A major coronal heating theory based on magnetic reconnection relies on the existence of braided magnetic field structures in the corona. In this small-angle reconnection scenario, numerical simulations indicate that the reconnected magnetic field lines are driven sideways by magnetic tension and can overshoot from their new rest position, thereby leading to low-amplitude transverse MHD waves. This provides an efficient mechanism for transverse MHD wave generation, and the direct causality also constitutes substantial evidence of reconnection from braiding. However, this wave-generation mechanism has never been directly observed. Recently, the telltale signature of small-angle reconnection in a sheared coronal structure has been identified through nanojets, which are small, short-lived, and fast jetlike bursts in the nanoflare range transverse to the guide field. We present for the first time Interface Region Imaging Spectrograph and Solar Dynamics Observatory observations of transverse MHD waves in a coronal loop that directly result from braiding-induced reconnection. The reconnection is identified by the presence of nanojets at the loop apex that release nanoflare-range energy. We find that the oscillations have an energy flux on the order of 106-108 erg cm-2 s-1, which is within the budget to power active region loops. The estimated kinetic and thermal energy from the nanojets is also sufficient to power the transverse waves and sustain the observed heating at the loop apex. This discovery provides major support to (a) existing theories that transverse MHD waves can be a signature of reconnection, (b) the existence of braiding in coronal structures, and (c) the coronal reconnection scenario identified by nanojets.

Partial redistribution in 3D non-LTE radiative transfer in solar-atmosphere models

Andrii V. **Sukhorukov**1,2 and Jorrit Leenaarts1
A&A 597, A46 (**2017**)

Context. Resonance spectral lines such as H i Ly α, Mg ii h&k, and Ca ii H&K that form in the solar chromosphere, are influenced by the effects of 3D radiative transfer as well as partial redistribution (PRD). So far no one has modeled these lines including both effects simultaneously owing to the high computing demands of existing algorithms. Such modeling is, however, indispensable for accurate diagnostics of the chromosphere.
Aims. We present a computationally tractable method to treat PRD scattering in 3D model atmospheres using a 3D non-local thermodynamic equilibrium (non-LTE) radiative transfer code.
Methods. To make the method memory-friendly, we use the hybrid approximation for the redistribution integral. To make the method fast, we use linear interpolation on equidistant frequency grids. We verify our algorithm against computations with the RH code and analyze it for stability, convergence, and usefulness of acceleration using model atoms of Mg ii with the h&k lines and H i with the Ly α line treated in PRD.
Results. A typical 3D PRD solution can be obtained in a model atmosphere with 252 × 252 × 496 coordinate points in 50 000–200 000 CPU hours, which is a factor ten slower than computations assuming complete redistribution. We illustrate the importance of the joint action of PRD and 3D effects for the Mg ii h&k lines for disk-center intensities, as well as the center-to-limb variation.
Conclusions. The proposed method allows for the simulation of PRD lines in a time series of radiation-magnetohydrodynamic models, in order to interpret observations of chromospheric lines at high spatial resolution.

Improved CGEM Electric Field Inversion for HMI Active Regions

Xudong **Sun**1, George Fisher2, and Todd Hoeksema3 (for the CGEM Team)
HMI Science Nuggets, #190 **2023**
http://hmi.stanford.edu/hminuggets/?p=4092

The PDFI_SS software[1], developed by the Coronal Global Evolutionary Model (CGEM) team, derives the photospheric electric field based on a time sequence of vector magnetic field and Doppler velocity maps. It has been applied to the Space-weather HMI Active Region Patch (SHARP) data archive: the electric field maps (cgem.pdfi_output) are now a routine product of the HMI pipeline. As of May 01, 2023, the electric fields have been calculated for 4972 active regions, with a total of 2.9 million snapshots. Details of the software and the data products can be found in ref. [1] and ref. [2]. **2012.07.10**

The Polar Field Reversal of Solar Cycle 24

Xudong **Sun**
HMI Science Nuggets, #32, Dec **2014**
http://hmi.stanford.edu/hminuggets/?p=1030

HMI observations reveal a slow, north-south asymmetric polar magnetic field reversal. Cycle 24 has been weak; an even weaker Cycle 25 seems probable.

On Polar Magnetic Field Reversal and Surface Flux Transport During Solar Cycle 24

Xudong **Sun**, J. Todd Hoeksema, Yang Liu, Junwei Zhao
ApJ **798** 114 **2015**
http://arxiv.org/pdf/1410.8867v1.pdf

As each solar cycle progresses, remnant magnetic flux from active regions (ARs) migrates poleward to cancel the old-cycle polar field. We describe this polarity reversal process during Cycle 24 using four years (2010.33--2014.33) of line-of-sight magnetic field measurements from the Helioseismic and Magnetic Imager. The total flux associated with ARs reached maximum in the north in 2011, more than two years earlier than the south; the maximum is significantly weaker than Cycle 23. The process of polar field reversal is relatively slow, north-south asymmetric, and episodic. We estimate that the global axial dipole changed sign in October 2013; the northern and southern polar fields (mean above 60◦ latitude) reversed in November 2012 and March 2014, respectively, about 16 months apart. Notably, the poleward surges of flux in each hemisphere alternated in polarity, giving rise to multiple reversals in the north. We show that the surges of the trailing sunspot polarity tend to correspond to normal mean AR tilt, higher total AR flux, or slower mid-latitude near-surface meridional flow, while exceptions occur during low magnetic activity. In particular, the AR flux and the mid-latitude poleward flow speed exhibit a clear anti-correlation. We discuss how these features can be explained in a surface flux transport process that includes a field-dependent converging flow toward the ARs, a characteristic that may contribute to solar cycle variability.

The SunPy Project: An Interoperable Ecosystem for Solar Data Analysis

The **SunPy Community**, Will Barnes, Steven Christe, Nabil Freij, Laura Hayes, David Stansby, Jack Ireland, Stuart Mumford, Daniel Ryan, Albert Shih
Frontiers in Astronomy and Space Sciences 10 (**2023**): 29
https://www.frontiersin.org/articles/10.3389/fspas.2023.1076726/pdf
The SunPy Project is a community of scientists and software developers creating an ecosystem of Python packages for solar physics. The project includes the sunpy core package as well as a set of affiliated packages. The sunpy core package provides general purpose tools to access data from different providers, read image and time series data, and transform between commonly used coordinate systems. Affiliated packages perform more specialized tasks that do not fall within the more general scope of the sunpy core package. In this article, we give a high-level overview of the SunPy Project, how it is broader than the sunpy core package, and how the project curates and fosters the affiliated package system. We demonstrate how components of the SunPy ecosystem, including sunpy and several affiliated packages, work together to enable multi-instrument data analysis workflows. We also describe members of the SunPy Project and how the project interacts with the wider solar physics and scientific Python communities. Finally, we discuss the future direction and priorities of the SunPy Project.

A Full-disk Image Standardization of the Chromosphere Observation at Huairou Solar Observing Station

Liu **Suo**
Advances in Space Research **2019**
https://arxiv.org/pdf/1911.06637.pdf
Observations of local features in the solar chromosphere began in 1992 at Huairou Solar Observing Station, while the full-disk chromosphere observations were carried out since 2000. In order to facilitate researchers to use full-disk chromosphere observation, algorithms have been developed to standardize the full-disk images. The algorithms include the determination of the center of the image and size standardization, geometric correction and intensity normalization. The solar limb of each image is determined from a histogram analysis of its intensity distribution. The center and radius are then calculated and the image is corrected for geometric distortions. Images are re-scaled to have a fixed radius of 500 pixels and centered within the 1024×1024 frame. Finally, large-scale variations in intensity, such as limb-darkening, are removed using a median filter. This paper provides a detailed description of these algorithms, and a summary of the properties of these chromosheric full-disk observations to be used for further scientific investigations.

Center to limb observations and modeling of the Ca I 4227 A line

H. D. **Supriya**, H. N. Smitha, K. N. Nagendra, J. O. Stenflo, M. Bianda, R. Ramelli, B. Ravindra, L. S. Anusha
ApJ 793 42 **2014**
http://arxiv.org/pdf/1407.5461v1.pdf
The observed center-to-limb variation (CLV) of the scattering polarization in different lines of the Second Solar Spectrum can be used to constrain the height variation of various atmospheric parameters, in particular the magnetic fields via the Hanle effect. Here we attempt to model non-magnetic CLV observations of the Q/I profiles of the Ca I 4227 A line recorded with the ZIMPOL-3 at IRSOL. For modeling, we use the polarized radiative transfer with partial frequency redistribution with a number of realistic 1-D model atmospheres. We find that all the standard FAL model atmospheres, used by us, fail to simultaneously fit the observed (I, Q/I) at all the limb distances (μ). However, an attempt is made to find a single model which can provide a fit at least to the CLV of the observed Q/I instead of a simultaneous fit to the (I, Q/I) at all μ. To this end we construct a new 1-D model by combining two of the standard models after modifying their temperature structures in the appropriate height ranges. This new combined model closely reproduces the observed Q/I at all the μ, but fails to reproduce the observed rest intensity at different μ. Hence we find that no single 1-D model atmosphere succeeds in providing a good representation of the real Sun. This failure of 1-D models does not however cause an impediment to the magnetic field diagnostic potential of the Ca I 4227 A line. To demonstrate this we deduce the field strength at various μ positions without invoking the use of radiative transfer.

