 094 и 335 Å, но установили, что

она составляет менее 15% от частоты в канале 171 Å. В канале 304 Å мы обнаружили большое число уярчений, которые не имеют соответствия в короне. Тем не менее около 40% корональных НВ имеют соответствие в линии 304 Å, с порогом выше 5σ.

ЭЛЕКТРОСТАТИЧЕСКАЯ ТУРБУЛЕНТНОСТЬ В ПЕРЕПАДАХ ЭЛЕКТРОННОЙ ТЕМПЕРАТУРЫ СОЛНЕЧНОЙ АТМОСФЕРЫ

БЕСПАЛОВ П.А.1, САВИНА О.Н

ПАЖ Том: 41Номер: 10 Год: **2015** Страницы: 651

Обсуждается связь процессов образования и свойств переходного слоя солнечной атмосферы, характеризующегося резким градиентом электронной температуры, с электростатической турбулентностью, обеспечивающей высокую эффективную частоту соударений электронов и низкую теплопроводность среды. Получена простая зависимость величины шумового электрического поля в переходном слое от эффективной частоты соударений. Для трубки относительно слабого магнитного поля, проходящей из хромосферы в корону, на основе известных экспериментальных моделей солнечной атмосферы оценен высотный ход теплопроводности и величина шумовых электрических полей.

РАСПРЕДЕЛЕНИЕ НАНОВСПЫШЕК В МИНИМУМЕ СОЛНЕЧНОЙ АКТИВНОСТИ

БОГАЧЁВ С. А.[*1]

ГиА Том: 63Номер: 4 Год: 2023 Страницы: 488-495

Мы используем данные телескопа Atmospheric Imaging Assembly (AIA) на космическом аппарате Solar Dynamics Observatory (SDO) в канале 171 Å, чтобы исследовать пространственное распределение вспышек малой энергии (нановспышек). Мы исследовали два периода: 20.05.2019 с 12:00 UT до 13:00 UT и 10.05.2020 с 12:00 UT до 13:00 UT. Всего нами было найдено 87 974 нановспышки со средним темпом формирования 6.0×10^{-21} см$^{-2}$ с$^{-1}$. Для солнечных широт от 0° до 50° темп формирования нановспышек является примерно равномерным со среднеквадратичным отклонением около 25%. Нами обнаружена асимметрия в темпе формирования нановспышек в южном и северном полушариях Солнца: темп формирования нановспышек в южном полушарии был на 34–42% больше, чем в северном. В этот период такая же асимметрия наблюдалась и для обычных вспышек. Мы также обнаружили слабую зависимость темпа формирования нановспышек от солнечного цикла: число нановспышек растет при более высокой активности Солнца.

ИЗМЕРЕНИЕ ЭНЕРГЕТИЧЕСКОГО РАСПРЕДЕЛЕНИЯ НАНОВСПЫШЕКМАЛОЙ МОЩНОСТИ

Богачёв С.А., Ерхова Н.Ф.

СЗФ Том: 9Номер: 1 Год: **2023** Страницы: 3-9

https://elibrary.ru/download/elibrary_50417067_38172738.pdf

В работе предложен метод измерения энергетического распределения вспышек малой энергии (нановспышек) в области ниже 10^{23} эрг. В качестве примера измерен спектр нановспышек в области 10^{21}-10^{26} эрг для двух участков спокойной короны Солнца, наблюдавшихся телескопом SDO/AIA в канале 171 Å в мае 2019 г. Показано, что спектр нановспышек является степенным в области энергий 10^{22}-10^{26} эрг. Наклон спектра в этой области является постоянным, т. е. не зависит от энергии. Ниже 10^{22} эрг начинается завал спектра. Для энергий менее 10^{21} эрг метод не дает статистически значимых результатов из-за высоких погрешностей. Результаты исследования указывают, что солнечные нановспышки могут быть обнаружены вплоть до энергий 10^{21}-10^{22} эрг. Ранее сообщалось об измерениях спектра только в области 10^{23} эрг и выше. Полный поток энергии нановспышек в области выше 10^{22} эрг для исследованных участков короны составил P »$2 \cdot 10^4$ эрг·см$^{-2}$·с$^{-1}$, что примерно в 15 раз меньше, чем требуется для полной компенсации тепловых потерь короны. **20 мая 2019**

Effect of Coulomb collisions on the particle acceleration in collapsing magnetic traps .

С. А. **Богачев,** Б. В. Сомов,

Письма в АЖ, 35, 63 (**2009**). **File.**

Abstract The problem of particle acceleration in collapsing magnetic traps in the solar corona has been solved by taking into account the particle scattering and braking in the high-temperature plasma of solar flares. The Coulomb collisions are shown to be weak in traps with lifetimes t l < 10 s and strong for t l > 100 s. In the approximation of strong collisions, collapsing magnetic traps are capable of confining up to 20% of the injected particles in the corona for a long time. In the collisionless approximation, this value exceeds 90%. The question about the observational manifestations of collisions is examined. For collision times comparable to t l , the electron spectrumat energies above 10 keV is shown to be a double-power-law one. Such spectra were found by the RHESSI satellite in flares.

ПОСТРОЕНИЕ СВЕТОВЫХ КРИВЫХ СОЛНЕЧНЫХ ВСПЫШЕК В ЛИНИИ Hα

БОРОВИК А.В.1, КОНЯЕВ П.А.2, ЖДАНОВ А.А.1

Г и А Том: 56Номер: 5 Год: **2016** Страницы: 547-557
Представлены результаты исследования ряда факторов, влияющих на построение световых кривых солнечных вспышек в линии Hα. Установлено, что вид световой кривой зависит от способа измерения интенсивности, размера окна измерений, колебаний яркости участков спокойной хромосферы (реперных областей). Реальную картину развития вспышечного процесса показывают световые кривые, построенные по максимальной интенсивности вспышки. Предложен метод отбора “реперных областей”.

РАСПРЕДЕЛЕНИЕ СОЛНЕЧНЫХ ВСПЫШЕК МАЛОЙ МОЩНОСТИ ПО ВРЕМЕНИ ПОДЪЕМА ЯРКОСТИ К МАКСИМУМУ

БОРОВИК А.В.1, ЖДАНОВ А.А.1

СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том: 4Номер: 3 Год: **2018** Страницы: 5-16
По сообщениям международного вспышечного патруля за 1972-2010 гг. сформирована электронная база данных, включающая параметры более 123 тысяч солнечных вспышек в линии Hα. Для классов площади и баллов вспышек определены средние продолжительности флэш-фаз. Показано, что с ростом класса площади время подъема яркости вспышек к максимуму увеличивается. Для классов яркости эта тенденция проявляется в более слабой форме. Самые короткие флэш-фазы имеют вспышки взрывного типа и вспышки с единственным центром повышенной яркости внутри вспышечной области, самые продолжительные - двухленточные вспышки и вспышки, демонстрирующие несколько максимумов интенсивности. Выделено 572 случая со временами подъема более 60 мин. Большинство (80 %) таких сверхпродолжительных вспышек имеют более короткую главную фазу. Установлено, что вспышки малой мощности с точки зрения особенностей развития не отличаются от крупных. Они так же, как и мощные вспышки, сопровождаются активизацией и исчезновением волокон, могут иметь взрывную фазу и многократные всплески интенсивности. Среди малых встречаются такие, которые покрывают тени солнечных пятен, а также двухленточные и белые вспышки.

Динамика жесткого рентгеновского, гамма- и микроволнового излучения солнечных вспышек, продуцированных активной областью 0069 в августе 2002 г.

А. В. **Богомолов**, Л. К. Кашапова, И. Н. Мягкова, Ю. Т. Цап
Астрономический журнал , 91(3), **2014**, С. 211-222
Проведен поиск закономерностей в изменении характеристик вспышечного солнечного излучения по мере развития активной области NOAA 0069 в период с **14 по 24 августа 2002** г. Прибором СОНГ (Солнечные Нейтроны и Гамма-кванты), установленным на борту российской солнечной обсерватории КОРОНАС-Ф, было зарегистрировано жесткое рентгеновское и гамма-излучение во время 9 из 30 вспышек класса выше C5, произошедших в данной активной области в указанный период времени. Было получено, что по мере развития данной активной области наблюдалась тенденция к нарастанию потока рентгеновского и гамма-излучения в максимумах вспышек, а также к уменьшению показателя спектра жесткого рентгеновского излучения, причем вспышки с более жестким спектром излучения происходили в тени пятна, т.е. в области наиболее сильных магнитных полей.

Динамика мелкомасштабных магнитных полей перед малыми и крупными солнечными вспышками.

Боровик А.В., Жданов А.А.
СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том 9 № 4 , 2023 С. 44–53
https://naukaru.ru/ru/storage/viewWindow/138049
По данным наблюдений SDO (Solar Dynamics Observatory) исследовалась динамика продольного магнитного поля активной области (АО) NOAA 12673. За время прохождения АО по диску Солнца пятна и фоновые поля в ней показывали сложные траектории движения, при этом наблюдалось образование многочисленных короткоживущих локальных мелкомасштабных линий раздела полярностей (ЛЛРП), которые формировались при появлении в АО новых магнитных потоков и их сближении с полями противоположной полярности. Протяженность таких ЛЛРП составляла менее 15000 км (~20 угл. сек), время существования — несколько часов. Исследование вспышечной активности NOAA 12673 показало, что вспышки малой мощности (оптический класс S, площадь <2 кв. град) обычно происходят вблизи ЛЛРП. Перед малыми вспышками, а также перед крупной вспышкой **06.09.2017** (оптический балл 3B, рентгеновский класс X9.3) на ограниченных участках локальных и главной ЛРП АО наблюдались сдвиговые напряжения магнитного поля и рост gradH: в области вспышек малой мощности — до значений 1.3–1.5 Гс/км, в области крупной вспышки — 3–3.5 Гс/км. Полученные результаты свидетельствуют о том, что перед малыми и крупными вспышками продольное магнитное поле ведет себя аналогичным образом.

СОЛНЕЧНЫЕ ВСПЫШКИ МАЛОЙ МОЩНОСТИ В ЛИНИИ H_α : РЕЗУЛЬТАТЫ ИССЛЕДОВАНИЙ

Боровик А.В.

Изв. КрАО Том: 119 Номер: 1 Год: 2023 Страницы: 27-41

В работе обобщаются результаты многолетних исследований вспышек малой мощности в линии Hα (оптический класс S), полученные с использованием данных международного вспышечного патруля, наблюдательных материалов в линии 6563 Å Байкальской астрофизической обсерватории ИСЗФ СО РАН и телескопов GONG, наблюдений обсерваторий SDO, SOHO и Kitt Peak. В результате проведенных исследований получены уточненные, статистически достоверные и наиболее полные на сегодняшний день данные о пространственно-временных параметрах солнечных вспышек, оценена их полная энергия в оптическом диапазоне длин волн. Установлено, что вспышки малой мощности (малые вспышки) образуют на Солнце плотные скопления - центры вспышечной активности (ЦВА), связанные с областями всплывающих магнитных потоков. Обнаружено, что такие вспышки возникают вблизи локальных мелкомасштабных короткоживущих линий раздела полярности (ЛЛРП) продольного магнитного поля. Одной из выявленных закономерностей возникновения малых вспышек является возрастание градиента магнитного поля на отдельных участках ЛЛРП в области вспышки. Продолжительность роста составляет от 40 минут до 1.5 часов. Максимального градиента (1.3-1.5 Гс/км) магнитное поле достигает на момент возникновения вспышки. Результаты исследования показывают, что вспышки малой мощности обладают схожими с крупными вспышками сценариями развития: сопровождаются активизациями и эрупцией волокон, имеют взрывную фазу, сопровождаются излучением разной мощности в рентгеновском и радиодиапазонах, потоками протонов. Среди них встречаются вспышки, покрывающие тени солнечных пятен, двухленточные и белые вспышки. Полученные результаты могут быть использованы для диагностики нестационарных процессов на Солнце, прогноза солнечной активности и геоэффективных солнечных событий.

Малые солнечные вспышки и локальные линии раздела полярности продольного магнитного поля активной области.

Боровик А. В., Жданов А. А.

СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том 8. **2022**. № 1 С. 19-23.
https://naukaru.ru/ru/storage/viewWindow/87252

По фотосферным данным и данным о продольном магнитном поле со спутника SDO, а также по наблюдениям в линии Hα на наземных станциях GONG исследована вспышечная активность группы солнечных пятен NOAA 12673, которая в сентябре 2017 г. произвела крупнейшую за последнее десятилетие вспышку класса X9.3. Активная область отличалась бурным развитием и сложными топологией и динамикой магнитного поля. Установлено, что в активной области на протяжении практически всего времени развития вследствие движений разнополярных магнитных потоков и их сближений происходило формирование многочисленных локальных линий раздела полярностей (ЛЛРП) магнитного поля. Обнаружено, что малые солнечные вспышки тесным образом связаны с ЛЛРП и возникают на тех участках ЛЛРП, где градиент продольного магнитного поля со временем достигает максимальных значений. **3-4 Сент 2017**

СОЛНЕЧНЫЕ ВСПЫШКИ МАЛОЙ МОЩНОСТИ В ОПТИЧЕСКОМ И РЕНТГЕНОВСКОМ ДИАПАЗОНАХ ДЛИН ВОЛН В 21-24-М СОЛНЕЧНЫХ ЦИКЛАХ

БОРОВИК А.В.1, ЖДАНОВ А.А.1

СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том: 6Номер: 3 Год: **2020** Страницы: 18-25

По данным в оптическом и рентгеновском диапазонах длин волн проанализирована вспышечная активность Солнца за 21-24-й циклы. Показано, что на протяжении последних четырех циклов активность Солнца постепенно снижалась. По отношению к 21-му циклу (самому активному за последние 50 лет) в 24-м цикле произошло в 4.4 раза меньше оптических крупных вспышек классов площади 2-4, в 8.2 раза меньше вспышек класса 1 и в 4.1 раза меньше малых вспышек (MB) оптического класса S. Число вспышек рентгеновского класса X уменьшилось в 3.7 раз, класса M - в 3.2 раза. Это подтверждает влияние вековых трендов активности Солнца на пиковые значения вспышечной активности в одиннадцатилетних циклах. Показано, что оптические вспышки малой мощности могут сопровождаться потоками протонов и всплесками рентгеновского излучения разной мощности, в том числе класса X. В мягком рентгене диапазоны излучения для оптических MB и вспышек высоких классов в значительной степени перекрываются. Подтверждено, что рентгеновское излучение солнечных вспышек возникает в среднем на 2 мин раньше оптического. Для оптических MB и вспышек класса 1 максимум излучения в рентгеновском диапазоне наступает позже максимума излучения в оптическом диапазоне примерно на 1 мин, для вспышек классов 2-4 - на 2 мин.

Процессы энерговыделения в солнечных вспышках малой мощности.

Боровик А.В., Жданов А.А.

СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том 5 Номер 4 С. 3–11. **2019**
https://naukaru.ru/ru/storage/viewWindow/43508

По данным международного вспышечного патруля за 1972–2010 гг. [http://www.ngdc. noaa.gov/stp/space-weather/solar-data/solar-features/so-lar-flares/] выполнены статистические исследования малых солнечных вспышек (класс площади S). Установлена высокая корреляционная зависимость между продолжительностью вспышек и временем подъема яркости к максимуму. Получены новые данные по относительным временам подъема яркости (отношение времени подъема к общей продолжительности вспышки). Установлено, что

распределения Тотн малых солнечных вспышек содержат ряд максимумов с наиболее значимыми 0.2, 0.25, 0.33 и 0.5. При переходе от вспышек низких оптических классов к более крупным вспышкам максимумы постепенно исчезают. Получены распределения солнечных вспышек по энергии в оптическом диапазоне длин волн, свидетельствующие о том, что интервалы энергий вспышек разного класса площади в значительной степени перекрываются. До 9.5 % малых вспышек попадает в интервал энергий крупных солнечных вспышек (класс площади 2–4). Еще более значительное перекрытие — со вспышками класса площади 1.

Статистические исследования солнечных вспышек малой мощности.

Боровик А.В., Жданов А.А.
СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том 4 Номер 2 **2018**
https://naukaru.ru/ru/nauka/article/19917/view
Работа является продолжением серии работ, посвященных исследованию временных параметров солнечных вспышек в линии Hα. По данным международного вспышечного патруля за период 1972–2010 гг. определены средние продолжительности вспышек различных баллов и классов пло-щади. Установлено, что 94.6 % вспышек имеют продолжительность не более 60 мин. Для 90 % вспышек с мин время жизни составляет 2.1–3.3 ч. В редких случаях вспышки могут существовать порядка 12 ч. Время жизни мощных солнечных вспышек не превышает 8.3 ч. Установлено, что продолжительности солнечных вспышек зависят от особенностей их развития. Самые короткие времена жизни имеют вспышки с одним центром повышенной яркости внутри вспышечной области, самые продолжительные — двухленточные вспышки и вспышки, демонстрирующие несколько всплесков интенсивности. Подтверждено, что с увеличением класса площади и яркости вспышек их продолжительность увеличивается.

СТАТИСТИЧЕСКИЕ ИССЛЕДОВАНИЯ СОЛНЕЧНЫХ ВСПЫШЕК МАЛОЙ МОЩНОСТИ. РАСПРЕДЕЛЕНИЯ ВСПЫШЕК ПО ПЛОЩАДИ, ЯРКОСТИ И БАЛЛАМ

Боровик А.В., Жданов А.А.
СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том: 3Номер: 1 Год: **2017** С. 34-45
Создана электронная база данных для 123801 солнечных вспышек, произошедших на Солнце с 1972 по 2010 гг. Основу составили каталоги Solar Geophysical Data (SGD) и квартального бюллетеня (Quarterly Bulletin on Solar Activity). С помощью разработанного пакета программ проведена предварительная статистическая обработка данных. Первые результаты позволили выявить ряд новых особенностей в распределении параметров солнечных вспышек, отличных от полученных ранее. Установлено, что более 90 % всех происходящих на Солнце вспышек имеют малую мощность. Самый многочисленный класс составляют вспышки балла SF (64 %). Вспышечная активность показывает хорошо выраженную цикличность и высокую корреляцию с числами Вольфа. Самые высокие коэффициенты корреляции имеют вспышки классов площади S и 1. Существует также высокая корреляция между отдельными классами вспышек: S и 1, 1 и (2-4). Полученные ранее [Mitra et al., 1972] результаты, свидетельствующие о превалировании на Солнце вспышек балла SN (47 %) и существовании значимых пиков в распределении для вспышек баллов SN и 1N, не подтвердились. Распределение числа солнечных вспышек с ростом оптического балла имеет плавный спад без существенных отклонений. С ростом оптического балла происходит постепенное перераспределение вспышек в сторону увеличения класса яркости. Большее число вспышек баллов SN и 1N, присутствующее на распределениях [Mitra et al., 1972], по всей вероятности, связано с недостаточной статистикой.

ВОЗНИКНОВЕНИЕ ЖЕСТКОГО РЕНТГЕНОВСКОГО ИЗЛУЧЕНИЯ ПРИ СЛАБЫХ НЕСТАЦИОНАРНЫХ ПРОЦЕССАХ В АКТИВНЫХ ОБЛАСТЯХ

Стр. 91-94
http://www.gao.spb.ru/russian/publ-s/conf_2014/conf_2014.pdf
We investigate solar A7-C6 flares, accompanied by the X-rays with energies E > 30keV, registered on the Suzaku satellite. Most events with hard X-rays arise in groups with a spot area of S > 500 mvh, a significant part of them develops during the decay phase of the powerful events and near the solar limb. As an example of events occurred on the disk, we examined flares on **17.11.05 and 19.05.07**. Due to the joint analysis of X-ray (Suzaku), microwaves (RATAN-600, SSRT) and magnetic field data (SOHO/MDI, SOT/Hinode) we are localized the sources of emission with a power-law spectrum with E > 30keV. These sources are situated apparently near to a small region of particle acceleration in these weak flares. We found new source in the polarized microwaves which is associated with acceleration and located over the neutral line in the region of high magnetic field strengths. Particles are accelerated more effectively when in this small region the new magnetic field emerges.

НАБЛЮДЕНИЯ МОЩНОЙ ВСПЫШКИ 27 ОКТЯБРЯ 2002 Г., ПРОИЗОШЕДШЕЙ НА ОБРАТНОЙ СТОРОНЕ СОЛНЦА

АЖ, 89(10), 888, **2012**
Анализируются результаты наблюдений мощной солнечной вспышки 27 октября 2002 г. в жесткой рентгеновской области и микроволновом диапазоне. Вспышка наблюдалась с околомарсианской орбиты аппаратурой HEND, разработанной в ИКИ РАН и установленной на космическом аппарате Mars-Odyssey. Хотя для земного наблюдателя эта мощная вспышка наблюдалась далеко за восточным лимбом Солнца, связанный с ней протяженный источник зарегистрирован RHESSI в области энергий до примерно 60 кэВ. Эруптивное событие наблюдалось в микроволновом диапазоне на обсерватории Nobeyama. По характеристикам рентгеновского излучения находится спектр электронов, ответственных за рассматриваемые излучения в рамках толстой мишени для наблюдений с околомарсианской и тонкой мишени – с околоземной орбиты. Выводы сопоставляются с результатами микроволновых наблюдений. Обсуждаются условия распространения электронов в солнечной короне.

Метод обнаружения нового магнитного потока на основе его скейлинговых свойств – **Головко** А.А., Салахутдинова И.И.
Солнечно-земная физика, **2014**

Вспышечная активность на Солнце и особенности выхода новых магнитных потоков в 2011-2013 гг.
А.А.**Головко**
ИКИ-**2014**, Сессия: Солнце
http://plasma2014.cosmos.ru/presentations
Периоды усиления вспышечной активности в течение 2011-2013 гг. соответствуют интервалам аномального поведения фотосферного магнитного поля, когда новый магнитный поток одной полярности увеличивается, в то время как поток противоположной полярности уменьшается.
Обнаруженный факт можно объяснить выходом новых порций крупномасштабного магнитного поля и их взаимодействием со старым магнитным полем.

We present a study of the dynamics of a GOES M5.7 class flare, which occurred on 10 May 2012 in NOAA 11476, in a small group of spots near the neutral line of the local magnetic field. The properties of the hard X-ray (HXR) and microwave (MW) radiation associated with this flare are analyzed. The HXR spectra are constructed according to the Space Telescope Konus-WIND and RHESSI. Detailed analysis of one-dimensional SSRT observations (5.7 GHz) and NoRP polarimeters is made. Two-dimensional radio images (SSRT and NoRH) are reconstructed. The LOS-magnetogram (SDO / HMI) detected the emergence of a new magnetic flux in a small region adjacent to the north-west of one of the EUV flare activity centers (according to SDO / AIA). Comprehensive analysis shows that the increase in the MW radiation and in the HXR occurred almost simultaneously. Two polarized MW bursts with different

properties are registered. The second burst was accompanied by appearance of a HXRsource (with energies up to 100 keV) in the loop top. We estimate the changes in the magnetic flux associated with the emergence of a new field with opposite polarity. These results directly suggest a link between the development of non-stationary processes (such as the current amplification and highly efficient particle acceleration) with the magnetic flux emergence. Such dramatic effects usually do not occur near the neutral line, but only in the events associated with large sunspots (like in powerful flares on 14 July 2000 and 20 May 2005).

НАБЛЮДЕНИЯ ЖЕСТКОГО РЕНТГЕНОВСКОГО ИЗЛУЧЕНИЯ СЛАБЫХ ВСПЫШЕК
И.Ю. **Григорьева**, М.А. Лившиц
ИКИ-**2014**, Сессия: Солнце
http://plasma2014.cosmos.ru/presentations
В некоторых слабых вспышках наблюдаются фотоны со степенным дифференциальным спектром в области 50-200 кэВ.
В активных областях, где развиваются эти вспышки B-C баллов, в дополнении к микроволновому источнику над пятном формируется источник поляризованного излучения с обратным знаком поляризации.
Для проанализированных случаев показано, что нагрев плазмы и ускорение электронов связаны с процессом всплытия нового магнитного поля в близи линии раздела полярности.
В предположении нелинейных бессиловых полей в короне всплытие магнитного поля приводит к накоплению свободной энергии на низких высотах хромосфы. И изменения в системе токов активной области приводит к слабым вспышечным процессам. В этой модели, полученные выше результаты, свидетельствуют об ускорении частиц в мелкомасштабных элементах.

ЭВОЛЮЦИЯ АКТИВНЫХ ОБЛАСТЕЙ НА СОЛНЦЕ: ВЫЯВЛЕНИЕ НОВОГО МАГНИТНОГО ПОЛЯ МЕТОДОМ МУЛЬТИФРАКТАЛЬНОГО СЕГМЕНТИРОВАНИЯ

ГОЛОВКО А.А.1, САЛАХУТДИНОВА И.И
АЖ Том: 92Номер: 8 Год: **2015** Страницы: 650

Идентификация новых магнитных потоков методом мультифрактального сегментирования применена для изучения закономерностей эволюции активных областей и комплексов активности. Использованы магнитограммы SOLIS, MDI SOHO и SOT Hinode. По наблюдениям активной области **26-28 октября 2003** г. № 10488 по каталогу данных NOAA обнаружена значительная вариабельность участков нового магнитного потока с характерным временем 1-2 ч. Уширение мультифрактального спектра в участках магнитограмм, соответствующих новому магнитному потоку, обусловливает его визуализацию на сегментированных мультифрактальных изображениях, соответствующих минимальным фрактальным размерностям. По данным за 2010-2014 гг. исследованы некоторые закономерности выхода новых магнитных потоков в 24-м солнечном

цикле. На всех этапах развития цикла преобладает положительная корреляция временн х вариаций площади новых магнитных потоков N- и S-полярности. Постепенное убывание коэффициента корреляции от 2010 к 2014 гг. можно объяснить прогрессирующим усложнением связей между активными областями, приводящим к кластеризации их в комплексы активности.х вариаций площади новых магнитных потоков N- и S-полярности. Постепенное убывание коэффициента корреляции от 2010 к 2014 гг. можно объяснить прогрессирующим усложнением связей между активными областями, приводящим к кластеризации их в комплексы активности.

Активные области минимума прошедшего солнечного цикла: связь нагрева плазмы с электрическими токами
И. Ю. **Григорьева**, М. А. Лившиц, Г. В. Руденко, И. И. Мышьяков
Астрономический журнал, 90(8) - **2013**, С. 665-675
Проанализирована совокупность данных о небольших активных областях (АО) на Солнце за три года (2007–2009 гг.). Показано, что в очень спокойных условиях (при низком уровне рентгеновского фона) форма корональных петель некоторых АО достаточно хорошо соответствует ходу силовых линий, вычисленному в

потенциальном приближении. Это относится к нескольким АО (например, к группе 10999 в июне 2008 г.), где вспышки мощнее B3 вообще не наблюдались. Микроволновое излучение этой АО, зарегистрированное на РАТАН-600, было очень слабым и поляризация фактически отсутствовала. В большинстве групп наблюдались субвспышки. На примере группы 10933 (январь 2007 г.) продемонстрировано, что для таких АО характерно возрастание мягкого рентгеновского излучения от нескольких до десяти раз, одновременно с некоторым увеличением потока микроволнового излучения. При этом к северо-западу от основного пятна АО 10933 развивается источник с противоположным направлением поляризации. Серия магнитограмм SOHO/MDI (а также Hinode) показывает, что перед развитием этого поляризованного источника происходит всплытие нового магнитного поля, продолжающееся несколько часов 8 января 2007 г. С использованием наблюдений полного вектора магнитного поля (данные Hinode) и метода нелинейной экстраполяции бессиловых магнитных полей получена оценка плотности тока на поверхностях, располагающихся на различных высотах. Проинтегрированный по высоте ток существенно усилен в двух узлах над нейтральной линией поля вблизи места основного всплытия поля. Таким образом, подтверждается то, что всплытие нового магнитного поля является основным фактором эволюции АО на всех стадиях их существования. Развитие этих представлений может помочь в выяснении взаимосвязи между усилением токов, нагревом плазмы и ускорением частиц, как в слабых АО, так и в мощных комплексах активности.

УСКОРЕНИЕ ЭЛЕКТРОНОВ В МАГНИТНЫХ ЛОВУШКАХ СОЛНЕЧНОЙ ВСПЫШКИ: МОДЕЛЬНЫЕ СВОЙСТВА И ИХ НАБЛЮДАТЕЛЬНЫЕ ПОДТВЕРЖДЕНИЯ

ГРИЦЫК П.А.1, СОМОВ Б.В.1

ПАЖ Том: 43Номер: 9 Год: **2017** Страницы: 676

С помощью аналитического решения кинетического уравнения мы исследовали модельные свойства коронального и хромосферного источников жесткого рентгеновского излучения в лимбовой вспышке **19 июля 2012** г. В приближении толстой мишени с обратным током мы рассчитали спектр излучения в основаниях вспышечной петли и показали, что он согласуется с наблюдаемым. Спектр коронального источника, расположенного над вспышечной петлей, рассчитан в приближении тонкой мишени. При этом показатель наклона спектра жесткого рентгеновского излучения воспроизводится очень точно, но интенсивность коронального излучения в несколько раз ниже наблюдаемой. Ранее нами было показано, что это противоречие полностью устраняется, если учесть дополнительное (относительно первичного ускорения в пересоединяющем токовом слое) ускорение электронов в корональной магнитной ловушке, которая сжимается в поперечном направлении и уменьшается по длине во время импульсной фазы вспышки. В настоящей статье мы детально исследуем данный эффект в контексте более реалистичного сценария вспышки, когда за время всплеска в жестком рентгеновском диапазоне существовал целый ансамбль ловушек, каждая из которых находилась на разных этапах своей эволюции: формирование, коллапс, уничтожение. Полученные в работе результаты указывают не только на существование ускорения Ферми первого порядка и бетатронного нагрева электронов в солнечных вспышках, но и на высокую их эффективность. На примере высокоточных наблюдений конкретной вспышки предсказанные ранее теоретические особенности модели находят убедительные подтверждения.

АНАЛИТИЧЕСКАЯ МОДЕЛЬ РАСПРОСТРАНЕНИЯ ТЕПЛОВЫХ УБЕГАЮЩИХ ЭЛЕКТРОНОВ В СОЛНЕЧНЫХ ВСПЫШКАХ

ГРИЦЫК П.А.1, СОМОВ Б.В.1

ПАЖ Том: 45Номер: 4 Год: **2019** Страницы: 279-289

Природа жесткого рентгеновского излучения солнечных вспышек хорошо известна. Наблюдаемое излучение как в короне, так и в хромосфере состоит из двух компонент: нетепловой и тепловой. Нетепловая компонента обусловлена тормозным излучением ускоренных электронов, тепловая - тормозным излучением нагретых электронов плазмы. Вследствие того, что спектры нетеплового и теплового жесткого рентгеновского излучения частично перекрываются, их корректная интерпретация напрямую зависит от точности кинетических моделей, описывающих распространение в атмосфере Солнца убегающих электронов тепловой и нетепловой природы. Эволюция функции распределения последних, т.е. электронов, ускоренных в области магнитного пересоединения, точно описывается в приближении современных моделей толстой мишени с обратным током. В настоящей работе рассмотрена модель теплового убегания электронов и найдено аналитическое решение соответствующего кинетического уравнения, в котором учтены кулоновские столкновения. Сделаны оценки степени поляризации излучения, которая не превышает $\sim 5\%$. Полученная функция распределения может быть также использована для расчета спектра теплового рентгеновского излучения и, как следствие, интерпретации наблюдений тепловой компоненты в рентгеновском спектре вспышки.