On the Long-Term Modulation of Solar Differential Rotation

M.**Suzuki**
E-print, July **2014**; Solar Phys., Volume 289, Issue 11, pp 4021-4029, **2014**
http://arxiv.org/pdf/1407.5735.pdf
Long-term modulation of solar differential rotation was studied with data from Mt. Wilson and our original observations during Solar Cycles 16 through 23. The results are: i) The global B-value (i.e. latitudinal gradient of differential rotation), is modulated in a period of about six or seven solar cycles. ii) The B-values of the northern and

southern hemispheres are also modulated with a similar period to the global one, but iii) they show quasi-oscillatory behavior with a phase shift between them. We examined the yearly fluctuations of the B-values in every solar cycle with reference to the phase of the sunspot cycle and found that the B-values show high values over the full-cycle years, when the cycle-averaged B-values are high. We discuss the independent long-term behavior of solar differential rotation between the northern and southern solar hemispheres and its implication for the solar dynamo.

Several Populations of Sunspot Group Numbers -- Resolving a Conundrum

Leif **Svalgaard**

2020

https://arxiv.org/ftp/arxiv/papers/2011/2011.05356.pdf

The long-standing disparity between the sunspot number record and the Hoyt and Schatten (1998, H&S) Group Sunspot Number series was initially resolved by the Clette et al. (2014) revision of the sunspot number and the group number series. The revisions resulted in a flurry of dissenting group number series while the revised sunspot number series was generally accepted. Thus, the disparity persisted and confusion reigned, with the choice of solar activity dataset continuing to be a free parameter. A number of workshops and follow-up collaborative efforts by the community have not yet brought clarity. We review here several lines of evidence that validate the original revisions put forward by Clette et al. (2014) and suggest that the perceived conundrum no longer need to delay acceptance and general use of the revised series. We argue that the solar observations constitute several distinct populations with different properties which explain the various discontinuities in the series. This is supported by several proxies: diurnal variation of the geomagnetic field, geomagnetic signature of the strength of the heliomagnetic field, and variation of radionuclides. The Waldmeier effect shows that the sunspot number scale has not changed over the last 270 years and a mistaken scale factor between observers Wolf and Wolfer explains the disparity beginning in 1882 between the sunspot number and the H&S reconstruction of the group number. Observations with replica of 18th century telescopes (with similar optical flaws) validate the early sunspot number scale; while a reconstruction of the group number with monthly resolution (with many more degrees of freedom) validate the size of Solar Cycle 11 given by the revised series that the dissenting series fail to meet.

Prediction of Solar Cycle 25 **Review**

Leif **Svalgaard**

Journal of Space Weather and Space Climate **2020**

https://arxiv.org/ftp/arxiv/papers/2010/2010.02370.pdf

Prediction of solar cycle is an important goal of Solar Physics both because it serves as a touchstone for our understanding of the sun and also because of its societal value for a space faring civilization. The task is difficult and progress is slow. Schatten et al. (1978) suggested that the magnitude of the magnetic field in the polar regions of the sun near solar minimum could serve as a precursor for the evolution and amplitude of the following solar cycle. Since then, this idea has been the foundation of somewhat successful predictions of the size of the last four cycles, especially of the unexpectedly weak solar cycle 24 ("the weakest in 100 years"). Direct measurements of the polar magnetic fields are available since the 1970s and we have just passed the solar minimum prior to solar cycle 25, so a further test of the polar field precursor method is now possible. The predicted size of the new cycle 25 is 128±10 (on the new sunspot number version 2 scale), slightly larger than the previous cycle.

Calibration of the Total Solar Irradiance Data Record

Leif **Svalgaard**

2018

https://arxiv.org/ftp/arxiv/papers/1812/1812.09301.pdf

Solar surface magnetic field seems to be able to explain variations in Total Solar Irradiance on timescales from hours to decades. Using magnetograms from spacecraft (MDI and HMI) and ground-based observatories (MWO and WSO) I build a composite dataset of the Total Line-of-Sight Unsigned Magnetic Flux over the solar disk stretching back to 1976, validated by excellent correlations with the solar microwave flux (F10.7) and the Sunspot Group Number. Direct measurements of TSI by space borne sensors have been carried out since late 1978. The early instruments were plagued by scattered light entering the aperture, but this construction flaw can be corrected for. At the AGU 2018 meeting, a new TSI composite has been proposed based on a novel mathematical method vetted by representatives from all current and most past TSI instruments. Although an 'official' release of the dataset has not been offered yet, a preliminary version is available. Anticipating that any last-minute changes might be minor, I compare this new version with the magnetic flux composite. It is clear that we have two TSI populations: values before 1993 that are seriously too low and values from 1993 onwards. I elect to normalize the magnetic flux (the driver of variations of TSI) to a New TSI using the regression equation for the recent population with the smallest

uncertainty. With this normalization, there is now total agreement between the variation of the magnetic flux and of the New TSI as well as with the F10.7 and Group Number proxies. We now have two choices: (1) the Sun underwent a dramatic change in how its magnetic field drives variation of TSI or (2) the New Consensus TSI reconstruction does not work and the new dataset is premature and not useful neither for solar nor for climate research. Following David Hume, we should always believe whatever would be the lesser miracle, which in our case would be choice (2).

Up to Nine Millennia of Multimessenger Solar Activity

Leif **Svalgaard**

2018

https://arxiv.org/ftp/arxiv/papers/1810/1810.11952.pdf

A nine-millennia reconstruction of decadal sunspot numbers derived from 10Be and 14C terrestrial archives for 6755 BC to 1885 AD has been extended to the present using several other messengers (Observed Sunspot Number, Group Number, range of the diurnal variation of the geomagnetic field, and the InterDiurnal Variation of the geomagnetic Ring Current) and scaled to the modern SILSO Version 2 sunspot number. We find that there has been no secular up tick of activity the last three hundred years and that recent activity has not been out of the ordinary. There is a sharp 87.6-year peak in the power spectrum, but no significant power at the Hallstatt 2300-year period. The reconciliation of the cosmogenic record with the modern sunspot record could be an important step to providing a vetted solar activity record for the use in climate research.

A Super-Synoptic Map of HMI Flux Density

Leif Svalgaard

HMI Science Nuggets # 82 **2018**

http://hmi.stanford.edu/hminuggets/?p=2146

25 Cycles of Solar Magnetic Dipole Moments

Leif Svalgaard

HMI Science Nuggets #78 **2018**

http://hmi.stanford.edu/hminuggets/?p=2084

The idea, based on the Babcock model of the cycle, that the solar polar fields near minimum can be used as predictor of the size of the following sunspot cycle1 has proven useful and successful the last four cycles, especially for the critical ‘lowest in a 100 years’ Cycle 242. The ‘Dipole Moment’ (DM), i.e. the difference between the polar fields (using the Wilcox Solar Observatory, WSO, convention that ‘polar fields’ be the average line-of-sight flux density [called the ‘field strength’] above latitudes 55°) in the North and in the South, was taken as a convenient parameter for the purpose of prediction. It was found that the value of DM over the three years preceding the minimum is relatively constant with only a slight decrease over time (due to pole-ward migration of emerging new-cycle flux), sufficiently stable that its average single value was a good precursor at least for the last four sunspot cycles.

Assessment of the Failure of Active Days Fraction Method of Sunspot Group Number Reconstructions

Leif **Svalgaard**, Kenneth H. Schatten

2017

https://arxiv.org/ftp/arxiv/papers/1706/1706.01154.pdf

We identify several pairs of 'equivalent' observers defined as observers with equal or nearly equal 'observational threshold' areas of sunspots on the solar disk as determined by the 'Active Days Fraction' method [e.g. Willamo et al., 2017]. For such pairs of observers, the ADF-method would be expected to map the actually observed sunspot group numbers for the individual observers to two reconstructed series that are very nearly equal and (it is claimed) represent 'real' solar activity without arbitrary choices and deleterious, error-accumulating 'daisy-chaining'. We show that this goal has not been achieved (for the critical period at the end of the 19th century and the beginning of the 20th), rendering the ADF-methodology suspect and not reliable nor useful for studying the long-term variation of solar activity.

Sunspot Group Numbers Since 1900 and Implications for the Long-term Record of Solar Activity

Leif **Svalgaard**, Kenneth H. Schatten

2017

https://arxiv.org/ftp/arxiv/papers/1705/1705.02024.pdf
Recent work on improving and revising estimates of solar activity [Clette et al., 2014] has resulted in renewed interest in what has been called the longest running 'Science Experiment'. We compare four reconstructions of solar activity as reflected in the number of sunspot groups ('active regions') constructed by different authors using very different methods. We concentrate on the period since AD 1900 where the underlying solar and geomagnetic data are plentiful and of sufficient quality and find that all four methods yield essentially the same Sunspot Group Number series. We take that as indicating that protracted and pernicious criticisms of the individual methods are neither fruitful nor helpful and we suggest that future efforts be directed towards understanding the specific reasons why the methods give discordant results for centuries prior to the 20th. The main area of disagreement occurs during the last 25 years of the 19th century and feeds back into the time prior to that. The solar Extreme Ultraviolet flux can be reconstructed since the 1740s [Svalgaard, 2016] and with suitable scaling fits the Svalgaard & Schatten [2016] Sunspot Group Number series since 1865 very well, so we argue that the discordant group series have problems once we move out of the 20th century, and that the community should concentrate on finding out what those are, so a true and useful consensus can emerge.