РЕНТГЕНОВСКОЕ И МИКРОВОЛНОВОЕ ИЗЛУЧЕНИЕ СОЛНЕЧНОЙ ВСПЫШКИ 19 ИЮЛЯ 2012 ГОДА: ВЫСОКОТОЧНЫЕ НАБЛЮДЕНИЯ И КИНЕТИЧЕСКИЕ МОДЕЛИ

ГРИЦЫК П.А.1, СОМОВ Б.В.1

ПАЖ Том: 42Номер: 8 Год: **2016** Страницы: 586

Солнечная вспышка класса M7.7 **19 июля 2012** г. в 05:58 UT наблюдалась с высоким пространственным, временным и спектральным разрешением в жестком рентгеновском и оптическом диапазонах. Вспышка имела место на краю солнечного диска, что позволило увидеть относительное расположение коронального и хромосферного источников рентгеновского излучения, определить их спектры. Для объяснения наблюдений коронального и незакрытого солнечным лимбом хромосферного источников мы применяем аккуратную аналитическую модель кинетического поведения ускоренных электронов во вспышке. Хромосферный источник жесткого рентгеновского излучения интерпретируется в приближении толстой мишени с обратным током, а корональный - в приближении тонкой мишени. Полученные оценки показателей наклона спектров жесткого рентгеновского излучения обоих источников согласуются с результатами наблюдений. Однако рассчитанная интенсивность излучения коронального источника в несколько раз ниже наблюдаемой. Учет эффекта ускорения быстрых электронов в коллапсирующей магнитной ловушке позволил нам устранить это противоречие. В результате моделирования получена оценка плотности потока энергии, переносимой электронами с энергиями выше 15 кэВ, которая составляет $\sim 5 \times 10^{10}$ erg cm^{-2} s^{-1}, что в ~5 раз превышает значения, характерные для модели толстой мишени без обратного тока. С целью независимой проверки модели рассчитан спектр микроволнового излучения в диапазоне 1-50 ГГц, который соответствует имеющимся данным радионаблюдений.

Связь множественности источников жесткого рентгеновского излучения солнечных вспышек со множественностью -особенностей магнитного поля

О. Г. **Ден**1, И. В. Зимовец

АЖ, **2014**, #7, С. 569-577

Исследована импульсная фаза мощной солнечной вспышки **13 сентября 2005** г. (UT), наблюдавшейся космическим аппаратом RHESSI в диапазоне жесткого рентгеновского излучения (кэВ). Проведено пространственное сопоставление наблюдавшихся в этом диапазоне множественных источников излучения и рассчитанных для вспышечной области -особенностей магнитного поля. Показано, что совокупности источников жесткого рентгеновского излучения можно сопоставить совокупность -особенностей - мест возможного первичного энерговыделения вспышки. Силовые линии магнитного поля, пущенные из окрестности найденных магнитных особенностей, оканчиваются в хромосфере в окрестности наблюдавшихся источников жесткого рентгеновского излучения. Вопрос о том, каким образом множественные магнитные особенности вовлекаются в процесс энерговыделения практически одновременно, требует дальнейшего изучения.

О НАИБОЛЕЕ ТИПИЧНОЙ СТРУКТУРЕ ТРЕХМЕРНОГО МАГНИТНОГО ПЕРЕСОЕДИНЕНИЯ

ДУМИН Ю.В.1,2, СОМОВ Б.В.

ПАЖ Том: 42Номер: 11 Год: **2016** Страницы: 850

В связи с проблемой магнитного пересоединения в турбулентной астрофизической плазме с сильным магнитным полем, в частности, в солнечных вспышках, мы рассчитали вероятность возникновения различных топологических структур трехмерного пересоединения в нулевой точке случайного магнитного поля. Установлено, что доминирующую роль играет специфическая неосесимметричная структура с шестью асимптотическими направлениями - “шестихвостка”, называемая также “неправильным радиальным нулем”. Все остальные структуры, в частности, осесимметричные (“правильные радиальные нули”) реализуются с гораздо меньшей вероятностью. Принципиальной особенностью “шестихвостки” является то, что на больших расстояниях она приближенно редуцируется к классической двумерной структуре X-типа.

ФИЗИЧЕСКИЕ СВОЙСТВА СПОКОЙНОГО ПЕРЕХОДНОГО СЛОЯ МЕЖДУ КОРОНОЙ И ХРОМОСФЕРОЙ СОЛНЦА

ДУНИН-БАРКОВСКАЯ О.В.1, СОМОВ Б.В.1

ПАЖ Том: 42 Номер: 12 Год: **2016** Страницы: 908

Представлены результаты исследований физических свойств переходного слоя между короной и хромосферой Солнца в спокойных областях. Здесь структура атмосферы Солнца определяется взаимодействием магнитных полей над фотосферой. Они концентрируются в тонкие трубки, внутри которых велика напряженность поля. Исследовано, как в зависимости от скорости плазмы на хромосферной границе переходного слоя меняются распределения температуры, концентрации и скорости плазмы вдоль магнитной трубки, один конец которой находится в хромосфере, а другой - в короне. Рассмотрены два предельных случая: горизонтально и вертикально расположенная магнитная трубка. Для различных концентраций плазмы определены диапазоны скоростей на хромосферной границе переходного слоя, для которых в переходном слое не должны

возбуждаться ударные волны. Показано, что наиболее благоприятными для возбуждения ударных волн в переходном слое являются направленные вниз течения плазмы в его основании. Для всех рассчитанных вариантов переходного слоя показано, что перенос тепловой энергии вдоль магнитных трубок может быть хорошо описан в приближении классической электронной столкновительной теплопроводности вплоть до очень больших скоростей в основании переходного слоя. Рассчитанное жесткое ультрафиолетовое (EUV) излучение хорошо согласуется с современными космическими наблюдениями Солнца.

МЕТОД ПОИСКА НАНОВСПЫШЕК И ИХ ПРОСТРАНСТВЕННОЕ РАСПРЕДЕЛЕНИЕ В КОРОНЕ СОЛНЦА

Завершинский Д.И., Богачёв С.А., Белов С.А., Леденцов Л.С.
ПАЖ Том: 48Номер: 9 Год: **2022** Страницы: 665-675
Солнечные нановспышки – мелкомасштабные события, которые могут играть значительную роль в нагреве короны. Из-за слабой величины сигнала поиск и исследование нановспышек представляют собой непростую задачу, которая по-разному решается разными авторами. Мы представляем собственный метод регистрации нановспышек, который, по нашему мнению, позволяет эффективно измерять темп формирования нановспышек, а также их пространственное распределение на изображениях Солнца в вакуумном УФ диапазоне спектра. Мы исследовали серию из 300 изображений Солнца, полученных телескопом SDO/AIA в канале 171 Å в период низкой активности Солнца (с 12:00 UT по 13:00 UT **20 мая 2019** г.) и определили темп формирования нановспышек: P≈4.23×10−21 см−2 с−1, который оказался в согласии с результатами других авторов, а также исследовали зависимость P от гелиографической широты и яркости короны Солнца. Согласно нашим результатам, темп формирования нановспышек не зависит от гелиошироты, что отличается от поведения обычных вспышек, формирующихся в узких поясах активности. Также обнаружена связь между величиной P [пикс−1 ч−1] и светимостью короны I [отсчеты]: lgP=−2.27+0.00327I. Мы оцениваем наши результаты как благоприятные для теории нагрева короны нановспышками.

ГЕНЕРАЦИЯ СУПЕРДРАЙСЕРОВСКИХ ЭЛЕКТРИЧЕСКИХ ПОЛЕЙ В СОЛНЕЧНОЙ ХРОМОСФЕРЕ

Зайцев В.В.1, Кронштадтов П.В.1, Степанов А.В.
Пулково *«Солнечная и солнечно-земная физика – **2015** с.149*
Excitation of the electric field on the front of the current pulse that occurs at the footpoints of a coronal magnetic loop as a result of the magnetic Rayleigh-Taylor instability is considered. For the time of ≈ / ≈ 5 ÷ 25 A A ᴛ l V s (where l is the scale of a plasma tongue invading the magnetic loop due to the Rayleigh-Taylor instability) a disturbance associated with the tension of the magnetic field B (r, t) ϕ , "running away" from the region of instability with the Alfven speed. As a result, a pulse of electric current I (z V t) z A − with a scale of Δξ ≈ l begins to propagate along the magnetic loop. Therewith the inductive electric field z E on the pulse front appears, directed along of the loop axis, i.e., capable of accelerating particles. For sufficiently high current value, B ρ > p ϕ 2 / 8 , a non-linear regime of propagation of the electric current pulse is realized and quite high longitudinal electric field is generated E I V c a B l z z A z≈ 2 3 / 4 2 2 which depending on the current magnitude can exceed the Dreicer field.

Корональные магнитные арки

Зайцев В.В., Степанов А.В.
УФН, т.178(11), 1165-1204, **2008, Файл**
Physics Uspekhi, Volume 51, Issue 11, pp. 1123-1160 (**2008**).
The goal of this review is to outline some new ideas in the physics of coronal magnetic loops, the fundamental structural elements of the atmospheres of the Sun and flaring stars, which are involved in phenomena such as stellar coronal heating, flare energy release, charged particle acceleration, and the modulation of optical, radio, and X-ray emissions. The Alfvén–Carlqvist view of a coronal loop as an equivalent electric circuit allows a good physical understanding of loop processes. Describing coronal loops as MHD-resonators explains various ways in which flaring emissions from the Sun and stars are modulated, whereas modeling them by magnetic mirror traps allows one to describe the dynamics and emission of high-energy particles. Based on these approaches, loop plasma and fast particle parameters are obtained and models for flare energy release and stellar corona heating are developed.

ПРЕДВСПЫШЕЧНЫЕ РЕНТГЕНОВСКИЕ ПУЛЬСАЦИИ С ИСТОЧНИКАМИ ВНЕ АКТИВНОЙ ОБЛАСТИ ОСНОВНОЙ ВСПЫШКИ

Зимовец И.В., Шарыкин И.Н., Кальтман Т.И., Ступишин А.Г., Низамов Б.А.

Г и А Том: 63Номер: 5 Год: **2023** Страницы: 547-560
Ранее мы показали, что по характеру расположения источников предвспышечных рентгеновских пульсаций относительно основной солнечной вспышки события разделяются по крайней мере на два типа: в событиях типа I источники пульсаций и основной вспышки находятся в одной активной области (АО), а в событиях типа II – в разных. В данной работе представлен анализ события типа II, в котором по данным космической обсерватории Ramaty High-Energy Solar Spectroscopic Imager (RHESSI) рентгеновские источники предвспышечных квазипериодических пульсаций (с периодом P = 1.5 ± 0.1 мин), начавшихся в ~18:02 UT, располагались в АО 11 884 в Западном полушарии, а источники основной вспышки M1.0 SOL**2013-11-05**T18:08 в АО 11 890 в Восточном полушарии. Пульсации также наблюдались с помощью Gamma-Ray Burst Monitor (GBM) на борту космической обсерватории Fermi и X-Ray Sensor (XRS) на борту Geostationary Operational Environmental Satellite (GOES), что исключает возможность их искусственного происхождения.. По данным Atmospheric Imaging Assembly (AIA) на борту Solar Dynamics Observatory (SDO) в экстремальном ультрафиолетовом диапазоне установлено, что источники пульсаций располагались в основании корональных струй (джетов), истекавших со скоростями ~100–1500 км/с. Расстояние между АО 11 884 и АО 11 890 составляло ~1.4 RS. Плазме струй потребовалось бы ~17–250 мин, чтобы достичь АО 11 890, что намного больше времени межу началом пульсаций (струй) и вспышкой (~6 мин), к тому же в картинной плоскости струи истекали в противоположном (западном) от активной области вспышки направлении. В короне не наблюдались петли, соединяющие АО 11 884 и АО 11 890. Более того, не обнаружено соединения этих областей силовыми линиями магнитного поля, экстраполированного с фотосферы в корону в потенциальном приближении. Эти аргументы свидетельствуют о том, что струи (и связанные с ними пульсации) не могли быть триггером вспышки. Таким образом, представлен яркий пример события, в котором не было физической связи между предвспышечными рентгеновскими пульсациями (и струями) и последовавшей за ними вспышкой. Это событие демонстрирует важное значение пространственно-разрешенных наблюдений при исследовании пульсаций на Солнце и звездах..

ИСТОЧНИКИ ДЛИННОПЕРИОДНЫХ РЕНТГЕНОВСКИХ ПУЛЬСАЦИЙ ПЕРЕД НАЧАЛОМ СОЛНЕЧНЫХ ВСПЫШЕК

Зимовец И.В., Нечаева А.Б., Шарыкин И.Н., Низамов Б.А.
Г и А Том: 62Номер: 4 Год: 2022 Страницы: 436-455
В работе [Tan et al., 2016] утверждается, что перед значительной долей (26–46%) “изолированных” солнечных вспышек наблюдаются длиннопериодные (с периодом P = 1.9–47.3 мин и длительностью 1–2 ч) квазипериодические пульсации (КПП) в диапазоне мягкого рентгеновского излучения. Результаты получены по данным инструмента GOES/XRS без пространственного разрешения. В данной работе мы выполнили анализ источников таких КПП перед 35 “изолированными” вспышками класса X на основе “quick-look” изображений RHESSI в диапазоне 6–12 кэВ и установили, что события можно разделить на два типа. В событиях типа I источники всех КПП и основной вспышки располагаются в одной активной области (АО) на Солнце, тогда как в событиях типа II источники по крайней мере части КПП располагаются в другой АО, нежели АО вспышки. Более детальный анализ двух событий типа I и трех событий типа II с помощью изображений RHESSI в рентгеновском и SDO/AIA в ультрафиолетовом диапазонах показывает, что источники рентгеновских пульсаций в одной АО располагаются в разных местах (в пределах ~20 Мм друг от друга и от основной вспышки), причем их появление соответствует появлению новых петлеобразных ультрафиолетовых источников. Мы приводим наблюдательные аргументы в пользу того, что предполагаемые в работе [Tan et al., 2016] механизмы, основанные на осцилляциях корональных петель как LRC электрических контуров или МГД-осцилляциях петель, маловероятны. Более перспективными для объяснения рассматриваемых КПП представляется механизм осциллирующего пересоединения. В событиях типа I оно происходит в одной АО, тогда как в событиях типа II оно может происходить параллельно в нескольких разнесенных АО, и для объяснения этого обстоятельства требуется предположить когерентность подфотосферного всплытия магнитных потоков в разных участках Солнца. Это предположение требует дальнейшей проверки.