On the Sunspot Group Number Reconstruction: The Backbone Method

Leif **Svalgaard**, Kenneth H. Schatten
2017
https://arxiv.org/pdf/1704.07061.pdf
We discuss two recent papers very critical of our Group Sunspot Number Series (Svalgaard & Schatten [2016]). Unfortunately, we cannot support any of the concerns they raise. We first show that almost always there is simple proportionality between the counts of different observers and that taking the small, occasional non-linearities into account makes very little difference. Among other examples: we verify that the RGO group count was drifting the first twenty years of observations. We then show that our group count matches the diurnal variation of the geomagnetic field with high fidelity, and that the heliospheric magnetic field derived from geomagnetic data is consistent with our group number series. We evaluate the 'correction matrix' approach [Usoskin et al. 2016] and show that it fails to reproduce the observational data. We clarify the notion of daisy-chaining and point out that our group number series has no daisy-chaining for the period 1794-1996 and therefore no accumulation of errors over that span. We compare with the cosmic ray record for the last 400+ years and find good agreement. We note that the Active Day Fraction method (of Usoskin et al.) has the problem that at sunspot maximum, every day is an 'active day' so ADF is nearly always unity and thus does not carry information about the statistics of high solar activity. This 'information shadow' occurs for even moderate group numbers and thus need to be extrapolated to higher activity. We compare a new application of the correction matrix method utilizing good RGO data after 1900 and find remarkable linear agreement (after correcting for an unphysical offset) with our group series. We conclude that the criticism of Svalgaard & Schatten [2016] is invalid and detrimental to progress in the important field of long-term variation of solar activity, although we would welcome well-reasoned re-examinations of our findings.

The Effect of Sunspot Weighting

Leif **Svalgaard**, Marco Cagnotti, Sergio Cortesi
Solar Physics February **2017**, 292:34
http://arxiv.org/ftp/arxiv/papers/1507/1507.01119.pdf
Although W. Brunner began to weight sunspot counts (from 1926), using a method whereby larger spots were counted more than once, he compensated for the weighting by not counting enough smaller spots in order to maintain the same reduction factor (0.6) as was used by his predecessor A. Wolfer to reduce the count to R. Wolf's original scale, so that the weighting did not have any effect on the scale of the sunspot number. In 1947, M. Waldmeier formalized the weighting (on a scale from 1 to 5) of the sunspot count made at Zurich and its auxiliary station Locarno. This explicit counting method, when followed, inflates the relative sunspot number over that which corresponds to the scale set by Wolfer (and matched by Brunner). Recounting some 60,000 sunspots on drawings from the reference station Locarno shows that the number of sunspots reported was "over counted" by \({\approx}\,44~\%\) on average, leading to an inflation (measured by an effective weight factor) in excess of 1.2 for high solar activity. In a double-blind parallel counting by the Locarno observer M. Cagnotti, we determined that Svalgaard's count closely matches that of Cagnotti, allowing us to determine from direct observation the daily weight factor for spots since 2003 (and sporadically before). The effective total inflation turns out to have two sources: a major one (15 – 18 %) caused by weighting of spots, and a minor source (4 – 5 %) caused by the introduction of the Zürich classification of sunspot groups which increases the group count by 7 – 8 % and the relative sunspot number by about half that. We find that a simple empirical equation (depending on the activity level) fits the observed factors well, and use that fit to estimate the weighting inflation factor for each month back to the introduction of effective inflation in 1947 and thus to be able to correct for the over-counts and to reduce sunspot counting to the Wolfer method in use from 1894 onwards.
Waldmeier in 1947 introduced a weighting (on a scale from 1 to 5) of the sunspot count made at Zurich and its auxiliary station Locarno, whereby larger spots were counted more than once. This counting method inflates the relative sunspot number over that which corresponds to the scale set by Wolfer and Brunner. Svalgaard re-counted

some 60,000 sunspots on drawings from the reference station Locarno and determined that the number of sunspots reported were 'over counted' by 44% on average, leading to an inflation (measured by a weight factor) in excess of 1.2 for high solar activity. In a double-blind parallel counting by the Locarno observer Cagnotti, we determined that Svalgaard's count closely matches that of Cagnotti's, allowing us to determine the daily weight factor since 2003 (and sporadically before). We find that a simple empirical equation fits the observed weight factors well, and use that fit to estimate the weight factor for each month back to the introduction of weighting in 1947 and thus to be able to correct for the over-count and to reduce sunspot counting without weighting to the Wolfer method in use from 1893 onwards.

A Recount of Sunspot Groups on Staudach's Drawings

Leif **Svalgaard**
Solar Phys. January **2017**, 292:4
We have examined the more than 1100 drawings of the solar disk made by the German amateur astronomer Johann Caspar Staudach during 1749 – 1799 and counted the spots on each image. Using the modern perception of how to group spots into active regions, we regrouped the spots as a modern observer would. The resulting number of groups was found to be higher on average by 25 % than the first count of groups performed by Wolf in 1857, which was used by Hoyt and Schatten (Solar Phys. 181, 491, 1998) in their construction of the group sunspot number. Compared to other observers at the time, Staudach's drawings have a very low average number, about two, of spots per group, possibly indicating an inferior telescope that probably suffered from spherical and chromatic aberration, as would be typical of amateur telescopes of the day. We have initiated an ongoing project aiming at observing sunspots with antique telescopes having similar defects in order to determine the factor necessary to bring the Staudach observations onto a modern scale.
Erratum Solar Physics January 2017, 292:14

Reconstruction of Solar Extreme Ultraviolet Flux 1740 – 2015

Leif **Svalgaard**
Solar Phys. **2016**
Solar extreme ultraviolet (EUV) radiation creates the conducting E-layer of the ionosphere, mainly by photo-ionization of molecular oxygen. Solar heating of the ionosphere creates thermal winds, which by dynamo action induce an electric field driving an electric current having a magnetic effect observable on the ground, as was discovered by G. Graham in 1722. The current rises and falls with the Sun, and thus causes a readily observable diurnal variation of the geomagnetic field, allowing us to deduce the conductivity and thus the EUV flux as far back as reliable magnetic data reach. High-quality data go back to the "Magnetic Crusade" of the 1830s and less reliable, but still usable, data are available for portions of the 100 years before that. J.R. Wolf and, independently, J.-A. Gautier discovered the dependence of the diurnal variation on solar activity, and today we understand and can invert that relationship to construct a reliable record of the EUV flux from the geomagnetic record. We compare that to the F10.7F10.7 flux and the sunspot number, and we find that the reconstructed EUV flux reproduces the F10.7F10.7 flux with great accuracy. On the other hand, it appears that the Relative Sunspot Number as currently defined is beginning to no longer be a faithful representation of solar magnetic activity, at least as measured by the EUV and related indices. The reconstruction suggests that the EUV flux reaches the same low (but non-zero) value at every sunspot minimum (possibly including Grand Minima), representing an invariant "solar magnetic ground state".

F10.7 Microwave Flux Matches the Total Disk Unsigned Magnetic Flux from MDI and HMI

Reconstruction of the Sunspot Group Number: The Backbone Method

Leif **Svalgaard**, Kenneth H. Schatten
Solar Phys. Volume 291, Issue 9, pp 2653–2684 **2016**
We have reconstructed the sunspot-group count, not by comparisons with other reconstructions and correcting those where they were deemed to be deficient, but by a re-assessment of original sources. The resulting series is a pure solar index and does not rely on input from other proxies,e.g. radionuclides, auroral sightings, or geomagnetic records. "Backboning" the data sets, our chosen method, provides substance and rigidity by using long-time observers as a stiffness character. Solar activity, as defined by the Group Number, appears to reach and sustain for extended intervals of time the same level in each of the last three centuries since 1700 and the past several decades do not seem to have been exceptionally active, contrary to what is often claimed.

Reconstruction of Solar Extreme Ultraviolet Flux 1740-2015

Leif **Svalgaard**

2015

http://arxiv.org/ftp/arxiv/papers/1506/1506.04408.pdf

Solar Extreme Ultraviolet (EUV) radiation creates the conducting E-layer of the ionosphere, mainly by photo ionization of molecular Oxygen. Solar heating of the ionosphere creates thermal winds which by dynamo action induce an electric field driving an electric current having a magnetic effect observable on the ground, as was discovered by G. Graham in 1722. The current rises and sets with the Sun and thus causes a readily observable diurnal variation of the geomagnetic field, allowing us the deduce the conductivity and thus the EUV flux as far back as reliable magnetic data reach. High-quality data go back to the 'Magnetic Crusade' of the 1830s and less reliable, but still usable, data are available for portions of the hundred years before that. J.R. Wolf and, independently, J.-A. Gautier discovered the dependence of the diurnal variation on solar activity, and today we understand and can invert that relationship to construct a reliable record of the EUV flux from the geomagnetic record. We compare that to the F10.7 flux and the sunspot number, and find that the reconstructed EUV flux reproduces the F10.7 flux with great accuracy. On the other hand, it appears that the Relative Sunspot Number as currently defined is beginning to no longer be a faithful representation of solar magnetic activity, at least as measured by the EUV and related indices. The reconstruction suggests that the EUV flux reaches the same low (but non-zero) value at every sunspot minimum (possibly including Grand Minima), representing an invariant 'solar magnetic ground state'.