О СВЯЗИ ВСПЫШЕЧНЫХ ИСТОЧНИКОВ ЖЕСТКОГО РЕНТГЕНОВСКОГО ИЗЛУЧЕНИЯ

И ЭЛЕКТРИЧЕСКИХ ТОКОВ НА ФОТОСФЕРЕ
Зимовец И.В., Шарыкин И.Н.
Пулково «Солнечная и солнечно-земная физика – **2015** с.153
There are some evidences that initial energy release and acceleration of electrons, at least in some solar flares, can occur inside magnetic tubes with strong electric currents, in the transition region and chromosphere, rather than in the corona. We report preliminary results of observational study of spatial relationship between hard X-ray (HXR; ≥50keV) sources detected by RHESSI in 12 flares and vertical currents in parental active regions (AOs) calculated using the HMI/SDO photospheric vector magnetograms. We found that in all flares at least one HXR source was in a region of strong currents within 10%–90% of the maximum current of an entire AO. Integral currents (of the same sign) across the HXR sources were in the range of 1.1–9.5.1011 A. We also found that there were multiple regions of strong currents in each AO where HXR sources were not detected. These results give evidence that there is link between flare HXR sources and strong vertical currents on the photosphere. However, this link is not clear. It seems that strong vertical currents is necessary but not sufficient condition for generation of flare HXR sources. This work should be expanded to try to find sufficient condition. **03.08.2011**

Статистика вспышек в комплексах активности на Солнце
Исаева Е.С.
Диссертация **2023**

РЕНТГЕНОВСКИЕ ВСПЫШКИ И КОМПЛЕКСЫ АКТИВНОСТИ НА СОЛНЦЕ В 24 ЦИКЛЕ

ИСАЕВА Е. С.[1,2], ТОМОЗОВ В. М.[2], ЯЗЕВ С. А.
АСТРОНОМИЧЕСКИЙ ЖУРНАЛ Том: 97 Номер: 1 Год: **2020** Страницы: 64-72
Проанализирована статистическая связь комплексов активности (КА) на Солнце и солнечных вспышек с рентгеновскими классами GOES выше M1.0 (744 события) в течение 24 цикла солнечной активности (до января 2019 г.). Все группы пятен разбиты на три класса: в ядрах КА, в ветвях КА, за пределами КА. Показано, что 78% вспышек указанных классов происходят преимущественно в группах пятен, расположенных в ядрах и в ветвях КА. Удельное число вспышек в ядрах КА в 2.5 раза превышает соответствующий параметр в ветвях КА и за пределами КА. С КА связаны 87% LDE-вспышек указанных классов, 82% всех сильных протонных вспышек, генерирующих потоки энергичных протонов на орбите Земли, а также 74% всех гамма-вспышек в 24 цикле.

ПРОТОННЫЕ ВСПЫШКИ В КОМПЛЕКСАХ АКТИВНОСТИ НА СОЛНЦЕ: ВОЗМОЖНЫЕ ПРИЧИНЫ И СЛЕДСТВИЯ

ИСАЕВА Е.С.[1,2], **ТОМОЗОВ В.М.**[1,2], **ЯЗЕВ С.А.**[1,2]

СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том: 95Номер: 3 Год: 2018 Страницы: 256-264
Вспышки на Солнце, которые сопровождались потоками частиц на орбите Земли, превышающими 10 частиц на квадратный сантиметр в секунду с энергией более 10 МэВ в 24 цикле, происходили преимущественно в комплексах активности (в 82%)и в 80% случаев не далее, чем в 20 гелиографических градусах от ближайших корональных дыр. При этом рентгеновский класс вспышек плохо коррелирует с потоком протонов на орбите Земли. В статье обосновывается гипотеза о том, что выход частиц в гелиосферу обусловлен существованием долгоживущих магнитных каналов, позволяющих обеспечить перенос ускоренных вспышкой частиц в пограничную область открытой магнитной структуры корональных дыр. Обсуждается возможный вклад процессов обменного пересоединения как в формирование таких каналов, так и роль обменного пересоединения в генерации самих вспышек.

РЕНТГЕНОВСКИЕ ВСПЫШКИ И КОМПЛЕКСЫ АКТИВНОСТИ НА СОЛНЦЕ

ИСАЕВА Е.С.[1], **ЯЗЕВ С.А.**[2,3]

СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Номер: 22 (135) Год: 2013 Страницы: 3-11
Проанализирована связь комплексов активности (КА) на Солнце и солнечных вспышек рентгеновских классов выше M0 на фазе роста 24-го цикла солнечной активности (до апреля 2012 г.). Все группы пятен разбиты на три класса: в ядрах КА, в ветвях КА, за пределами КА. Показано, что вспышки происходят преимущественно в группах пятен, расположенных в ядрах и в ветвях КА. Для вспышек рентгеновского класса X не отмечено особой роли ядер КА (в группах пятен вне КА наблюдается такое же число X-вспышек), но суммарная мощность вспышек класса X в ядрах КА оказывается выше, чем в активных областях вне КА. LDE-вспышки (long decay events, или вспышки с длительным затуханием всплеска (более 4 ч) в мягком рентгеновском излучении) происходят преимущественно в КА, при этом наиболее мощные события наблюдаются в основном в ветвях, а не в ядрах КА. Показано, что в течение фазы роста 24-го цикла вспышечная деятельность проявлялась в виде всплесков продолжительностью около двух солнечных оборотов. Эти всплески хорошо коррелируют с импульсами пятнообразовательной деятельности Солнца, связанными с активностью КА. В исследуемый период девять из одиннадцати мощных протонных вспышек произошли в КА.

ЭРУПТИВНЫЕ ПРОЦЕССЫ В НАЧАЛЕ РАЗВИТИЯ МОЩНЫХ ВСПЫШЕЧНО-АКТИВНЫХ ОБЛАСТЕЙ НА СОЛНЦЕ

Л. К. **Кашапова**1, М. А. Лившиц

АСТРОНОМИЧЕСКИЙЖУРНАЛ, **2008**, том 85,№12, с. 1129–1142 **File**

Изучается эволюция больших центров активности на Солнце и выясняются условия, приводящие к мощным нестационарным процессам. В дополнение к рассматриваемым в таких случаях обычным факторам (изменение площади пятен, структуры магнитных полей и характера движений), изучается вопрос о том, насколько наблюдения собственно нестационарных процессов (вспышек и связанных с ними корональных выбросов массы) могут быть полезны для предсказания развития таких процессов в ходе последующей эволюции центра активности. Данная проблема обсуждается на примере мощной группы10486 октября 2003 г., наблюдения которой удалось провести еще до выхода этой группына восточный лимб, используя наблюдения на космическом аппарате, располагающемся на околомарсианской орбите. Для событий 2003 г. появилась возможность строить изображения вспышек в различных спектральных диапазонах, и можно было подробно изучать высокоэнергичные процессы в изолированной в начале своего развития группе 486 и затем в событиях связанных между собой групп 486 и 484. Анализ своеобразного первого периода развития группы486 показал, что в дальнейшем можно ожидать усиления активности не только вследствие всплытия новых магнитных потоков (и групп-сателлитов), но и взаимодействия и синхронизации двух, а затем и трех больших групп конца октября 2003 г. Иначе говоря, появление экстремально мощных нестационарных процессов связано в данном случае с относительно более высоким вкладом крупномасштабных магнитных полей. Сделанные выводы сопоставляются с результатами изучения характера движений и магнитных полей в обсуждаемом центре активности за время всего прохождения по диску с **21 октября по 5 ноября 2003** г. 21,23, 24 октября 2003

Широтные распределения солнечных микровспышек и высокотемпературной плазмы в минимуме солнечной активности.

Кириченко А.С., Лобода И.П., Рева А.А., Ульянов А.С., Богачев С.А.

СЗФ, Т 9, №2, С. 5–11 **2023**

https://naukaru.ru/ru/storage/viewWindow/121954

В работе проанализировано распределение по широте высокотемпературной плазмы (T> 4 МК) и рентгеновских микровспышек на солнечном диске в период низкой активности Солнца в 2009 г. Распределение микровспышек классов A0.1–A1.0 содержит пояса, характерные для обычных вспышек класса B и выше. Всего нами зарегистрировано 526 микровспышек, большинство из которых, около 96 %, наблюдалось на высоких широтах. Около 4 % микровспышек было обнаружено около экватора. Мы полагаем, что они сформированы остаточным магнитным полем предыдущего , 23-го цикла активности. Обычные вспышки класса B и выше в этот период около экватора почти не наблюдались. Число микровспышек в южном полушарии в этот период было незначительно выше, чем в северном. Это отличается от распределения обычных вспышек, для которых ранее сообщалось о доминировании северного полушария по числу вспышек.

ДЛИТЕЛЬНЫЙ НАГРЕВ ПЛАЗМЫ В СОЛНЕЧНЫХ МИКРОВСПЫШКАХ РЕНТГЕНОВСКОГО КЛАССА A1.0 И НИЖЕ

КИРИЧЕНКО А. С.1, БОГАЧЕВ С. А.

Письма в АЖ, т.39, №11, стр. 884, **2013**

Представлены результаты исследования трех солнечных микровспышек рентгеновского класса порядка A1.0 и ниже, наблюдавшихся в минимуме солнечной активности в 2009 году: вспышка **19.04.2009** (класс A0.38), вспышка **24.06.2009** (класс A0.47), вспышка **18.07.2009** (класс A2.2). Отличительной особенностью данных событий от других микровспышек низких рентгеновских классов являлось поддержание высокой температуры плазмы (МК) на фазе спада излучения спустя значительное время после максимума вспышки. Времена жизни высокотемпературного источника излучения в короне во всех трех случаях существенно превышают времена его теплопроводного и лучистого охлаждения, а тепловая энергия, выделяемая на фазе спада вспышки, на порядок превышает тепловую энергию, высвобождаемую во время ее импульсной фазы. Высказано предположение, что длительное поддержание высокой температуры плазмы в микровспышках низких рентгеновских классов может осуществляться за счет процесса магнитного пересоединения, связанного с выбросами массы из области вспышки. Время жизни горячей плазмы в короне в этом случае может заметно превышать время охлаждения плазмы. Исследование показало, что во всех трех исследованных микровспышках действительно происходила эрупция вещества.

СКИН-СЛОЙ ЭРУПТИВНОГО МАГНИТНОГО ЖГУТА В КРУПНЫХ СОЛНЕЧНЫХ ВСПЫШКАХ

Эволюция магнитного поля вспышечно-активных областей Солнца из геометрии и топологии HMI/SDO-магнитограмм

И. С. **Князева**, Н. Г. Макаренко

Астрономический журнал, **2014**, Том 91, Номер 3, С. 200-210

Представлены апробация и дальнейшее развитие топологических подходов для анализа магнитного поля Солнца. С целью описания и диагностики предвспышечной динамики магнитного поля активных областей Солнца по HMI-магнитограммам обсерватории SDO использован аппарат, основанный на методах геометрии случайных полей, математической морфологии и топологии и масштабируемого пространства (scale-space). Полученные результаты показали, что предложенный формализм позволяет диагностировать предвспышечную динамику для практически представляющих интерес интервалов времени.

О ФОРМИРОВАНИИ НИТЕПОДОБНЫХ СТРУКТУР НА РАННЕЙ ФАЗЕ СОЛНЕЧНЫХ ВСПЫШЕК

В. А. **Ковалев**, *, Е. Д. Куретовab, Е. С. Куркинab

ФИЗИКА ПЛАЗМЫ, **2020**, том 46, № 4, с. 351–357

Предложена модель, описывающая начальную фазу вспышечного нагрева в короне Солнца. Уравнение энергии для вспышечной плазмы в магнитной трубке приведено к двумерному уравнению теплопроводности с нелинейным объемным источником, обеспечивающим нагрев плазмы в режиме с обострением, и нелинейным анизотропным коэффициентом теплопроводности. Показано, что взрывной нагрев плазмы может сопровождаться формированием высокотемпературных структур, вытянутых вдоль магнитной трубки.

Микроволновый индикатор потенциальной геоэффективности и жгутовая магнитная структура солнечной активной области.

Кудрявцева А.В., Мышьяков И.И., Уралов А.М., Гречнев В.В.

СЗФ Том 7. **2021**. № 1. С. 3–12.

https://naukaru.ru/ru/storage/viewWindow/66383

Выполнен анализ присутствия микроволнового источника над нейтральной линией (ИНЛ) в суперактивной области NOAA 12673, породившей ряд геоэффективных событий в сентябре 2017 г. Для оценки положения ИНЛ использовались данные Сибирского радиогелиографа в диапазоне 4–8 ГГц и Радиогелиографа Нобеяма на частоте 17 ГГц. Расчет коронального магнитного поля в нелинейном бессиловом приближении выявил протяженную структуру, состоящую из взаимосвязанных магнитных жгутов, расположенных практически по всей длине главной линии раздела полярностей фотосферного магнитного поля. ИНЛ проецируется в зону максимальных значений горизонтального магнитного поля — основной энергосо-держащей части этой структуры. В ходе каждой вспышки балла X активная область теряла магнитную спиральность и становилась источником КВМ. **6-7 Sep 2017**

ПОЛЯРИЗАЦИЯ ЖЕСТКОГО РЕНТГЕНОВСКОГО ИЗЛУЧЕНИЯ ПРИ ДЛИТЕЛЬНОЙ И ИМПУЛЬСНОЙ ИНЖЕКЦИИ РЕЛЯТИВИСТСКИХ ЭЛЕКТРОНОВ ВО ВСПЫШЕЧНУЮ ПЕТЛЮ

Кудрявцев И.В.1,2, Мельников В.Ф.2, Чариков Ю.Е.1,3

Пулково «Солнечная и солнечно-земная физика – **2015** с.239

In this paper a comparison of polarization properties of impulsive and gradual HXR bursts on the basis of theoretical analysis of their emissions is conducted. Numerical simulation is carried out for the impulsive and gradual injections, lasting a few seconds, and a few tens of seconds, respectively. In the latter case one can speak on a quasi-stationary mode of changes of the angular distribution of nonthermal electrons. Various cases of the angular dependence of the injected electrons are considered. To obtain the parameters of HXR, the relativistic kinetic equation for fast electrons and the relativistic bremsstrahlung cross-section are used. The differences in the dynamics of the degree of polarization are discussed. For example, in the case of the impulsive injection, the degree of polarization rapidly decreases after reaching the peak rate of the injected electrons due to the effect of fast isotropization of electrons in the process of their scattering on the background plasma particles. In the case of the gradual injection, a high value (25–50%) of polarization degree remains during tens of seconds

after the intensity peak and can be experimentally registered even now.

ИССЛЕДОВАНИЕ ПРОСТРАНСТВЕННОЙ ДИНАМИКИ ИСТОЧНИКОВ КВАЗИПЕРИОДИЧЕСКИХ ПУЛЬСАЦИЙ ЖЕСТКОГО РЕНТГЕНОВСКОГО ИЗЛУЧЕНИЯ СОЛНЕЧНЫХ ВСПЫШЕК

Пулково «Солнечная и солнечно-земная физика – **2015** с. 249
We present a brief description of the method, which we are currently developing for study physical properties of quasi-periodic pulsations in solar flare with hard X-ray emission. The preliminary analysis of the M4.6-class flare of **9 November 2002** is given as an example. It is shown that the double footpoint-like hard X-ray (25–50 keV) sources move along the magnetic neutral line in course of the flare. This can be interpreted as successive involvement of new flaring loops of the magnetic arcade into the energy release process. Our observational results are in agreement with some previous works on this topic. Description of the systematic study of this phenomenon for a large number of events will be presented later.

ЭВОЛЮЦИЯ СОЛНЕЧНОЙ ВСПЫШКИ SOL 2013-05-17: АНАЛИЗ ОПТИЧЕСКИХ СПЕКТРОВ (СЕРИЯ БАЛЬМЕРА) И КВАЗИПЕРИОДИЧЕСКИЕ ПУЛЬСАЦИИ

Купряков Ю.А., Бычков К.В., Белова О.М., Горшков А.Б., Barta M.
Изв. КрАО Том: 119Номер: 4 Год: 2023 Страницы: 5-11
Цель работы - изучение поведения кривых интенсивности излучения в линиях Hϵ, Hβ и Hα в процессе развития вспышки и сравнение результатов с расчетными значениями. Наблюдения проводились на горизонтальной солнечной установке HSFA-2 (Ondˇrejov Observatory). Для обработки была отобрана вспышка 2013-05-17 класса M 3.2 в активной области NOAA 11748, для которой были определены абсолютные значения потоков в спектральных линиях. Показано, что наблюдениям удовлетворяет модель нагрева хромосферного газа потоком магнитогидродинамических волн из конвективной зоны и его ионизация и возбуждение потоком надтепловых частиц из короны. Выполнены расчеты в линиях водорода с учетом основных процессов, определяющих излучение газа, непрозрачного в спектральных линиях. Плоский декремент бальмеровской серии свидетельствует о неоднородности излучающей области по вертикали. Поиск квазипериодических пульсаций показал, что в данной вспышке они обнаруживаются только в линии Hα с уровнем значимости 95 %. В других спектральных диапазонах они отсутствуют.

Квазипериодические пульсации в солнечных и звездных вспышках. Обзор Review

Куприянова Е.Г., Колотков Д.Ю., Накаряков В.М., Кауфман А.С.
СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том 6. **2020**. № 1 С. 3–29.

В статье представлен обзор современного состояния исследований колебательных процессов в солнечных и звездных вспышках, основанных на наблюдательных данных наземных и космических инструментов с высоким временны́м, пространственным и спектральным разрешением в разных диапазонах электромагнитного спектра. Рассматриваются механизмы генерации вспышечного излучения и его квазипериодической модуляции. Обсуждаются сходство и различие солнечных и звездных вспышек, а также связанные с этим проблемы супервспышек на Солнце и космической погоды. Показано, что квазипериодические пульсации (КПП) вспышечного излучения являются эффективным инструментом диагностики как самих вспышечных процессов, так и параметров тепловой плазмы и ускоренных частиц. Рассматриваются виды КПП, их статистические свойства и методы анализа с учетом нестационарности параметров КПП. Сделан обзор предполагаемых механизмов КПП и открытых вопросов. **2005-05-06, 2013-05-14, 29 Mar 2014**

Долгопериодические пульсации теплового микроволнового излучения солнечной вспышки 2 июня 2007 г. по данным с высоким пространственным разрешением

Е. Г. **Куприянова**, В. Ф. Мельников, В. М. Пузыня, К. Шибасаки, Х. С. Джи
АЖ, т. 91, №8, С. 662-667, **2014**
На основе данных радиогелиографа Нобеяма (NoRH) на 17 ГГц с высоким угловым и временным разрешением в тепловой компоненте микроволнового излучения вспышечной петли 02.06.2007 на Солнце обнаружены и исследованы квазипериодические пульсации с постоянными во времени периодами в диапазоне от 55 до 250 с. Выделены колебания с периодом около 110–120 с, отличающиеся от других своей синфазностью вдоль оси петли. Наблюдаемые периодичности вероятнее всего вызваны модуляцией радиоизлучения медленными магнитозвуковыми волнами, захваченными в филаментированной вспышечной петле.

МЕТОД ОЦЕНКИ ПРОСТРАНСТВЕННОГО ПЕРИОДА ЭНЕРГОВЫДЕЛЕНИЯ В СОЛНЕЧНЫХ ВСПЫШКАХ

Леденцов Л.С.
ПАЖ Том: 49Номер: 11 Год: **2023** Страницы: 819-828

С целью анализа современных спутниковых наблюдений аркад вспышечных корональных петель предложен метод оценки пространственного периода энерговыделения в солнечных вспышках. Метод основывается на применении анализа Фурье к разностным изображениям вспышечных аркад в далеком ультрафиолетовом диапазоне. Работа метода продемонстрирована на примере наблюдения Бастильской вспышки с космического аппарата TRACE в канале 171 Å. Среднее значение пространственного периода энерговыделения в Бастильской вспышке, определенное предложенным методом, составляет 5–8 Мм, что хорошо согласуется со сценарием развития тепловой неустойчивости предвспышечного токового слоя в солнечных вспышках.

ТЕПЛОВАЯ НЕУСТОЙЧИВОСТЬ ПЕРЕСОЕДИНЯЮЩЕГО ТОКОВОГО СЛОЯ В СОЛНЕЧНЫХ ВСПЫШКАХ

ЛЕДЕНЦОВ Л.С.1, СОМОВ Б.В.

ПАЖ Том: 42 Номер: 12 Год: **2016** Страницы: 925

С целью интерпретации современных спутниковых наблюдений последовательного увеличения яркости корональных петель в солнечных вспышках мы решили задачу об устойчивости малых продольных возмущений однородного пересоединяющего токового слоя. В рамках магнитогидродинамического приближения показано, что условием неустойчивости служит эффективное подавление теплопроводности плазмы возмущением магнитного поля внутри слоя. Неустойчивость в линейной фазе нарастет за характерное время лучистого охлаждения плазмы. В результате неустойчивости в токовом слое может образовываться периодическая структура холодных и горячих волокон, расположенных поперек направления электрического тока. Предлагаемый механизм тепловой неустойчивости пересоединяющего токового слоя может быть полезен для объяснения последовательного увеличения яркости, “поджига”, вспышечных петель в солнечных вспышках.

КАТАЛОГ ЖЕСТКИХ РЕНТГЕНОВСКИХ ВСПЫШЕК НА СОЛНЦЕ, ЗАРЕГИСТРИРОВАННЫХ С ОКОЛОМАРСИАНСКОЙ ОРБИТЫ MARS ODYSSEY/HEND В 2001-2016 ГГ

АЖ Том: 94Номер: 9 Год: **2017** Страницы: 778-792

Изучение нестационарных процессов на Солнце представляет большой интерес, и в последние годы многоволновые наблюдения излучения и регистрация магнитных полей проводятся как наземными телескопами, так и несколькими специализированными космическими аппаратами на околоземных орбитах. Однако получение новой надежной информации о жестком рентгеновском излучении остается востребованным, особенно, если соответствующие космические аппараты обеспечивают дополнительную информацию, например, при наблюдениях вспышек с иных направлений, отличающихся от направления Солнце-Земля. В статье представлен каталог мощных солнечных вспышек, зарегистрированных прибором High Energy Neutron Detector(HEND), разработанным в Институте космических исследований РАН. Прибор HEND установлен на космическом аппарате "2001 Mars Odyssey", успешно работал при полете к Марсу и в настоящее время функционирует на околомарсианской орбите. Помимо нейтронов, аппаратура HEND чувствительна к жесткому рентгеновскому (до 300 кэВ) и гамма-излучению (выше 300 кэВ). Это излучение регистрируется двумя сцинтилляторами: внешний сцинтиллятор регистрирует фотоны с энергиями выше 40 кэВ, внутренний - свыше 200 кэВ. При создании каталога проведена новая процедура калибровки данных. Кратко обсуждаются методы калибровки внешнего детектора. Для 60 наиболее мощных солнечных вспышек на видимой с Земли и обратной сторонах Солнца приведены временные профили излучения, суммированные по всем каналам рентгеновского, а в некоторых случаях и гамма-диапазонов, спектры и характеристики их степенной аппроксимации. Кратко обсуждаются результаты прежних работ по изучению Солнца с аппаратурой HEND и возможности дальнейшего использования этих данных.

НАБЛЮДАТЕЛЬНЫЕ СВИДЕТЕЛЬСТВА СВЯЗИ ВСПЛЫТИЯ МАГНИТНЫХ ПОЛЕЙ, ТОКОВ И СОЛНЕЧНЫХ ВСПЫШЕК 10 МАЯ 2012 Г.

М. А. **Лившиц**,1, * И. Ю. Григорьева,2, ** И. И. Мышьяков,3, *** Г. В. Руденко

АЖ Том: 93 Номер: 10 Страницы: 907 **2016**

Мы проанализировали многоволновые наблюдения и данные о магнитном поле солнечной вспышки **10 мая 2012** г. (04:18 UT). Было зарегистрировано обращение знака сигнала в измерениях магнитного поля вдоль луча зрения в тени небольшого пятна. Этот эффект, по крайней мере, частично, связан со всплытием нового магнитного поля. Практически одновременно с этим, произошел всплеск жесткого рентгеновского излучения, и возникла волна в диапазонах вакуумного ультрафиолета (ВУФ) – «солнцетрясение», связанная с воздействием

возмущения в области энерговыделения на фотосферу. В начале события зарегистрировано появление вспышки типа "сигмоид», но она не распространилась, как обычно, вдоль нейтральной линии. По данным о полном векторе (SDO/HMI) была проведена экстраполяция магнитных полей активной области (АО) 11476 в корону и получено распределение вертикальных токов jz на фотосфере. Известно, что при изучении распределения токов во всей АО, связь между ними и возникновением вспышек очень сложная. В данном случае мы подтвердили, что ожидаемая "идеальная» связь и изменение системы токов до и после вспышки, описанная, например, в работе Шарыкина и Косовичева, реализуются только в области сигмоида. Проведено сравнение результатов с наблюдениями двух вспышек этой АО в этот день, одна из которых имела другой тип, а другая – аналогична исследуемой. Эти результаты – аргумент в пользу того, что формирование и выброс крупномасштабных замагниченных жгутов в сигмоидных вспышках связаны с влиянием сдвиговых движений в фотосфере и выносом спиральности в магнитной трубке и дальнейшим развитием неустойчивости тороидального плазменного шнура.

Связь нетепловых и газодинамических процессов в мощных солнечных вспышках

Лившиц М.А.1, Кашапова Л.К.

Геом. и аэрон. №7 **2012**

Связь между газодинамическими процессами и ускорением частиц иллюстрируется на трех примерах. Во вспышке **6 июля 2006** г наблюдения позволяют убедиться в реализации процесса взрывного испарения хромосферы в импульсной фазе. Кроме того, связанный с этой вспышкой СМЕ отражает процесс первичного выделения энергии. В мощной лимбовой вспышке **14 июля 2005** г СМЕ, наблюдающийся во внешних слоях короны, вероятно, является следствием неоднократного энерговыделения и выбросов плазмы. Об этом, по-видимому, свидетельствует дополнительное излучение в дециметровом диапазоне, характерное обычно для постэруптивных процессов. Один пример слабой вспышки на фазе затухания мощного явления **15 апреля 2001** г также сопровождается дециметровым всплеском.

МОЩНЫЕ НЕСТАЦИОНАРНЫЕ ПРОЦЕССЫ НА СОЛНЦЕ: ПРОСТРАНСТВЕННО-ВРЕМЕННАЯ СТРУКТУРА И ЭФФЕКТИВНОЕ УСКОРЕНИЕ ЧАСТИЦ

ЛИВШИЦ М.А.

Солнечно=земн. Физика Номер: 12-1 Год: **2008** Страницы: 3-4

Обобщаются сведения о высокоэнергичных процессах на Солнце. Уточняется классификация вспышек и обосновывается точка зрения о том, что корональный выброс массы и собственно вспышка являются проявлениями одного и того же общего процесса, по крайней мере в случае самых мощных событий. Затем проанализированы данные об ускорении электронов (RHESSI, «Марс-Одиссей») и протонов. Показано, что существование двух пиков жесткого рентгеновского излучения, разнесенных на 10-20 мин, и эволюция спектров этого излучения свидетельствуют о двух эпизодах ускорения. Проанализированы спектры 172 протонных возрастаний, отождествляемых с отношением потоков протонов с энергиями более 10 и 100 МэВ около Земли. Оказалось, эти спектры остаются практически теми же самыми у большинства мощных вспышек при благоприят-ных условиях выхода из короны и распространения частиц в межпланетном пространстве. Это является аргументом в пользу инвариантности основных черт эффективного ускорения частиц в мощных событиях. Этот процесс происходит на взрывной фазе вспышки, и его источник располагается низко, непосредственно над хромосферой, в области, примыкающей к пятнам. Имеются основания полагать, что при этом происходит быстрое одновременное ускорение электронов и протонов с захватом некоторой доли частиц в магнитные ловушки. Существует, однако, небольшое количество событий, в которых уже на постэ-руптивной фазе развития вспышки из короны выходит дополнительное количество протонов с энергией до 10-30 МэВ. Ана-лиз этих случаев с более мягким спектром частиц скорее свидетельствует о дополнительном ускорении частиц на корональ-ных высотах (около 30 000 км), чем об облегчении выхода частиц из ловушек. В статье оценен вклад потока протонов с энер-гией более 10 МэВ, возникающего на постэруптивной фазе вспышки, в общий поток частиц в максимуме протонного возрас-тания и кратко обсуждаются возможные механизмы ускорения частиц на значительных высотах в короне.

Рентгеновское и гамма-излучение солнечных вспышек **Review**

УФН **2020** **File**

Приводится краткий обзор современного состояния и актуальных проблем физики солнечных вспышек, которые можно прояснить методами рентгеновской и гамма-астрономии. Подробно рассмотрены несколько вопросов, среди которых – условия и механизмы ускорения электронов во вспышке, распределение вспышечной энергии между тепловой и нетепловой компонентами, гамма-излучение вспышек и его динамика,

пространственная структура источников в рентгеновском и гамма-диапазонах. В данном контексте обсуждаются последние результаты российско-американского эксперимента Konus-Wind, отметившего в 2019 г. 25-летие непрерывной работы в космосе.

ПРОЯВЛЕНИЯ НАГРЕВА В НАЧАЛЕ ВСПЫШКИ 29 ИЮНЯ 2012 Г

МЕШАЛКИНА Н.С.[1], **АЛТЫНЦЕВ А.Т.**[1]

СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том: 10 Номер: 3 Год: 2024 Страницы: 13-20

Анализ данных GOES для вспышки SOL2012-06-29T04:09 класса C4.6 показывает тепловой характер энерговыделения в течение нескольких минут перед импульсной стадией. Нагрев плазмы до температур выше 10 МК приводит к появлению струй плазмы вдоль открытых силовых линий и в больших петлях. В работе исследуется взаимосвязь нагретой плазмы со вспышечной структурой и ее динамикой по данным наблюдений в рентгеновском, крайнем ультрафиолетовом и радиоволновом диапазонах. Особое внимание привлекает обнаружение на динамических спектрах тонких временных структур узкополосного радиоизлучения до и после импульсной стадии вспышки. На начальной стадии наблюдаются широкополосные импульсы в дециметровом диапазоне, которые можно связать с формированием тепловых фронтов в струях. Серия сверхъярких всплесков в сантиметровом диапазоне, характеризующихся частотным дрейфом, наблюдается после окончания импульсного энерговыделения в ядре вспышки. По данным Сибирского солнечного радиотелескопа (5.7 ГГц) было установлено, что источники этих субсекундных всплесков находятся в удаленном основании крупномасштабной вспышечной петли.

The aim of the thesis is the study of properties of solar flares via reconstruction of energy distributions of accelerated/heated electrons, diagnostics of flare plasma based on EUV and X-ray observations, as well as the estimation of the thermal balance within the "standard" flare model. The X-ray data were obtained from the Ramaty High Energy Solar Spectroscopic Imager (RHESSI) and the Russian solar observatory KORONAS-F (IRIS experiment). The EUV data were obtained from the Solar Dynamics Observatory / Atmospheric Imaging Assembly (SDO/AIA). In the first chapter a new technique is presented, which allowed to determine at first the photon spectra based on the KORONAS-F/IRIS observations and then to reconstruct the energy spectra of the emitting electrons using the random search method and the Tikhonov regularization method. In the second chapter the developed technique of simultaneously fitting the model differential emission measure functions (DEM) to RHESSI and SDO/AIA data is introduced, which allowed to infer the electron distribution from X-ray and EUV observations. The proposed method allows to reconstruct of both the spectra of accelerated/heated electrons and the basic parameters of the flare plasma, such as temperature, emission measure, total electron number density, and flare energy. In addition, the analytical function suitable for both DEM analysis and mean electron flux spectra in flares has been developed and applied, as well as kappa-distribution in the form of differential emission measure. The thermal balance and hard X-ray emission of coronal loops from different flare regions within the "standard" flare model is considered in the third chapter. This thesis is based on the next papers: Motorina et al., TePh, 2012, Motorina & Kontar, Ge&Ae, 2015, Battaglia et al., ApJ, 2015, Motorina et al., TePh, 2016, Tsap et al., Ge&Ae, 2016. **15 апреля 2002, 23 июля 2002, 26 июля 2002, 19 января 2005, 23.08.2005, 14 Aug 2010, 09.11.2013, 8 мая 2015**

ИССЛЕДОВАНИЕ ПРОЦЕССОВ ОХЛАЖДЕНИЯ НА ФАЗЕ СПАДА СОЛНЕЧНЫХ И ЗВЕЗДНЫХ ВСПЫШЕК

МОТЫК И.Д.[*1], **КАШАПОВА Л.К.**[*1]

АЖ Том: 99Номер: 11 Год: **2022** Страницы: 1008-1015

Работа посвящена исследованию процессов охлаждения и потери энергии на фазе спада вспышек. Именно во время этой фазы одновременно с процессами охлаждения и потери энергии могут возникать различные волновые процессы, приводящие к дополнительному энерговыделению, что делает ее интересным объектом исследования. Считается, что охлаждение вспышечной плазмы на фазе спада происходит за счет двух процессов – теплопроводности и потерь за счет излучения. В начале доминирует процесс теплопроводности, а затем наступает полное доминирование процесса потерь за счет излучения. Мы провели анализ средних временн{\cyrery}'х профилей солнечных вспышек в полосах SDO/AIA 304, 1600 и 1700 Å и среднего временно́го профиля вспышки в белом свете карлика спектрального класса M4. Для описания временн{\cyrery}'х профилей была предложена аналитическая модель, основанная на известных формулах поведения температуры. Результаты анализа с помощью разработанной модели показали, что доминирование процесса охлаждения за счет потерь на излучение для полосы SDO/AIA 304 Å наступает раньше, чем это определено в стандартной модели. Для других спектральных полос процесс потерь за счет излучения практически все время доминирует на фазе спада. Сравнение результатов, полученных для вспышек на красном карлике M4 и в солнечных вспышках, показало, что процессы охлаждения в солнечных и звездных вспышках схожи и зависят от структуры атмосферы. Предложенная аналитическая модель может использоваться для разделения классической формы затухания и накладывающихся на нее процессов энерговыделения.