Reconstruction of the Sunspot Group Number: the Backbone Method **Review**

Leif **Svalgaard**, Kennuth H. Schatten

Topical Issue of Solar Physics on "Recalibration of the Sunspot Number", **2015**

http://arxiv.org/ftp/arxiv/papers/1506/1506.00755.pdf

We have reconstructed the sunspot group count, not by comparisons with other reconstructions and correcting those where they were deemed to be deficient, but by a re-assessment of original sources. The resulting series is a pure solar index and does not rely on input from other proxies, e.g. radionuclides, auroral sightings, or geomagnetic records. 'Backboning' the data sets, our chosen method, provides substance and rigidity by using long-time observers as a stiffness character. Solar activity, as defined by the Group Number, appears to reach and sustain for extended intervals of time the same level in each of the last three centuries since 1700 and the past several decades do not seem to have been exceptionally active, contrary to what is often claimed.

Solar activity – past, present, future **Review**

http://www.swsc-journal.org/articles/swsc/abs/2013/01/swsc130003/swsc130003.html

As our civilization depends increasingly on space-borne assets and on a delicate and vulnerable earth-bound infrastructure, solar activity and its potential impact becomes of increasing importance and relevance. In his famous paper on the Maunder Minimum, Eddy (1976) introduced the notion that the Sun is a variable star on long time scales. After the recent decade of vigorous research based on cosmic ray and sunspot data as well as on geomagnetic activity, an emerging consensus reconstruction of solar wind magnetic field strength has been forged for the last century. The consensus reconstruction shows reasonable agreement among the various reconstructions of solar wind magnetic field the past ~ 170 years. New magnetic indices open further possibilities for the exploitation of historic data. The solar wind is a direct result of solar magnetic activity providing an important link to the effects on the Earth's environment. Reassessment of the sunspot series (no Modern Grand Maximum) and new reconstructions of Total Solar Irradiance also contribute to our improved knowledge (or at least best guess) of the environment of the Earth System, with obvious implications for management of space-based technological assets or, perhaps, even climate. Several lines of evidence suggest that the Sun is entering a period of low activity, perhaps even a Grand Minimum. Average space weather might be "milder" with decreased solar activity, but the extreme events that dominate technological effects are not expected to disappear. Prediction of solar activity has a poor track record, but the progression of the current Cycle 24 is in accordance with its behavior predicted from the evolution of the solar polar fields, so perhaps there is hope.

FLARING SOLAR HALE SECTOR BOUNDARIES
L. **Svalgaard**1, I. G. Hannah2 and H. S. Hudson
2011 ApJ 733 49
The sector structure that organizes the magnetic field of the solar wind into large-scale domains has a clear pattern in the photospheric magnetic field as well. The rotation rate, 27-28.5 days, implies an effectively rigid rotation originating deeper in the solar interior than the sunspots. The photospheric magnetic field is known to be concentrated near that portion (the Hale boundary) in each solar hemisphere, where the change in magnetic sector polarity matches that between the leading and following sunspot polarities in active regions in the respective hemispheres. We report here that flares and microflares also concentrate at the Hale boundaries, implying that flux emergence and the creation of free magnetic energy in the corona also have a direct cause in the deep interior.

Iterative construction of the optimal sunspot number series

Michal **Švanda** (1 and 2), Martina Pavelková (1), Jiří Dvořák (3), Božena Solarová (1),
Solar Phys. **2022**
https://arxiv.org/pdf/2211.03332
The relative number of sunspots represents the longest evidence describing the level of solar activity. As such, its use goes beyond solar physics, e.g. towards climate research. The construction of a single representative series is a delicate task which involves a combination of observation of many observers. We propose a new iterative algorithm that allows to construct a target series of relative sunspot number of a hypothetical stable observer by optimally combining series obtained by many observers. We show that our methodology provides us with results that are comparable with recent reconstructions of both sunspot number and group number. Furthermore, the methodology accounts for the possible non-solar changes of observers' time series such as gradually changing observing conditions or slow change in the observers vision. It also provides us with reconstruction uncertainties. We apply the methodology to a limited sample of observations by ČESLOPOL network and discuss its properties and limitations.

Evolution and motions of magnetic fragments during the active region formation and decay: A statistical study

Michal **Švanda**1,2, Michal Sobotka2, Lucia Mravcová2,1 and Tatiana Výbošťoková3
A&A 647, A146 (**2021**)
https://www.aanda.org/articles/aa/pdf/2021/03/aa40127-20.pdf
https://doi.org/10.1051/0004-6361/202040127
Context. The evolution of solar active regions is still not fully understood. The growth and decay of active regions have mostly been studied in case-by-case studies.
Aims. Instead of studying the evolution of active regions case by case, we performed a large-scale statistical study to find indications for the statistically most frequent scenario.
Methods. We studied a large sample of active regions recorded by the Helioseismic and Magnetic Imager instrument. The sample was split into two groups: forming (367 members) and decaying (679 members) active regions. We tracked individual dark features (i.e. those that are assumed to be intensity counterparts of magnetised fragments from small objects to proper sunspots) and followed their evolution. We investigated the statistically most often locations of fragment merging and splitting as well as their properties.
Results. Our results confirm that statistically, sunspots form by merging events of smaller fragments. The coalescence process is driven by turbulent diffusion in a process similar to random-walk, where supergranular flows seem to play an important role. The number of appearing fragments does not seem to significantly correlate with the number of sunspots formed. The formation seems to be consistent with the magnetic field accumulation. Statistically, the merging occurs most often between a large and a much smaller object. The decay of the active region seems to take place preferably by a process similar to the erosion

Exploiting solar visible-range observations by inversion techniques: from flows in the solar subsurface to a flaring atmosphere

Michal **Švanda** (1 and 2), Jan Jurčák (2), David Korda (1), Jana Kašparová (2)
in the book "Reviews in Frontiers of Modern Astrophysics: From Space Debris to Cosmology" (eds Kabath, Jones and Skarka; publisher Springer Nature) **2020**
https://arxiv.org/pdf/2001.03874.pdf
Observations of the Sun in the visible spectral range belong to standard measurements obtained by instruments both on the ground and in the space. Nowadays, both nearly continuous full-disc observations with medium resolution and dedicated campaigns of high spatial, spectral and/or temporal resolution constitute a holy grail for studies that can capture (both) the long- and short-term changes in the dynamics and energetics of the solar atmosphere. Observations of photospheric spectral lines allow us to estimate not only the intensity at small regions, but also various derived data products, such as the Doppler velocity and/or the components of the magnetic field vector. We show that these measurements contain not only direct information about the dynamics of solar plasmas at the surface

of the Sun but also imprints of regions below and above it. Here, we discuss two examples: First, the local time-distance helioseismology as a tool for plasma dynamic diagnostics in the near subsurface and second, the determination of the solar atmosphere structure during flares. The methodology in both cases involves the technique of inverse modelling. **6 Sept 2017**

Polar cap magnetic field reversals during solar grand minima: could pores play a role?

Michal **Švanda**1,2, Allan Sacha Brun3, Thierry Roudier4 and Laurène Jouve
A&A 586, A123 (**2016**)
We study the magnetic flux carried by pores located outside active regions with sunspots and investigate their possible contribution to the reversal of the global magnetic field of the Sun. We find that they contain a total flux of comparable amplitude to the total magnetic flux contained in polar caps. The pores located at distances of 40–100 Mm from the closest active region systematically have the correct polarity of the magnetic field to contribute to the polar cap reversal. These pores can be found predominantly in bipolar magnetic regions. We propose that during grand minima of solar activity, such a systematic polarity trend, which is akin to a weak magnetic (Babcock-Leighton-like) source term, could still be operating but was missed by the contemporary observers because of the limited resolving power of their telescopes.

Issues with time–distance inversions for supergranular flows

Michal **Švanda**
A&A 575, A122 (**2015**)
Aims. Recent studies have shown that time–distance inversions for flows start to be dominated by a random noise at a depth of only a few Mm. It was proposed that the ensemble averaging might be a solution for learning about the structure of the convective flows, e.g. about the depth structure of supergranulation.
Methods. Time–distance inversion is applied to the statistical sample of ∼ 104 supergranules, which allows the inversion cost function to be regularised weakly about the random-noise term and thus provides a much better localisation in space. We compare these inversions at four depths (1.9, 2.9, 4.3, and 6.2 Mm) when using different spatio-temporal filtering schemes in order to gain confidence about these inferences.
Results. The flows inferred by using different spatio-temporal filtering schemes are different (even by the sign) even though the formal averaging kernels and the random-noise levels are very similar. The inverted flows changes its sign several times with depth. I suggest that this is due to the inaccuracies in the forward problem that are possibly amplified by the inversion. It is also possible that other time–distance inversions are affected by this.

Moat Flow System around Sunspots in Shallow Subsurface Layers

Michal **Švanda**1,2, Michal Sobotka1, and Tomáš Bárta
2014 ApJ 790 135
We investigate the subsurface moat flow system around McIntosh H-type symmetrical sunspots and compare it to the flow system within supergranular cells. Representatives of both types of flows are constructed by means of the statistical averaging of flow maps obtained by time-distance helioseismic inversions. We find that moat flows around H-type sunspots replace supergranular flows but there are two principal differences between the two phenomena: the moat flow is asymmetrical, probably due to the proper motion of sunspots with respect to the local frame of rest, while the flow in the supergranular cell is highly symmetrical. Furthermore, the whole moat is a downflow region, while the supergranule contains the upflow in the center, which turns into the downflow at about 60% of the cell radius from its center. We estimate that the mass downflow rate in the moat region is at least two times larger than the mass circulation rate within the supergranular cell.

The response of clouds and aerosols to cosmic ray decreases†

J. **Svensmark**, M. B. Enghoff, N. J. Shaviv, H. Svensmark
JGR Volume 121, Issue 9 September 2016 Pages 8152–8181 **2016** DOI: 10.1002/2016JA022689
A method is developed to rank Forbush Decreases (FDs) in the galactic cosmic ray radiation according to their expected impact on the ionization of the lower atmosphere. Then a Monte Carlo bootstrap based statistical test is formulated to estimate the significance of the apparent response in physical and micro-physical cloud parameters to FDs. The test is subsequently applied to one ground based and three satellite based datasets. Responses (> 95%) to FDs are found in the following parameters of the analyzed datasets. AERONET: Ångström exponent (cloud condensation nuclei changes), SSM/I: liquid water content, ISCCP: total, high and middle, IR detected clouds over the oceans, MODIS: cloud effective emissivity, cloud optical thickness, liquid water, cloud fraction, liquid water path, liquid cloud effective radius. Moreover, the responses in MODIS are found to correlate positively with the strength of the FDs, and the signs and magnitudes of the responses agree with model based expectations. The effect

is mainly seen in liquid clouds. An impact through changes in UV driven photo chemistry is shown to be negligible and an impact via UV absorption in the stratosphere is found to have no effect on clouds. The total solar irradiance has a relative decrease in connection with FDs of the order of 10−3, which is too small to have a thermodynamic impact on timescales of a few days. The results demonstrate that there is a real influence of FDs on clouds probably through ions.

Sixty Years in Solar Physics

Zdenˇek **Švestka**

Solar Phys (**2010**) 267: 235–250, **File**

I recount my career in solar physics beginning at Ondˇrejov Observatory in 1948 and ending with my ~30 year stay at the Laboratory of Space Research in Utrecht.

The reported durations of GOES Soft X-Ray flares in different solar cycles

Bill **Swalwell**, Silvia Dalla, Stephen Kahler, Stephen White, Alan Ling, Rodney Viereck, and Astrid Veronig

Space Weather **2018**

https://arxiv.org/pdf/1805.10246.pdf

The Geostationary Orbital Environmental Satellites (GOES) Soft X-ray (SXR) sensors have provided data relating to, \textit{inter alia}, the time, intensity and duration of solar flares since the 1970s. The GOES SXR Flare List has become the standard reference catalogue for solar flares and is widely used in solar physics research and space weather. We report here that in the current version of the list there are significant differences between the mean duration of flares which occurred before May 1997 and the mean duration of flares thereafter. Our analysis shows that the reported flare timings for the pre-May 1997 data were not based on the same criteria as is currently the case. This finding has serious implications for all those who used flare duration (or fluence, which depends on the chosen start and end times) as part of their analysis of pre-May 1997 solar events, or statistical analyses of large samples of flares, \textit{e.g.} as part of the assessment of a Solar Energetic Particle forecasting algorithm.

The dynamics of 3-minute wavefronts and their relation to sunspot magnetic fields

Robert **Sych**, David B. Jess, Jiangtao Su

Royal Society Philosophical Transactions A **2020**

https://arxiv.org/pdf/2007.09369.pdf

We present a study of wave processes occurring in solar active region NOAA 11131 on **2010 December 10**, captured by the Solar Dynamics Observatory in the 1600A, 304A, and 171A channels. For spectral analysis we employed pixelised wavelet filtering together with a developed digital technique based on empirical mode decomposition. We studied the 3-minute wave dynamics to obtain relationships with the magnetic structuring of the underlying sunspot. We found that during development of wave trains the motion path occurred along a preferential direction, and that the broadband wavefronts can be represented as a set of separate narrowband oscillation sources. These sources become visible as the waves pass through the umbral inhomogeneities caused by the differing magnetic field inclination angles. We found the spatial and frequency fragmentation of wavefronts, and deduced that the combination of narrowband spherical and linear parts of the wavefronts provide the observed spirality. Maps of the magnetic field inclination angles confirm this assumption. We detect the activation of umbral structures as the increasing of oscillations in the sources along the front ridge. Their temporal dynamics are associated with the occurrence of umbral flashes. Spatial localisation of the sources is stable over time and depends on the oscillation period. We propose that these sources are the result of wave paths along the loops extending outwards from the magnetic bundles of the umbra.

Chromospheric Heating from Local Magnetic Growth and Ambipolar Diffusion Under Non-Equilibrium Conditions

Juan Martínez **Sykora**, Jaime de la Cruz Rodríguez, Milan Gošić, Alberto Sainz Dalda, Viggo H. Hansteen, Bart De Pontieu

ApJL **2022**

https://arxiv.org/pdf/2211.08472.pdf

The heating of the chromosphere in internetwork regions remains one of the foremost open questions in solar physics. In the present study we tackle this old problem by using a very high spatial-resolution simulation of quiet-Sun conditions performed with radiative MHD numerical models and IRIS observations. We have expanded a previously existing 3D radiative MHD numerical model of the solar atmosphere, which included self-consistently locally driven magnetic amplification in the chromosphere, by adding ambipolar diffusion and time-dependent non-equilibrium hydrogen ionization to the model. The energy of the magnetic field is dissipated in the upper chromosphere, providing a large temperature increase due to ambipolar diffusion and the non-equilibrium ionization (NEQI). At the same time, we find that adding the ambipolar diffusion and NEQI in the simulation has a minor

impact on the local growth of the magnetic field in the lower chromosphere and its dynamics. Our comparison between synthesized Mg II profiles from these high spatial resolution models, with and without ambipolar diffusion and NEQI, and quiet Sun and coronal hole observations from IRIS now reveal a better correspondence. The intensity of profiles is increased and the line cores are slightly broader when ambipolar diffusion and NEQI effects are included. Therefore, the Mg II profiles are closer to those observed than in previous models, but some differences still remain. **2016 March 25** and **2017 October 15**

Analysis of Quiescent Corona X-ray Spectra from SphinX during the 2009 Solar Minimum

Janusz **Sylwester**, B. Sylwester, M. Siarkowski, K. J. H. Phillips, P. Podgorski, M. Gryciuk

Solar Phys. **294**, Article number: 176 **2019**

https://arxiv.org/pdf/1912.03082.pdf

https://link.springer.com/content/pdf/10.1007/s11207-019-1565-9.pdf

The SphinX X-ray spectrophotometer on the {\em CORONAS-PHOTON}\/ mission observed the 1~--~15\,keV X-ray spectrum of the spatially integrated solar corona during the deep minimum of 2009, when solar activity was exceptionally low. Its sensitivity for energies >1.2\,keV was higher than that of any other solar X-ray spectrometer in orbit at the time, including the detectors on GOES. Using much improved instrumental data than was used previously, we analyzed SphinX spectra in 576 intervals for which there was no discernible activity (NA), 40 intervals when there were X-ray brightenings (B), and sixteen intervals when there were micro-flares with peak emission less than GOES A1 (F). An instrumental background spectrum, formed over 34 hours of spacecraft night-time periods and including electronic noise and particle radiation, was subtracted from the solar spectra. Theoretical spectra were used to deduce temperatures on an isothermal assumption for the NA, B, and F intervals (1.69, 1.81, and 1.86\,MK respectively). Differential emission measure (DEM) analysis for the same spectra revealed a "cooler" component (log\,T=6.2 or T≈1.6\,MK) in each case, but with a second hotter component having a less well-defined peak temperature varying from ≈2.5 to ≈3.5\,MK (log\,T=6.4 and 6.55) and an emission measure between two and three orders smaller than that of the cooler component. These results are similar to those obtained at times just after solar minimum with the EVE instrument. A very hot component that might indicate the signature of nano-flare heating of the corona is not evident in SphinX data.

https://link.springer.com/content/pdf/10.1007%2Fs10686-018-09618-4.pdf

We present a novel X-ray assembly of functionally related instrument blocks intended to measure solar flare and active region (AR) spectra from within the Russian instrument complex KORTES, to be mounted aboard the International Space Station (ISS). SolpeX consists of three blocks: fast-rotating multiple flat crystal Bragg spectrometer, pin-hole X-ray spectral imager and Bragg polarimeter. This combination of measuring blocks will offer an opportunity to detect/measure possible X-ray polarization in soft X-ray emission lines/continuum and record spectra of solar flares, in particular during their impulsive phases. Polarized Bremsstrahlung and line emission may arise from presence of directed particle beams colliding with denser regions of flares. As a result of evaporation, the X-ray spectral-components are expected to be Doppler shifted, which will also be measured. In this paper, we present details of the construction of three SolpeX blocks and discuss their functionality. Delivery of KORTES with SolpeX to ISS is expected in 2020/2021.