ЭВОЛЮЦИЯ ХАРАКТЕРИСТИК ВЕРТИКАЛЬНОГО ЭЛЕКТРИЧЕСКОГО ТОКА И МАГНИТНОГО ПОЛЯ В АКТИВНЫХ ОБЛАСТЯХ СОЛНЦА И ИХ СВЯЗЬ С МОЩНЫМИ ВСПЫШКАМИ

Нечаева А.Б., Зимовец И.В., Зубик В.С., Шарыкин И.Н.

ГиА Том: 64Номер: 2 Год: 2024 Страницы: 175-198

Изучение эволюции магнитного поля и электрических токов в активных областях Солнца на длительном интервале времени представляет интерес для понимания процессов накопления и выделения энергии в них, приводящих к разнообразным явлениям, оказывающим влияние на космическую погоду. В этой работе на основе фотосферных векторных магнитограмм инструмента Helioseismic and Magnetic Imager на борту Solar Dynamics Observatory был проведен анализ эволюции ряда характеристик магнитного поля и вертикального электрического тока в трех активных областях 11158, 11675 и 12673, произведших вспышки классов M и X, на протяжении времени от их зарождения в восточном полушарии, во время прохождения по солнечному диску и до исчезновения вблизи западного лимба с шагом 2 часа. Рассматриваемые характеристики включали в себя: показатель степенной функции плотности вероятности абсолютного значения плотности вертикального электрического тока, максимум абсолютного значения плотности вертикального тока, знаковый и беззнаковый вертикальный ток, беззнаковые вертикальный и горизонтальный магнитные потоки, энергия нелинейного бессилового и потенциального магнитного поля, свободная магнитная энергия, а также количество островов с сильными вертикальными токами. Найдены некоторые закономерности в поведении рассматриваемых характеристик при эволюции активных областей, в частности относительно возникновения вспышек. Рассчитаны коэффициенты корреляции между парами всех рассматриваемых характеристик. Дополнительно, показана перспективность подхода М. Ашвандена для прогнозирования максимального рентгеновского класса вспышки на основе вычисления энергии потенциального магнитного поля в активных областях. Полученные результаты могут использоваться при прогнозировании мощных солнечных вспышек.

Evolution of the Photospheric Magnetic Field and Coronal Null Points before Solar Flares

А. В. **Орешина**, Б. В. Сомов,

Письма в АЖ, **35**, 234-240 (**2009**). (See ADS)

Based on a topological model for the magnetic field of a solar active region (AR), we suggest a criterion for the existence of magnetic null points on the separators in the corona. With the problem of predicting solar flares in mind, we have revealed a model parameter whose decrease means that the AR evolves toward a major eruptive flare. We analyze the magnetic field evolution for AR 9077 within two days before the Bastille Day flare on **July 14, 2000.** The coronal conditions are shown to have become more favorable for magnetic reconnection, which led to a 3B/X5.7 eruptive flare.

Analytical Description of Charged Particle Motion in a Reconnecting Current Sheet

А. В. **Орешина**, Б. В. Сомов,

Письма в АЖ, **35**, 221-233 (**2009**). (See ADS)

Abstract—We have obtained an analytical solution to the equation of motion in the guiding center approximation for nonrelativistic charged particles in a reconnecting current sheet with a three-component magnetic field. Given the electric field attributable to magnetic reconnection, the solution describes stable and unstable three-dimensional particle orbits. We have found the domain of input parameters at which the motion is stable. A physical interpretation of the processes affecting the stability of the motion is given. Charge separation is shown to take place in the sheet during the motion: oppositely charged particles are localized mostly in different regions of the current sheet. A formula is derived for the particle energy in stable and unstable orbits. The results obtained by numerical and analytical methods are compared.

ФИЗИЧЕСКИЙ МЕХАНИЗМ СОЛНЕЧНОЙ ВСПЫШКИ, ОСНОВАННЫЙ НА НАКОПЛЕНИИ ЭНЕРГИИ В МАГНИТНОМ ПОЛЕ ТОКОВОГО СЛОЯ В СОЛНЕЧНОЙ КОРОНЕ

Подгорный И.М., Подгорный А.И.

КОСМИЧЕСКИЕ ИССЛЕДОВАНИЯ Том: 57Номер: 6 Год: **2019** Страницы: 403-422

DOI: 10.1134/S0023420619060062

Во время солнечной вспышки за несколько десятков минут освобождается магнитная энергия ~1032 эрг. Неизменность магнитного поля на солнечной поверхности во время вспышек доказывает появление вспышки в короне. Анализ динамики электронной температуры солнечной атмосферы дает независимое доказательство коронального происхождения вспышки. Появление вспышки в короне объясняется освобождением энергии, накопленной в магнитном поле токового слоя. Для исследования вспышечной ситуации проводилось численное МГД моделирование над реальной активной областью. Результаты моделирования показали появление токового слоя, положение которого совпадает с положением наблюдаемого источника теплового рентгеновского излучения. Разработана методика проведения расчетов в реальном масштабе времени. Основываясь на механизме освобождения энергии в токовом слое предложена электродинамическая модель солнечной вспышки, объясняющая ее основные наблюдаемые проявления. Источники жесткого рентгеновского излучения появляются вследствие торможения в нижних плотных слоях солнечной атмосферы пучков электронов, ускоренных в продольных токах. Ускорение солнечных космических лучей происходит в токовом слое электрическим полем $E = -V \times B/c$, а не в ударных волнах.

ГЕНЕРАЦИЯ ТОКОВОГО СЛОЯ В КОРОНЕ, АККУМУЛИРУЮЩЕГО ЭНЕРГИЮ ДЛЯ ВСПЫШКИ

Подгорный1 А.И., Подгорный2 И.М.

Астрономия-**2018** Том 2 Солнечно-земная физика – современное состояние и перспективы с. 190
http://www.izmiran.ru/library/eaas2018/eaas-2018-2.pdf
The flare mechanism based on the energy accumulation in the magnetic field of a current sheet explains the slow energy accumulation in corona and then its explosive release. The position of the current sheet obtained by numerical MHD simulation above a real active region coincides with the position of source of flare thermal X-ray emission. Flare energy accumulation is demonstrated by positions of 2D magnetic field lines in the plane perpendicular to the magnetic vector in the point of the current density maximum.

УСКОРЕНИЕ СОЛНЕЧНЫХ КОСМИЧЕСКИХ ЛУЧЕЙ ВО ВСПЫШЕЧНОМ ТОКОВОМ СЛОЕ И ИХ РАСПРОСТРАНЕНИЕ В МЕЖПЛАНЕТНОМ ПРОСТРАНСТВЕ

ПОДГОРНЫЙ А.И.1, ПОДГОРНЫЙ И.М.
АЖ Том: 92Номер: 9 Год: **2015** Страницы: 767
Анализ данных космических аппаратов GOES показал, что быстрая компонента протонов высокой энергии приходит к Земле от вспышки, происшедшей на западной части солнечного диска, с пролетным временем, а запаздывающая компонента начинает регистрироваться через несколько часов. Ускорение всех протонов происходит во вспышке единым механизмом. Частицы быстрой компоненты распространяются вдоль магнитных линий спирали Архимеда, которые связывают вспышку с Землей. Быстрая компонента не регистрируется на Земле от вспышек, происшедших на восточной части солнечного диска. Частицы от таких вспышек не попадают на линию магнитного поля, связывающую вспышку с Землей. Эти частицы достигают Земли, перемещаясь поперек межпланетного магнитного поля. Захваченные магнитным полем частицы переносятся солнечным ветром благодаря вмороженности межпланетного магнитного поля в плазму и диффундируют поперек поля. Длительность запаздывающей компоненты достигает нескольких суток.

ДИНАМИКА МАГНИТНОГО ПОЛЯ АКТИВНЫХ ОБЛАСТЕЙ В ПРЕДВСПЫШЕЧНОМ СОСТОЯНИИ И ВО ВРЕМЯ СОЛНЕЧНЫХ ВСПЫШЕК

ПОДГОРНЫЙ А.И.1, ПОДГОРНЫЙ И.М.2, МЕШАЛКИНА Н.С.
АЖ Том: 92 Номер: 8 Год: **2015** Страницы: 669
Проведен анализ вспышечной активности активных областей Солнца NOAA **10656, 11429, 10930**. Показано сохранение во время вспышки не только магнитного потока с точностью до 2%, но и распределения магнитного поля в активной области. Анализ подтвердил ранее опубликованные авторами выводы о возникновении больших (класса X) солнечных вспышек при магнитных потоках активных областей больших 10^{22} Мкс. Для возникновения большой вспышки недостаточно только большого магнитного потока активной области. Показано, что распределение поля активной области перед вспышкой должно иметь сложную структуру типа $\beta\gamma\delta$. Такие активные области могут создавать в короне особые линии магнитного поля, в окрестности которых формируются токовые слои. Над простыми, дипольного типа ативными областями магнитные линии имеют арочную форму, особые линии отсутствуют, и токовые слои образоваться не могут. Дипольного типа активные области не производят вспышек. Дисбаланс магнитного потока активной области и скорость нарастания магнитного потока не являются признаками появления вспышки.

НАКОПЛЕНИЕ МАГНИТНОЙ ЭНЕРГИИ В КОРОНАЛЬНОМ ТОКОВОМ СЛОЕ В ПРЕДВСПЫШЕЧНОМ СОСТОЯНИИ АКТИВНОЙ ОБЛАСТИ СОЛНЦА

http://plasma2014.cosmos.ru/presentations
1. Необходимое условие возникновения большой вспышки (класса X) – возрастание магнитного потока АО Ф > 10^22 Макс.
2. Вспышки происходят над АО со сложной конфигурация магнитного поля. Простые биполярные АО вспышек не производят.
3. Распределение B в АО сохраняется во время большинства в том числе и больших вспышек.
4. Полученные результаты показывают, что энергия вспышки выделяется высоко в короне, и токи, ответственные за аккумулированную для вспышки энергию локализованы в короне. Такой токовой системой может быть **токовый слой**.

ВСПЫШЕЧНОЕ ИЗЛУЧЕНИЕ СОБЫТИЯ 04.05.2022 И ЕГО МИЛЛИМЕТРОВАЯ КОМПОНЕНТА

ГиА Том: 63Номер: 5 Год: **2023** Страницы: 561-569

На основе наблюдений на радиотелескопе РТ-7.5 МГТУ им. Н.Э. Баумана на волне 3.2 мм (93 ГГц), а также других (Сибирского радиогелиографа, Solar Dynamics Observatory (SDO), радиообсерватории Metsähovi) наземных и космических инструментах исследовано происхождение миллиметрового излучения солнечной вспышки SOL**2022-05-04T08**:45 рентгеновского класса M5.7. Анализ временны́х профилей излучения в рентгеновском и сантиметровом диапазонах показал, что миллиметровый источник излучения едва ли связан с горячей (5 × 105–107 K) корональной плазмой. Об этом также свидетельствует оценка суб-ТГц потока излучающей горячей плазмы по данным AIA/SDO, который оказался значительно меньше наблюдаемых значений. Получены указания о развитии тепловой неустойчивости во вспышечных ультрафиолетовых петлях. Обосновывается связь миллиметровой компоненты вспышки с тепловым источником в хромосфере Солнца.

МАГНИТНЫЕ ЖГУТЫ С ТОКОВОЙ ОБОЛОЧКОЙ КАК ВСПЫШЕЧНЫЕ СОЛНЕЧНЫЕ СТРУКТУРЫ

СОЛОВЬЕВ А.А.[1], **КИРИЧЕК Е.А.**[1]

ПАЖ Том: 50 Номер: 9 Год: 2024 Страницы: 616-624

Модели бессиловых магнитных жгутов различаются по их внутренней токовой структуре: в одном случае сильные электрические токи сосредоточены на оси жгута, а в другом - в тонкой периферической оболочке. В настоящей работе проводится сравнительный анализ трех новых моделей второго типа. Все бессиловые магнитные жгуты имеют одно общее физическое свойство, приводящее к вспышечному энерговыделению: при выходе вершины петельного жгута в хромосферу и корону Солнца, внешнее давление, удерживающее жгут от бокового расширения, неуклонно падает; при некотором критическом его уменьшении продольное магнитное поле жгута стремится к нулю на поверхности смены знака токов. При этом азимутальный ток jϕ(r) и бессиловой параметр α(r), приближаясь к разрыву на этой поверхности, начинают неограниченно расти вблизи нее. Это приводит к возбуждению плазменной ионно-звуковой неустойчивости, резкому понижению проводимости плазмы, быстрой диссипации магнитной энергии в жгуте и генерации супер-дрейсеровских электрических полей. Совокупность таких процессов в сочетании с эффектом Паркера - выравниванием с альвеновской скоростью вращательного момента (torque) вдоль оси жгута - хорошо описывает основные проявления солнечной вспышки.

МАГНИТОГИДРОСТАТИКА ВЕРТИКАЛЬНОЙ СИЛОВОЙ ТРУБКИ В СОЛНЕЧНОЙ АТМОСФЕРЕ: КОРОНАЛЬНЫЕ ПЕТЛИ, МОДЕЛЬ КОЛЬЦЕВОГО ВСПЫШЕЧНОГО ВОЛОКНА

СОЛОВЬЕВ А.А.1, КИРИЧЕК Е.А

ПАЖ 41(5) 234 **2015**

Магнитогидростатическая теория скрученной магнитной силовой трубки (жгута), погруженной в реалистическую солнечную атмосферу, впервые представлена в замкнутой аналитической форме. Выведены общие формулы, позволяющие рассчитывать равновесные распределения плотности, давления и температуры плазмы внутри аксиальносимметричной вертикальной силовой трубки по ее магнитной структуре, которая предполагается известной (заданной). Построена аналитическая модель свободной от магнитного поля внешней гидростатической среды - солнечной атмосферы, в которой использован температурный профиль полуэмпирической табличной модели Авретта [illegible] формул рассчитано распределение параметров плазмы в скрученной магнитной силовой трубке при небольших отклонениях ее внутренней магнитной структуры от бессиловой. Поперечное сечение трубки не меняется с высотой, поэтому полученную модель можно применять для описания вертикальных частей корональных петель. Найдено, что при превышении скрученности поля над бессиловым состоянием плотность плазмы в магнитной трубке растет, а при уменьшении скрученности поля по сравнению с бессиловым уровнем - падает. Это свойство скрученной магнитной трубки имеет принципиальное значение для обоснования механизма вспышечного энерговыделения в магнитных жгутах. Рассмотрена модель вспышки в кольцевой хромосферной конфигурации.