Chromospheric and coronal heating and jet acceleration due to reconnection driven by flux cancellation. II. Cancellation of two magnetic polarities of unequal flux

Syntelis P., Priest E. R

A&A 649, A101 **2021**

https://arxiv.org/pdf/2103.16184.pdf

https://doi.org/10.1051/0004-6361/202140474

Context. Recent observations have shown that magnetic flux cancellation occurs at the photosphere more frequently than previously thought.

Aims. In order to understand the energy release by reconnection driven by flux cancellation, we previously studied a simple model of two cancelling polarities of equal flux. Here, we further develop our analysis to achieve a more general setup where the two cancelling polarities have unequal magnetic fluxes and where many new features are revealed.

Methods. We carried out an analytical study of the cancellation of two magnetic fragments of unequal and opposite flux that approach one another and are located in an overlying horizontal magnetic field.

Results. The energy release as microflares and nanoflares occurs in two main phases. During phase 1a, a separator is

formed and reconnection is driven at it as it rises to a maximum height and then moves back down to the photosphere, heating the plasma and accelerating plasma jets in the process. During phase 1b, once the separator moves back to the photosphere, it bifurcates into two null points. Reconnection is no longer driven at the separator and an isolated magnetic domain connecting the two polarities is formed. During phase 2, the polarities cancel out at the photosphere as magnetic flux submerges below the photosphere and as reconnection occurs at and above the photosphere and plasma jets and a mini-filament eruption can be produced.

A Cancellation Nanoflare Model for Solar Chromospheric and Coronal Heating III. 3D Simulations and Atmospheric Response

P. **Syntelis**, E.R. Priest

ApJ **891** 52 **2020**

https://arxiv.org/pdf/2001.10456.pdf

https://doi.org/10.3847/1538-4357/ab6ffc

Inspired by recent observations suggesting that photospheric magnetic flux cancellation occurs much more frequently than previously thought, we analytically estimated the energy released from reconnection driven by photospheric flux cancellation, and proposed that it can act as a mechanism for chromospheric and coronal heating (Priest et al., 2018). Using two-dimensional simulations we validated the analytical estimates and studied the resulting atmospheric response (Syntelis et al. 2019). In the present work, we set up three-dimensional resistive MHD simulations of two cancelling polarities in a stratified atmosphere with a horizontal external field to further validate and improve upon the analytical estimates. The computational evaluation of the parameters associated with the energy release are in good qualitative agreement with the analytical estimates. The computational Poynting energy flux into the current sheet is in good qualitative agreement with the analytical estimates, after correcting the analytical expression to better account for the horizontal extent of the current sheet. The atmospheric response to the cancellation is the formation of hot ejections, cool ejections, or a combination of both hot and cool ejections, which can appear with a time difference and/or be spatially offset, depending on the properties of the cancelling region and the resulting height of the reconnection. Therefore, during the cancellation, a wide spectrum of ejections can be formed, which can account for the variety of multi-thermal ejections associated with Ellerman bombs, UV bursts and IRIS bombs, and also other ejections associated with small-scale cancelling regions and spicules.

Successful and Failed Flux Tube Emergence in the Solar Interior

P. **Syntelis**, V. Archontis, A. Hood

2019 *ApJ* **874** 15

https://arxiv.org/pdf/1902.07969.pdf

sci-hub.tw/10.3847/1538-4357/ab0959

We report on our three-dimensional (3D) magnetohydrodynamic (MHD) simulations of cylindrical weakly twisted flux tubes emerging from 18 Mm below the photosphere. We perform a parametric study, by varying the initial magnetic field strength (B0), radius (R), twist (α) and length of the emerging part of the flux tube (λ) to investigate how these parameters affect the transfer of the magnetic field from the convection zone to the photosphere. We show that the efficiency of emergence at the photosphere (i.e. how strong the photospheric field will be in comparison to B0) depends not only on the B0 but also the morphology of the emerging field and the twist. We show that parameters such as B0 and magnetic flux cannot alone determine whether a flux tube will emerge to the solar surface. For instance, high-B0(weak-B0) fields may fail (succeed) to emerge at the photosphere, depending on their geometrical properties. We also show that the photospheric magnetic field strength can vary greatly for flux tubes with the same B0 but different geometric properties. Moreover, in some cases we have found scaling laws, whereby the magnetic field strength scales with the local density as $B \propto \rho^{\kappa}$, where $\kappa \approx 1$ deeper in the convection zone and $\kappa < 1$, close to the photosphere. The transition between the two values occurs approximately when the local pressure scale (Hp) becomes comparable to the diameter of the flux tube ($Hp \approx 2R$). We derive forms to explain how and when these scaling laws appear and compare them with the numerical simulations.

A Cancellation Nanoflare Model for Solar Chromospheric and Coronal Heating II. 2D Theory and Simulations

P. **Syntelis**, E.R. Priest, L.P. Chitta

2019 *ApJ* **872** 32

https://arxiv.org/pdf/1901.02798.pdf

Recent observations at high spatial resolution have shown that magnetic flux cancellation occurs on the solar surface much more frequently than previously thought, and so this led Priest et al 2018 to propose magnetic reconnection driven by photospheric flux cancellation as a mechanism for chromospheric and coronal heating. In particular, they estimated analytically the amount of energy released as heat and the height of the energy release during flux cancellation. In the present work, we take the next step in the theory by setting up a two-dimensional resistive MHD simulation of two canceling polarities in the presence of a horizontal external field and a stratified atmosphere in order to check and improve upon the analytical estimates. Computational evaluation of the energy release during

reconnection is found to be in good qualitative agreement with the analytical estimates. In addition, we go further and undertake an initial study of the atmospheric response to reconnection. We find that, during the cancellation, either hot ejections or cool ones or a combination of both hot and cool ejections can be formed, depending on the height of the reconnection location. The hot structures can have the density and temperature of coronal loops, while the cooler structures are suggestive of surges and large spicules.

Simulation Study of Hemispheric Phase-Asymmetry in the Solar Cycle

D. **Syukuya**, K. Kusano
ApJ **2016**
https://arxiv.org/pdf/1612.03294v1.pdf

Observations of the sun suggest that solar activities systematically create north-south hemispheric asymmetries. For instance, the hemisphere in which the sunspot activity is more active tends to switch after the early half of each solar cycle. Svalgaard & Kamide (2013) recently pointed out that the time gaps of polar field reversal between the north and south hemispheres are simply consequences of the asymmetry of sunspot activity. However, the mechanism underlying the asymmetric feature in solar cycle activities is not yet well understood. In this paper, in order to explain the cause of the asymmetry from the theoretical point of view, we investigate the relationship between the dipole- and quadrupole-type components of the magnetic field in the solar cycle using the mean-field theory based on the flux transport dynamo model. As a result, we found that there are two different attractors of the solar cycle, in which either the north or the south polar field is first reversed, and that the flux transport dynamo model well explains the phase-asymmetry of sunspot activity and the polar field reversal without any ad hoc source of asymmetry.

A deep learning virtual instrument for monitoring extreme UV solar spectral irradiance

Alexandre **Szenicer**, David F. Fouhey, Andres Munoz-Jaramillo, Paul J. Wright, ...
Science Advances 02 Oct **2019**: Vol. 5, no. 10, eaaw6548
https://sci-hub.se/10.1126/sciadv.aaw6548

Measurements of the extreme ultraviolet (EUV) solar spectral irradiance (SSI) are essential for understanding drivers of space weather effects, such as radio blackouts, and aerodynamic drag on satellites during periods of enhanced solar activity. In this paper, we show how to learn a mapping from EUV narrowband images to spectral irradiance measurements using data from NASA's Solar Dynamics Observatory obtained between 2010 to 2014. We describe a protocol and baselines for measuring the performance of models. Our best performing machine learning (ML) model based on convolutional neural networks (CNNs) outperforms other ML models, and a differential emission measure (DEM) based approach, yielding average relative errors of under 4.6% (maximum error over emission lines) and more typically 1.6% (median). We also provide evidence that the proposed method is solving this mapping in a way that makes physical sense and by paying attention to magnetic structures known to drive EUV SSI variability.

Coronal Imaging with the Solar UltraViolet Imager

Sivakumara K. **Tadikonda**, Douglas C. Freesland, Robin R. Minor, Daniel B. Seaton, Gustave J. Comeyne, Alexander Krimchansky
Solar Physics March **2019**, 294:28
https://arxiv.org/ftp/arxiv/papers/1901/1901.08531.pdf
https://link.springer.com/content/pdf/10.1007%2Fs11207-019-1411-0.pdf

We investigate the coronal imaging capabilities of the Solar UltraViolet Imager (SUVI) on the Geostationary Operational Environmental Satellite-R series spacecraft. Nominally Sun-pointed, SUVI provides solar images in six Extreme UltraViolet (EUV) wavelengths. On-orbit data indicated that SUVI had sufficient dynamic range and sensitivity to image the corona to the largest heights above the Sun to date while simultaneously imaging the Sun. We undertook a campaign to investigate the existence of the EUV signal well beyond the nominal Sun-centered imaging area of the solar EUV imagers. We off-pointed SUVI line-of-sight by almost one imaging area around the Sun. We present the details of the campaign conducted when the solar cycle is at near the minimum and some results that affirm the EUV presence to beyond three solar radii.

Readdressing the UV solar variability with SATIRE-S: non-LTE effects

R. V. **Tagirov**, A. I. Shapiro, N. A. Krivova, Y. C. Unruh, K. L. Yeo, S. K. Solanki
A&A 631, A178 **2019**
https://arxiv.org/pdf/1909.11736.pdf
https://doi.org/10.1051/0004-6361/201935121

Context. Solar spectral irradiance (SSI) variability is one of the key inputs to models of the Earth's climate. Understanding solar irradiance fluctuations also helps to place the Sun among other stars in terms of their brightness variability patterns and to set detectability limits for terrestrial exo-planets.
Aims. One of the most successful and widely used models of solar irradiance variability is SATIRE-S. It uses

spectra of the magnetic features and surrounding quiet Sun computed with the ATLAS9 spectral synthesis code under the assumption of Local Thermodynamic Equilibrium (LTE). SATIRE-S has been at the forefront of solar variability modelling, but due to the limitations of the LTE approximation its output SSI has to be empirically corrected below 300 nm, which reduces the physical consistency of its results. This shortcoming is addressed in the present paper.
Methods. We replace the ATLAS9 spectra of all atmospheric components in SATIRE-S with the spectra calculated using the non-LTE Spectral Synthesis Code (NESSY). We also use Fontenla et al. (1999) temperature and density stratification models of the solar atmosphere to compute the spectrum of the quiet Sun and faculae.
Results. We compute non-LTE contrasts of spots and faculae and combine them with the SDO/HMI filling factors of the active regions to calculate the total and spectral solar irradiance variability during solar cycle 24.
Conclusions. The non-LTE contrasts result in total and spectral solar irradiance in good agreement with the empirically corrected output of the LTE version. This suggests that empirical correction introduced into SATIRE-S output is well judged and that the corrected total and spectral solar irradiance obtained from the SATIRE-S model in LTE is fully consistent with the results of non-LTE computations.

Reconstructing solar magnetic fields from historical observations X. Effect of magnetic field inclination and boundary structure on AIA 1600 Å emission

Ismo **Tähtinen**, Alexei A. Pevtsov, Timo Asikainen, Kalevi Mursula
A&A **2024**
https://arxiv.org/pdf/2409.17771

The relation between the intensity of chromospheric emissions and the photospheric magnetic field strength has been examined in several studies, but the effect of the magnetic field inclination on chromospheric emissions remains almost unexplored. We study how the inclination of the photospheric magnetic field, as measured by the full 3D magnetic vector from the Helioseismic and Magnetic Imager (HMI), affects the relationship between the magnetic field strength and the far-ultraviolet emission at around 1600 Å observed by the Atmospheric Imaging Assembly (AIA). We also study how these parameters change spatially close to the active region perimeter. We analyzed the mutual dependence of 1168 co-temporal AIA and HMI observations from 2014 to 2017. We focused on magnetically active regions outside sunspots (e.g., plages and network) close to the solar disk center. We studied how the AIA and HMI parameters change with distance from the active region perimeter. The AIA 1600 emission typically decreases with increasing (more horizontal) inclination. For all inclinations, AIA 1600 emission increases with increasing magnetic field strength until saturating at some peak intensity, which depends on the cosine of the inclination, with horizontal regions saturating at lower intensities. In addition, we find that activity clusters have a narrow boundary (< 2 arcseconds) in which the AIA 1600 intensity, magnetic field strength, and inclination distributions and relations differ significantly from those in the inner layers. This study demonstrates the significant effect that magnetic field inclination and activity cluster border regions have on chromospheric emissions. Although the observed effects are likely reduced in low-resolution observations where different regions are averaged together, a detailed study is needed to examine the emission--magnetic field relation at different resolutions.

Straight outta photosphere: Open solar flux without coronal modeling

Ismo **Tähtinen**, Timo Asikainen, Kalevi Mursula
A&A 688, L32 **2024**
https://arxiv.org/pdf/2408.11525
https://www.aanda.org/articles/aa/pdf/2024/08/aa51267-24.pdf

The open solar flux, that is, the total magnetic flux escaping the Sun, is one of the most important parameters connecting solar activity to the Earth. The open solar flux is commonly estimated from photospheric magnetic field measurements by making model assumptions about the solar corona. However, the question in which way the open solar flux is directly related to the distribution of the photospheric magnetic field is still partly unknown. We aim to reconstruct the open solar flux directly from the photospheric magnetic fields without making any assumptions about the corona and without using coronal hole observations, for instance. We modified an earlier vector sum method by taking magnetic field polarities into account and applied the method to the synoptic magnetograms of six instruments to determine the open solar flux from solar cycles 21-24. Results. The modified vector sum method produces a vector of the global solar magnetic field whose magnitude closely matches the open solar flux from the potential field source surface (PFSS) model both by the absolute scale and the overall time evolution for each of the six magnetograms. The latitude of this vector follows the Hale cycle by always pointing toward the dominantly positive-polarity hemisphere, and its longitude coincides with the location of the main coronal holes of the McIntosh Archive. We find multi-year periods during which the longitude of the vector slowly drifts or stays rather stationary in the Carrington frame. These periods are punctuated by times when the longitude moves rapidly in the Carrington frame. By comparing the magnitude of this vector to the open solar flux calculated from the PFSS model with different source surface heights, we find that the best match is produced with a source surface height $R_{ss}=2.4-2.5R_{\odot}$.

Reconstructing solar magnetic fields from historical observations

VIII. AIA 1600 Å contrast as a proxy of solar magnetic fields

I. **Tähtinen**1, I. I. Virtanen1,2, A. A. Pevtsov3 and K. Mursula1
A&A 664, A2 (**2022**)
https://www.aanda.org/articles/aa/pdf/2022/08/aa41164-21.pdf

Context. The bright regions in the solar chromosphere and temperature minimum have a good spatial correspondence with regions of intense photospheric magnetic field. Bright regions are visible in different emission lines and parts of the continuum. Their observation started more than a hundred years ago with the invention of the spectroheliograph. While the historical spectroheliograms are essential for studying the long-term variability of the Sun, the modern satellite-borne observations can help us reveal the nature of chromospheric brightenings in previously unattainable detail.
Aims. Our aim is to improve the understanding of the relation between magnetic fields and radiative structures byf studying modern seeing-free observations of far-ultraviolet (FUV) radiation around 1600 Å and photospheric magnetic fields.
Methods. We used Helioseismic and Magnetic Imager (HMI) observations of photospheric magnetic fields and Atmospheric Imaging Assembly (AIA) observations of FUV contrast around 1600 Å. We developed a robust method to find contrast thresholds defining bright and dark AIA 1600 Å pixels, and we combine them to bright and dark clusters. We investigate the relation of magnetic fields and AIA 1600 Å radiation in bright and dark clusters.
Results. We find that the percentage of bright pixels (ranging from 2% to 10%) almost entirely explains the observed variability of 1600 Å emission. We developed a multilinear regression model based on the percentages of bright and dark pixels, which can reliably predict the magnitude of the disk-averaged unsigned magnetic field. We find that bright and dark clusters closely correspond respectively to the populations of moderate ($B > 55$ G) and strong ($B > 1365$ G) magnetic field HMI clusters. The largest bright clusters have a constant mean unsigned magnetic field, as found previously for Ca II K plages. However, the magnetic field strength of bright clusters is 254.7 ± 0.1 G, which is roughly 100 G larger than found earlier for Ca II K plages.

Relationship between magnetic field properties and statistical flow using numerical simulation and magnetic feature tracking on solar photosphere

K. **Takahata**, H. Hotta, Y. Iida, T. Oba
MNRAS Volume 503, Issue 3, May **2021**, Pages 3610–3616,
https://doi.org/10.1093/mnras/stab710
https://arxiv.org/pdf/2103.03789

We perform radiative magnetohydrodynamic calculations for the solar quiet region to investigate the dependence of statistical flow on magnetic properties and the three-dimensional (3D) structure of magnetic patches in the presence of large-scale flow that mimics differential rotation. It has been confirmed that strong magnetic field patches move faster in the longitudinal direction at the solar surface. Consequently, strong magnetic patches penetrate deeper into the solar interior. The motion of the deep-rooted magnetic patches is influenced by the faster differential rotation in the deeper layer. In this study, we perform realistic radiative magnetohydrodynamic calculations using R2D2 code to validate that stronger patches have deeper roots. We also add large-scale flow to mimic the differential rotation. The magnetic patches are automatically detected and tracked, and we evaluate the depth of 30,000 magnetic patches. The velocities of 2.9 million magnetic patches are then measured at the photosphere. We obtain the dependence of these values on the magnetic properties, such as field strength and flux. Our results confirm that strong magnetic patches tend to show deeper roots and faster movement, and we compare our results with observations using the point spread function of instruments at the Hinode and Solar Dynamics Observatory (SDO). Our result is quantitatively consistent with previous observational results of the SDO.