РАСШИРЕНИЕ ИСТОЧНИКА МЯГКОГО РЕНТГЕНОВСКОГО ИЗЛУЧЕНИЯ И ‘‘МАГНИТНАЯ ДЕТОНАЦИЯ’’ В СОЛНЕЧНЫХ ВСПЫШКАХ

Струминский А.Б., Садовский А.М., Григорьева И.Ю.

ПАЖ Том: 49Номер: 11 Год: 2023 Страницы: 806-818
DOI: 10.31857/S0320010823110086

Регистрация радиоизлучения солнечных вспышек на частотах ниже ~2 ГГц позволяет делать верхние оценки характерного размера источника мягкого рентгеновского (SXR) излучения $L(t)$ в предположении, что плотность $n(t)$ определяется плазменной частотой ν_p. Если SXR источник с большей плотностью находится внутри радиоисточника, то размер SXR источника будет$L(t)<(EM(t)/2n(t)^2)^{1/3}$, где $EM(t)$ — мера эмиссии. Для трех вспышек (C7.2 **22.12.2009**), (M2.9 **06.07.2012**) и (X1.1 **06.07.2012**) рассчитываются скорости расширения SXR источника $V(t)\sim dL(t)/dt$, которые сравниваются с оценками скорости звука и альвеновской скорости. Под “магнитной детонацией” мы понимаем процесс распространения магнитного пересоединения со сверхзвуковой скоростью в эруптивных вспышках. “Магнитная детонация” и последующий корональный выброс массы (КВМ) реализовывались во вспышках (C7.2 22.12.2009) и (X1.1 06.07.2012), в которых сверхзвуковые и сверхальвеновские скорости достигались, если плотность SXR источника была ниже 2.1×10^9 и 7.4×10^8 см$^{-3}$ (ν_p<410 и <245 МГц) соответственно. “Магнитной детонации” и КВМ не было во вспышке (M2.9 06.07.2012), частоты радиоизлучения которой были только выше 1415 МГц ($n>2.5\times10^{10}$ см$^{-3}$). Для “магнитной детонации” во вспышке (X1.1 06.07.2012) сделаны оценки величин магнитного поля, напряженности электрического поля пересоединения, потока плазмы и массы КВМ.

СВЯЗЬ МЕЖДУ ДЛИТЕЛЬНОСТЬЮ И ВЕЛИЧИНОЙ УСКОРЕНИЯ КОРОНАЛЬНЫХ ВЫБРОСОВ МАССЫ

Струминский А. Б., Григорьева И. Ю., Логачев Ю. И., Садовский А. М.

ГЕОМАГНЕТИЗМ И АЭРОНОМИЯ Том: 61Номер: 6 Год: 2021 Страницы: 683-693
DOI: 10.31857/S001679402105014X

Исследуется вопрос о том, какая последовательность процессов на Солнце приводит к положительной обратной связи между движением и нагревом плазмы, ускорением электронов, а в итоге, к формированию корональных выбросов массы, ударных волн и ускорению протонов. Для этого проведен анализ солнечных событий, связанных с тремя импульсными вспышками: M2.9 **6 июля 2012** г., X2.2 и X9.3 **6 сентября 2017** г. и одной длительной вспышкой M3.7 **7 марта 2011** г. Электроны ускорялись до релятивистских энергий во всех четырех вспышках, но две последние сопровождались корональными выбросами массы, ударными волнами и ускорением протонов с энергией >300 МэВ. Найдено два отличия вспышек без корональных выбросов массы. Первое отличие – были ограничены высотой, которая характерна для радиоизлучения 1415 МГц (верхняя хромосфера). Второе отличие – максимум меры эмиссии в них запаздывал относительно максимума температуры на время менее 2 мин. Если считать, что вспышка и корональные выбросы массы черпают энергию из одного резервуара, то время запаздывания можно рассматривать как характерное время ускорения корональных выбросов массы – существование дополнительного оттока энергии. Из теоретических оценок максимальной величины ускорения корональных выбросов массы, значений их минимальной и максимальной скорости следует возможный разброс времени ускорения корональных выбросов массы. Сравнения оценок и наблюдений показывает, что необходимая длительность ускорения для реализации межпланетного коронального выброса массы была достигнута в событиях M3.7 7 марта 2011 г. и X9.3 6 сентября 2017 г.

ПРОГНОЗИРОВАНИЕ СОЛНЕЧНЫХ ВСПЫШЕК И ФОНОВЫХ ПОТОКОВ РЕНТГЕНОВСКОГО ИЗЛУЧЕНИЯ ПО ДАННЫМ СИНОПТИЧЕСКИХ НАЗЕМНЫХ НАБЛЮДЕНИЙ С ПОМОЩЬЮ МЕТОДОВ МАШИННОГО ОБУЧЕНИЯ

Косм. Исслед. Том: 58Номер: 6 Год: **2020** Страницы: 479-484

В работе представлены модели машинного обучения для прогнозирования мощных солнечных вспышек и фоновых потоков рентгеновского излучения в диапазоне 1–8 Å. Для прогнозирования солнечных вспышек на следующий день использовалась информация о текущем уровне солнечной активности, получаемая с наземных синоптических наблюдений, таких как характеристики солнечных пятен, потоки радиоизлучения на длинах волн 10.7 и 5 см, а также уровень фонового потока и количества солнечных вспышек текущего дня, полученных со спутника GOES. Для прогнозирования фоновых потоков рентгеновского излучения использовались только данные наземных телескопов. Показана высокая эффективность прогноза на следующий день. Нейронные сеть обучалась на данных, доступных с 2002 г.

ГАММА-ВСПЫШКИ И КОМПЛЕКСЫ АКТИВНОСТИ НА СОЛНЦЕ

ТОМОЗОВ В.М.1, ЯЗЕВ С.А.*1, ИСАЕВА Е.С.

АЖ Том: 97Номер: 8 Год: **2020** Страницы: 695-704

Проведен анализ мощных вспышечных событий из каталога Share и др. с длительной фазой гамма- излучения с целью объяснения особенностей импульсной и длительных фаз таких вспышек и выявления их связи с комплексами активности и корональными дырами. Показано, что 74% таких событий оказались тесно связанными с комплексами активности. Качественно продемонстрирована связь процессов ускорения частиц в ходе развития вспышки с изменениями магнитной топологии во вспышечной области и с эволюцией

коронального выброса массы. Обсуждаются возможная связь корональных дыр с комплексами активности и роль “обменного” пересоединения в этих процессах.

РАСПРЕДЕЛЕНИЕ ЭНЕРГИИ НАНОВСПЫШЕК В МИНИМУМЕ И НА ФАЗЕ РОСТА 24 СОЛНЕЧНОГО ЦИКЛА

А. С. **Ульянов**, С. А. Богачёв, А. А. Рева, А. С. Кириченко, И. П. Лобода

ПАЖ Том: 45Номер: 4 Год: **2019** Страницы: 290-300

Представлено распределение по энергиям слабых эмиссионных событий (нановспышек) в короне Солнца, измеренное для двух стадий 24-го солнечного цикла, - в минимуме и в начале роста солнечной активности. Исследование проведено по данным двух инструментов, ТЕСИС/КОРОНАС-ФОТОН (для минимума цикла; 2009 г.) и AIA/SDO (фаза роста, 2010–2011 гг.), для которых мы применили единый алгоритм детектирования событий. Собранная нами база составляет более 10^5вспышек. Для всех событий мы измерили поток излучения в ВУФ-диапазоне спектра и определили тепловую энергию, которая находилась в диапазоне от 10^{23} до 10^{26} эрг и была распределенной по степенному закону: $N(E)dE \sim N^{-\alpha}dE$ ...

СТРУКТУРА И ФИЗИЧЕСКИЕ УСЛОВИЯ В НА-ПЕТЛЯХ ВСПЫШКИ БАЛЛА М7.7

ФИРСТОВА Н.М.1, ПОЛЯКОВ В.И.

ПАЖ Том: 43Номер: 11 Год: **2017** Страницы: 845-856

Вспышка балла М7.7 **19 июля 2012** г. представляет собой наиболее яркий пример вспышки "Масуда" с четко определенным вторым рентгеновским источником выше вершины петли. Поведение системы петель, сопровождающих эту вспышку, подробно исследовано Лиу и др. по данным Reuven Ramaty High Energy Solar Spectroscopic Imager (RHESSI) и Solar Dynamics Observatory/Atmospheric Imaging Assembly (SDO/AIA). Мы провели на Большом солнечном вакуумном телескопе (БСВТ) спектральные и фильтровые наблюдения На-петель в этой вспышке. Основные физические параметры в петлях этой особенной вспышки в целом совпадают с известными данными в На-петлях. Однако электронная концентрация 1011 см-3 и интегральная интенсивность 12% непрерывного излучения центра солнечного диска являются довольно высокими, если учесть, что наблюдения получены почти через 3 ч после начала вспышки. Проведена оценка скорости подъема аркады петель (^3.5 км/с) и разности высот между На-петлями и петлями в 94 А, которая составляет ^2 х 104 км.

СВЯЗЬ МЕЖДУ ПОЯВЛЕНИЕМ ИСТОЧНИКОВ ГАММА-ИЗЛУЧЕНИЯ И УДАРНОЙ ЛИНЕЙНОЙ ПОЛЯРИЗАЦИЕЙ ЛИНИИ Н ВО ВСПЫШКЕ 23 ИЮЛЯ 2002 ГОДА

ФИРСТОВА Н.М.

ПАЖ Том: 41Номер: 10 Год: **2015** Страницы: 642

При спектро-поляриметрических наблюдениях на Большом солнечном вакуумном телескопе вспышки балла 2В/4.8Х **23 июля 2002** г. нами в южной ленте была обнаружена ударная линейная поляризация. Максимальная поляризация превысила 10 . В целом поляризация наблюдалась только в течение 6 мин из почти 2 ч наблюдений этой вспышки. Профили линии Н имели в это время глубокое самообращение в центре. В настоящей работе проведено сопоставление наблюденной на БСВТ с данными Reuven Ramaty High Energy Solar Spectroscopic Imager (RHESSI), где впервые были получены местоположения -излучения. При точном сопоставлении выяснилось, что эффекты в линии Н наблюдались на участке <10, который был расположен между двумя рентгеновскими источниками в южной ленте. В этом же месте, по данным RHESSI, наблюдался источник -излучения, обусловленный потоком высокоэнергичных (1 МэВ) электронов. События в короне и в верхней хромосфере совпадают с наблюденными эффектами в линии Н также и по времени. В работе делается предположение, что два рентгеновских источника представляют собой общее основание южной ветви петли, раздвоенное из-за высыпания высокоэнергичных электронов. Предполагается, что внедрение этих электронов в плотные слои хромосферы могло привести к ударной поляризации и провалу интенсивности в линии Н в южной ленте вспышки в отличие от северной ленты, где наблюдался типичный источник жесткого рентгена с энергией 20 120 кэВ, самообращение в цен

ПОПЕРЕЧНЫЕ ГРАДИЕНТЫ ПРОДОЛЬНОГО МАГНИТНОГО ПОЛЯ В АКТИВНЫХ ОБЛАСТЯХ С РАЗНЫМ УРОВНЕМ ВСПЫШЕЧНОЙ ПРОДУКТИВНОСТИ: РАЗЛИЧНЫЕ ПОДХОДЫ К ВЫЧИСЛЕНИЮ, ДИНАМИКА И ВЕРОЯТНЫЕ КРИТИЧЕСКИЕ ЗНАЧЕНИЯ

ФУРСЯК ЮРИЙ

Изв. КрАО Том: 118Номер: 3 Год: 2022 Страницы: 39-57
https://www.elibrary.ru/download/elibrary_49967263_79839761.pdf

Основной задачей исследования является анализ величины и динамики поперечной составляющей градиента продольного магнитного поля в активных областях (АО) с различным уровнем вспышечной продуктивности. В работе использованы данные о пространственном распределении на уровне фотосферы Солнца Bz-компоненты вектора магнитного поля, предоставляемые инструментом Helioseismic and Magnetic Imager (HMI) на борту Solar Dynamics Observatory (SDO). Для анализа отобраны 13 АО: 6 областей с низкой активностью и 7 с высокой, из них две области с дополнительным всплытием магнитного потока. Мониторинг каждой из областей осуществлялся на протяжении 3–5 суток в пределах 30–35 гелиографических градусов относительно центрального меридиана. Рассмотрены два подхода к вычислению градиента продольного магнитного поля – современный, требующий магнитографических данных высокого пространственного разрешения, и классический. Для каждого подхода определены параметры, характеризующие градиент продольного магнитного поля в АО. Для современного подхода это средняя по АО величина поперечной составляющей градиента продольного магнитного поля $< \nabla \perp Bz >$, для классического подхода – максимальное значение поперечной составляющей градиента продольного магнитного поля совокупности пар пятен в АО ($max(\nabla \perp Bz)$). Динамика выбранных параметров сопоставлена с уровнем вспышечной продуктивности АО. Показано, что: 1. Существуют пороговые значения параметров, характеризующих градиент продольного магнитного поля АО. Для величины $< \nabla \perp Bz >$ критическое значение равно 0.08 Гс км$^{-1}$, а для параметра $max(\nabla \perp Bz)$ – 0.115 Гс км$^{-1}$. 2. Первые мощные вспышки рентгеновских классов M и выше наблюдаются в АО через 23–25 часов после превышения вышеуказанными параметрами соответствующих критических значений.

МОРФОЛОГИЯ, ДИНАМИКА И ОСОБЕННОСТИ МАГНИТНОЙ КОНФИГУРАЦИИ АКТИВНЫХ ОБЛАСТЕЙ ПЕРЕД ВСПЫШКАМИ РЕНТГЕНОВСКОГО КЛАССА X

Фурсяк Ю.А.

Пулково «Солнечная и солнечно-земная физика – **2015**», с.371

We analyzed morphological and evolutionary characteristics of several active regions in the solar cycle 24, that launched at least two or more X-class flares. Transverse gradients of the longitudinal magnetic field, proper motions of sunspots, as well as features of the magnetic configuration of sunspot groups before the powerful flare were investigated. We used data from SDO/HMI (magnetic fields of active regions), X-ray flux data from the spacecraft GOES-15, and information about the magnetic fields of sunspots obtained from the Tower Solar Telescope TST-2 of the Crimean Astrophysical Observatory and the Mt. Wilson 150-foot Solar Telescope. We found that during at least 1–2 days before the launch of the first Xclass flare, the magnetic gradient has to exceed the Severny's critical threshold of 0.1 G/km. **04-08.09.2011, 04-08.03.2012, 09-17.10.2013, 21-27.10.2014**

ТЕМПЕРАТУРА СТОЛКНОВИТЕЛЬНОЙ ПЛАЗМЫ И БЕТАТРОННОЕ УСКОРЕНИЕ КВАЗИТЕПЛОВЫХ ЭЛЕКТРОНОВ В СОЛНЕЧНЫХ ВСПЫШКАХ

ЦАП Ю. Т.[*1], **МЕЛЬНИКОВ В. Ф.**[*2]

ПАЖ Том: 49Номер: 4 Год: **2023** Страницы: 289-298

На основе модели коллапсирующей магнитной ловушки рассмотрено влияние температуры максвелловской вспышечной плазмы на эффективность бетатронного ускорения квазитепловых быстрых электронов в области каспа корональных петель. Показано, что увеличение температуры приводит к резкому росту (на 6–8 порядков) числа квазитепловых электронов, способных преодолеть "барьер кулоновских потерь". Это предполагает необходимость преднагрева фоновой плазмы в области каспа до $\gtrsim$10 МК, за которое может отвечать бетатронный механизм. Обсуждается связь между импульсной фазой вспышечного энерговыделения и рентгеновскими предвестниками солнечных вспышек.

УСКОРЕНИЕ ЭЛЕКТРОНОВ И СУБСЕКУНДНЫЕ ВРЕМЕННЫЕ ЗАДЕРЖКИ ЖЕСТКОГО РЕНТГЕНОВСКОГО ИЗЛУЧЕНИЯ СОЛНЕЧНЫХ ВСПЫШЕК ПО ДАННЫМ РОССИЙСКОГО СПУТНИКА ЛОМОНОСОВ

Цап Ю.Т., Петров В.Л., Яшин И.В., Богомолов В.В., Богомолов А.В., Свертилов С.И., Панасюк М.И., Гольдварг Т.Б., Моторина Г.Г., Копылова Ю.Г., Мягкова И.Н.

ПАЖ Том: 56Номер: 6 Год: **2018** Страницы: 404-409

На основе спутниковых наблюдений, полученных с помощью блоков детектирования рентгеновского и гамма-излучения (БДРГ/Ломоносов), используя методы цифровой фильтрации, проведен анализ временных задержек

между секундными пульсациями временных профилей жесткого рентгеновского излучения различных диапазонов солнечной вспышки **21.VII.2016** г. Показано, что скорости счета квантов в энергетических каналах 10–20, 20–35 и 35–60 кэВ, зарегистрированные на БДРГ/Ломоносов, являются коррелированными с точностью до 0.1 с. Это сравнительно хорошо согласуется с результатами наблюдений на гамма-мониторе Gamma-ray Burst Monitor, установленном на спутнике Fermi, и предполагает эффективное ускорение заряженных частиц на протяжении всей длины вспышечной магнитной арки.

ВРЕМЕННЫЕ ЗАДЕРЖКИ НЕТЕПЛОВОГО ИЗЛУЧЕНИЯ СОЛНЕЧНЫХ ВСПЫШЕК ПО НАБЛЮДЕНИЯМ НА КОРОНАС-Ф

Косм. Исслед. Том: 54Номер: 4 Год: **2016** Страницы: 302-307

In 2001–2003, the X-ray and microwave observations of ten solar flares of M- and X-classes were carried out by the CORONAS-F orbital station, the RSTN Sun service, and Nobeyama radio polarimeters. Based on these observations, a correlation analysis of time profiles of nonthermal radiation was performed. On average, hard X-ray radiation outstrips the microwave radiation in 9 events, i.e., time delays are positive. The appearance of negative delays is associated with effective scattering of accelerated electrons in pitch angles, where the length of the free path of a particle is less than the half-length of a flare loop. The additional indications are obtained in favor of the need to account for the effect of magnetic mirrors on the dynamics of energetic particles in the coronal arches.

УСКОРЕНИЕ ЭЛЕКТРОНОВ И НАГРЕВ ВСПЫШЕЧНОЙ ПЛАЗМЫ КОРОНАЛЬНЫХ ПЕТЕЛЬ

Пулково «Солнечная и солнечно-земная физика – **2015**», с.379

The peculiarities of the SXR and HXR time profiles as well as the temperature and the emission measure of the **23 August 2005** (M3.0) and **9 November 2013** (C2.7) solar flares based on observations with RHESSI satellite are analysed. The dynamics of main parameters of the thermal coronal plasma was studied. The spectral index, integral flux, and low energy cutoff were found using the HXR spectrum fitting. It has been shown that the HXR peaks can be delayed with respect to the temperature ones. In terms of the energy balance and the relationship of HXR emission from the loop top and footpoints evidences in favor of an important role of the Joule dissipation and the electron acceleration in the chromosphere have been obtained.

МОДУЛИРОВАННЫЕ ВСПЫШКОЙ 3- И 5-МИНУТНЫЕ КОЛЕБАНИЯ КАК СРЕДСТВО ЗОНДИРОВАНИЯ СОЛНЕЧНОЙ АТМОСФЕРЫ

А. А. **Челпанов**, Н. И. Кобанов

АЖ т. 97, №4, 341-347, **2020**

Мы применяем новый подход для измерения временных задержек магнитогидродинамических волн, распространяющихся в солнечной атмосфере. Малая вспышка в факельной области послужила модулятором уже существующих в хромосфере 3- и 5-минутных колебаний. Амплитуда этих колебаний увеличилась в несколько раз, что сделало возможным легко фиксировать образовавшийся волновой цуг при его распространении вверх через слои солнечной атмосферы. Такой кратковременный и хорошо выраженный волновой цуг служит удобным инструментом для определения скорости распространяющихся магнитогидродинамических волн, поскольку он позволяет избежать неопределенностей в измерении фазового сдвига, которые возникают в обычных условиях. Преимущество использования амплитудной модуляции от малой вспышки состоит в том, что это дает возможность исследовать атмосферу Солнца в условиях, приближенных к условиям в невозмущенной атмосфере.

Вариации магнитного поля в акивнной области NOAA 10486 и их связь с рентгеновскими вспышками и корональными выбросами масс

О. В. Чумак[1], Х.-К. Цанг[2], Ж. Гуо[2]

Астрономический журнал, **2008, С. 946-960**

На основе магнитограмм SOHO/MDI проанализированы временны̀е изменения параметров магнитного поля активной области (АО) NOAA 10486, входившей в большой комплекс активности 23-го солнечного цикла, в течение ее прохождения по диску Солнца с **26 по 31 октября 2003 г.** Результаты сопоставлены с рентгеновскими вспышками в этой АО и параметрами корональных выбросов массы, ассоциированных с данной АО. Рассмотрены временны̀е вариации распределений по величине поля полного магнитного потока (Fa), имбаланса потоков северной и южной полярностей (Im), сложности(Co) как меры взаимоперекрытия противоположных полярностей, угла наклона магнитной оси (An). Временны̀е вариации свободной энергии, накопленной в токовых слоях АО, отслеживались с помощью специально введенного параметра (Sh). Получены следующие результаты. Во-первых, параметры Fa, Im, Co, An, Sh количественно идентифицируют текущее

состояние АО и позволяют отслеживать и анализировать динамическую эволюцию ее магнитного поля. Во-вторых, вариации распределений по величине магнитного поля и средние значения параметров Fa, Im, Co, An и Sh связаны со вспышками и корональными выбросами массы и демонстрируют значительную амплитуду. В-третьих, параметр Sh, характеризующий непотенциальность магнитного поля в областях, примыкающих к главной нейтральной линии, демонстрирует рост своих значений перед эруптивными событиями и представляет особый интерес в плане мониторинга состояния АО в реальном времени. В-четвертых, магнитное поле АО обнаруживает своеобразную “квазиупругость” — структура поля после активных событий восстанавливается в среднем за 1–3 ч.

Пулково «Солнечная и солнечно-земная физика – **2015**», с.383

It is shown that turbulent pitch-angle scattering leads to increasing of Hard X-Ray intensity predominantly in loop’s footpoints for isotropic initial electron source and contrary strengthening at looptop for anisotropic beams for δB/B = 10-3.

РАСЧЕТ СТЕПЕНИ ЛИНЕЙНОЙ ПОЛЯРИЗАЦИИ ИЗЛУЧЕНИЯ ЛИНИИ Hα, ВОЗБУЖДАЕМОЙ ПРОТОНАМИ, ВО ВСПЫШКАХ СОЛНЦА

ШАПОЧКИН М. Б.*

АЖ Том: 98Номер: 4 Год: **2021** Страницы: 305-313

Приводится оригинальный аналитический расчет степени линейной поляризации линий Hα во время солнечных вспышек, вызванной анизотропными протонами, когда в хромосфере Солнца температура тепловых протонов больше температуры тепловых электронов. Анализируются зависимости степени линейной поляризации от параметров функции распределения тепловых и нетепловых протонов во время вспышек Солнца. Обсуждается диагностика вспышечной плазмы.

НАБЛЮДЕНИЕ ГЕЛИОСЕЙСМИЧЕСКИ АКТИВНОЙ СОЛНЕЧНОЙ ВСПЫШКИ С МАЛЫМ ПОТОКОМ ЖЕСТКОГО РЕНТГЕНОВСКОГО ИЗЛУЧЕНИЯ ДО 50 КЭВ

ШАРЫКИН И.Н.[1], **ЗИМОВЕЦ И.В.**[1], **КОСОВИЧЕВ А.Г.**[2], **МЫШЬЯКОВ И.И.**[3]

ПАЖ Том: 50Номер: 3 Год: **2024** Страницы: 233-250

Рассматривается солнечная вспышка класса M1.1, произошедшая **5 июля 2012** г. в 06:49 UT. Событие уникально тем фактом, что в нем было обнаружено гелиосейсмическое возмущение, несмотря на малый поток жесткого рентгеновского излучения в диапазоне 25-50 кэВ и очень мягкий спектр по данным RHESSI. Как правило, большинство известных солнцетрясений детектировалось в солнечных вспышках с большими потоками жесткого рентгеновского излучения на высоких энергиях (как минимум до 100-300 кэВ). Рассматриваемое событие противоречит популярной гипотезе о генерации солнцетрясений пучками ускоренных электронов высоких энергий. Анализ доступных рентгеновских спектров по данным RHESSI показывает, что их можно объяснить двумя способами. Рентгеновский спектр в диапазоне 25-50 кэВ объясняется степенным распределением ускоренных электронов с индексом 7-9, либо наличием сверхгорячей плазмы с температурой T ~ 30-60 МК. В том и другом случае мы имеем дело с электронами относительно низких энергий, которые либо являлись причиной генерации солнцетрясения, либо их следует рассматривать как вторичное (сопутствующее) явление по отношению к истинной причине фотосферного возмущения. Впервые для гелиосейсмически активной солнечной вспышки приводятся результаты совместного анализа рентгеновских и микроволновых спектров. Анализ показывает, что спектры в обоих диапазонах, могут хорошо объясняться излучением сверхгорячей замагниченной плазмы, а не ускоренными электронами с мягким спектром. Но также возможно объяснение спектров при рассмотрении ускоренных электронов, частично захваченных в магнитную ловушку. Получены оценки параметров тепловой плазмы, ускоренных электронов, потоков энергий различных видов. Проведен анализ динамики ультрафиолетовых и рентгеновских источников излучения. Также приводится анализ структуры магнитного поля по векторным магнитограммам и нелинейной бессиловой экстраполяции коронального магнитного поля. Обсуждаются механизмы генерации гелиосейсмического возмущения во время данной солнечной вспышки. Вероятно, эруптивный процесс мог быть как первичной, так и вторичной причиной

солнцетрясения. Появление сверхгорячей плазмы в короне могло привести к формированию распространяющихся тепловых фронтов в нижние слои солнечной атмосферы, где возбуждаются гелиосейсмические волны. Анализ не позволяет исключать и возможность генерации солнцетрясения ускоренными электронами с мягким спектром.

НАГРЕВ ПЛАЗМЫ ДО СВЕРХВЫСОКИХ ТЕМПЕРАТУР (МК) В СОЛНЕЧНОЙ ВСПЫШКЕ 9 АВГУСТА 2011 ГОДА

ШАРЫКИН И.Н.1, СТРУМИНСКИЙ А.Б.1,2, ЗИМОВЕЦ И.В.

ПАЖ Том: 41Номер: 1 Год: **2015** Страницы: 57

Astronomy Letters Volume 41, Issue 1-2, pp 53-66 **2015**

http://arxiv.org/pdf/1502.03220v1.pdf

Исследуется солнечная вспышка 9 августа 2011 г. рентгеновского класса X6.9, которая является самой “горячей” вспышкой с 2000 по 2012 гг., с максимальной температурой плазмы по данным GOES МК. Целью работы является определение причины такой аномально высокой температуры плазмы, а также исследование энергетического баланса во вспышечной области с учетом наличия сверхгорячей плазмы (МК). Мы анализируем данные RHESSI, GOES, AIA/SDO и EVE/SDO, обсуждаем пространственную структуру вспышечной области и результаты спектрального анализа ее рентгеновского излучения. Анализ рентгеновских спектров по данным RHESSI проводится в рамках одно- и двухтемпературного приближения с учетом излучения горячей (МК) и сверхгорячей (МК) плазмы. Спектр жесткого рентгеновского излучения в обеих моделях аппроксимируется степенными функциями. Показано, что наблюдаемые особенности вспышки лучше объясняются с помощью двухтемпературной модели, в которой сверхгорячая плазма располагается в вершинах вспышечных петель (или области магнитного каспа). Формирование сверхгорячей плазмы может быть связано с ее нагревом за счет первоначального энерговыделения и подавлением теплопроводности. Аномально высокая температура (33 МК по GOES) скорее всего является артефактом метода расчета температуры по двухканальным измерениям GOES в рамках однотемпературного приближения, примененного к излучению многотемпературной вспышечной плазмы с малым вкладом низкотемпературной части дифференциальной меры эмиссии.

РОЛЬ ВЫБРОСОВ ПЛАЗМЫ В РАЗВИТИИ МОЩНЫХ СОЛНЕЧНЫХ ВСПЫШЕК РАЗЛИЧНОЙ ДЛИТЕЛЬНОСТИ

А. Н. **Шаховская**1, М. А. Ли вши ц2, И. М. Черток2

АСТРОНОМИЧЕСКИЙЖУРНАЛ, **2006***, том 83,№12, с. 1128–1141*

Современные наблюдения показывают, что достаточно мощный выброс плазмы сопровождается формированием системы корональных петель и появлением двух лент, светящихся близ их оснований. Однако в одних случаях двухленточная вспышка длится, например, в мягком рентгеновском диапазоне много часов, в других — затухает в течение десятков минут. На примере четырех мощных вспышек **15–18 июля 2002** г. исследуется вопрос о причинах, влияющих на длительность вспышек. На основе разнообразных наземных и спутниковых наблюдений показано, что кратковременные быстрые события включали в себя коллимированные (узкие) выбросы плазмы в северном направлении и последующее формирование компактных петель в головной части активной области. В одном из событий, вслед за мощным выбросом в широком телесном угле в восточном направлении, в хвостовой части области сформировалась протяженная арочная система, определившая длительный характер вспышки. Есть основания полагать, что в тех событиях, где присутствуют коллимированные (узкие) выбросы и соответствующие узкие детали корональных выбросов массы (КВМ), система корональных петель образуется, но постэруптивное энерговыделение не возникает или выражено очень слабо, энергия из этой области не поступает вниз, и плазма в корональных петлях свободно высвечивается. В отличие от этих быстрых вспышек, широкий выброс и крупномасштабный яркий КВМсопровождаютсяформированием и длительным существованием протяженной арочной системы. Таким образом, мощные нестационарные процессы на Солнце включают в себя крупномасштабный КВМ и собственно вспышку, в которых реализация процесса пересоединения вместе с эволюцией вынесенной наружу плазмы определяют характер конкретного явления.

АКТИВНЫЕ ОБЛАСТИ НА СОЛНЦЕ С ПОВЫШЕННОЙ ВСПЫШЕЧНОЙ АКТИВНОСТЬЮ В 24 ЦИКЛЕ

ЯЗЕВ С. А.*1,2, ИСАЕВА Е. С.1,2, ИШМУХАМЕТОВА Ю. В.1

АЖ Том: 98 Номер: 6 Год: **2021** Страницы: 506-517

Проанализированы активные области (АО) на Солнце, отличающиеся высокими значениями вспышечного индекса и в то же время развивавшиеся вне комплексов активности (КА). Таких объектов в 24 цикле выделено 13. Показано, что эти АО относятся к разряду сравнительно долгоживущих крупных групп пятен, отличающихся повышенной скоростью роста площади. Эти АО входят в состав комплексов АО, соединяются с

другими АО системами высоких корональных систем, включая трансэкваториальные. Часть таких АО ассоциируется авторами с короткоживущими (менее 3 кэррингтоновских оборотов) комплексами активности, часть является компонентами комплексов активных областей. Все 13 рассмотренные АО находились рядом с корональными дырами.