The Instantaneous Response of Geomagnetic Field, near-Earth IMF and Cosmic-Ray Intensity to Solar Flares

Jouni J. **Takalo**
Sol. Phys. **2024**
https://arxiv.org/pdf/2405.15340

We show using superposed epoch analysis (SEA) that the most energetic protons (greater than 60 MeV) in near-Earth IMF have a peak almost immediately (less than a day) after peak in solar flare index (SFI), while protons greater than 10 MeV peak one day after the SFI and protons greater than 1 MeV two days after the SFI. The geomagnetic indices AU, -AL, PC, Ap and -Dst peak after two to three days in SEAs after the peak in SFI. The auroral electrojet indices AU and -AL, however, have only low peaks. Especially, the response of the eastward electrojet, AU, to SFI is negligible compared to other geomagnetic indices. The SEAs of the SFI and cosmic ray counts (CR) show that the deepest decline in the CR intensity follows also with 2-3 day lag the maximum of the SFI for the Solar Cycles 20-24. The depth of the declines are related to the SFI strength of each cycle, i.e, the average decline is about 5% for the Cycles 21 and 22, but only 3% for the Cycle 24. The strongest Cycle 19, however, differs from the other cycles such that it has double-peaked decline and lasts longer than the decline of the other

cycles. The double superposed epoch analyses show that the response of IMF Bv2, which is about two days, and CR to SFI are quite simultaneous, but sometimes Bv2 may peak somewhat earlier than the decline existing in CR.

Analysis of the Solar Flare Index for Solar Cycles 18 – 24: Extremely Deep Gnevyshev Gap in the Chromosphere

Jouni **Takalo**

Solar Phys. **298**, Article number: 86 **2023**

https://arxiv.org/pdf/2306.04239.pdf

https://doi.org/10.1007/s11207-023-02177-8

We study the solar flare index (SFI) for the solar cycles 18\,--\,24. We find that SFI has deeper Gnevyshev gap (GG) in its first principal component than other atmospheric parameters. The GG is extremely clear especially in the even cycles.

The GG of the SFI appears about a half year later as a drop in the interplanetary magnetic field near the Earth and in the geomagnetic Ap-index. The instantaneous response of the magnetic field to solar flares, however, shows about two to three days after the eruption as a high, sharp peak in the cross-correlation of the SFI and Ap-index and as a lower peak in SFI vs. IMF B cross-correlation. We confirm these rapid responses using superposed-epoch analysis. The most active flare cycles during 1944-2020 are the Cycles 19 and 21. The Cycle 18 has very strong SFI days as much as Cycle 22, but it has least nonzero SFI days in the whole interval. Interestingly Cycle 20 can be compared to the Cycles 23 and 24 in its low flare activity, although it locates between the most active SFI cycles.

Temporal and Latitudinal Variation in Penumbra-Umbra Ratios of the Sunspots: Analyses of RGO, Kodaikanal and Debrecen Databases

Jouni **Takalo**

Solar Phys. **2023**

https://arxiv.org/pdf/2305.10757.pdf

We study the latitudinal distribution and temporal evolution of the sunspot penumbra-umbra ratio (q) for the even and odd Solar Cycles 12-24 of RGO sunspot groups, SC21-SC24 of Debrecen sunspot groups and Kodaikanal sunspot dataset for SC16-SC24. We find that RGO even (odd) Cycles have q-values 5.20 (4.75), Kodaikanal even (odd) cycles have q-values 5.27 (5.43), and Debrecen cycles has q-value 5.74 on the average. We also show that q is at lowest around the Equator of the Sun and increases towards higher latitudes having maximum values at about 10-25 degrees. This is understandable, because smaller sunspots and groups locate nearer to Equator and have smaller q-values than larger sunspots and groups, which maximize at about 10-20 degrees at both hemispheres. The error limits are very wide and thus the confidence of this result is somewhat vague. For Debrecen dataset we find a deep valley in the temporal q-values before the middle of the cycle. We show that this exists simultaneously with the Gnevyshev gap (GG) in the graph of the total and umbral areas of the large sunspot groups. Other databases do not show GG in their q-graphs, although GG exists in their temporal total area and umbral area.

Extracting Hale Cycle Related Components from Cosmic-Ray Data Using Principal Component Analysis

Jouni J. **Takalo**

Solar Phys. **297**, Article number: 113 **2022**

https://arxiv.org/pdf/2206.09350.pdf

https://link.springer.com/content/pdf/10.1007/s11207-022-02048-8.pdf

We decompose the monthly cosmic-ray data, using several neutron monitor count rates, of Cycles 19-24 with principal component analysis (PCA). We show using different cycle limits that the first and second PC of cosmic-ray (CR) data explain 77-79% and 13-15% of the total variation of the Oulu CR Cycles 20-24 (C20- C24), 73-77% and 13-17% of the variation of Hermanus C20-C24, and 74-78% and 17-21% of the Climax C19-C22, respectively. The PC1 time series of the CR Cycles 19-24 has only one peak in its power spectrum at the period 10.95 years, which is the average solar cycle period for the interval SC19-SC24. The PC2 time series of the same cycles has a clear peak at period 21.90 (Hale cycle) and another peak at 1/3 of that period with no peak at the solar cycle period. We show that the PC2 of the CR is essential in explaining the differences in the intensities of the even and odd cycles of the CR. The odd cycles have positive phase in the first half and negative phase in the second half of their PC2. This leads to slow decrease of the intensity in the beginning of the cycle and at minimum for the odd cycles. On the contrary, for the even cycles the phases are vice versa and this leads to faster decrease and more rapid recovery in the CR intensity of the cycle. As a consequence the even cycles have more peak-like structure. The only exceptions of this rule are Cycles 23 and 24 such the former has almost zero line PC2, and the latter has similar PC2 than the earlier odd cycles. These results are confirmed with skewness-kurtosis (S-K) analysis. Furthermore, S-K shows that other even and odd cycles, except Cycle 21, are on the regression line with correlation coefficient 0.85. The Cycles 21 of all calculated eight stations are compactly located in the S -K coordinate system and have smaller skewnesses and higher kurtoses than the odd Cycles 23.

Spatial and Temporal Distribution of Solar Green Line Corona for Solar Cycles 18-24

Jouni J. **Takalo**

Solar Phys. **2022**

https://arxiv.org/pdf/2206.09351.pdf

Homogeneous coronal data set (HCDS) of the green corona (Fe XIV) and coronal index of the solar activity (CI) have been used to study time-latitudinal distribution in solar cycles 18-24 and compared with similar distribution of sunspots, the magnetic fields and the solar radio flux 10.7 cm. The most important results are: (a) distribution of coronal intensities related to the cycle maximum are different for individual cycles, (b) the poleward migration of the HCDS from mid latitudes in each cycle exists, even in extremely weak Cycle 24, and the same is valid for the equatorward migration (c) the overall values of HCDS are slightly stronger for the northern hemisphere than for the southern one, (d) distribution of the HDCS are in coincidence with strongest photospheric magnetic fields (B>50 Gauss) and histogram of the sunspot groups, (e) Gnevyshev gap was confirmed with at least 95% confidence in the CI, however, with different behavior for odd and even cycles. Principal component analysis (PCA) showed that the first and second component account for 87.7% and 7.3% of the total variation of the CI. Furthermore, the PC2 of the green corona was quite different for cycle 21, compared with other cycles.

Separating the aa-index into Solar and Hale Cycle Related Components Using Principal Component Analysis

Jouni **Takalo**

Solar Physics volume 296, Article number: 80 (**2021**)

https://link.springer.com/content/pdf/10.1007/s11207-021-01825-1.pdf

https://doi.org/10.1007/s11207-021-01825-1

We decompose the monthly aa-index of Cycles 10 to 23 using principal component analysis (PCA). We show that the first component (PC1) is related to the 11-year solar cycle, and accounts for 41.5% of the variance of the data. The second component (PC2) is related to 22-year Hale cycle, and explains 23.6% of the variance of the data. The PC1 time series of the aa-index for Cycles 10 – 23 has only one peak in its power spectrum at the period 10.95 years, which is the average solar cycle (SC) period for the interval SC10 – SC23. The PC2 time series of the same cycles has a clear peak at period 21.90 (Hale cycle) and a smaller peak at 3/4 of that period. We also study the principal components of the sunspot number (SSN) for Cycles 10 – 23, and compare the mutual behavior of the PC2 components of the aa-index and SSN PCA analyses. We note that they are in the same phase in all other cycles but Solar Cycles 15 and 20. The aa-index of Cycle 20 also differs from other even aa-index cycles in its shape, especially in anomalously high peaks during its descending phase. Even though there is a coherence in the PC2 time series phases of the aa-index and sunspot number, this effect is too small to be the origin of all the differences between the shape of even and odd aa cycles. We estimate that 30% of the shape of the PC2 component of the aa-index is due to the shape of the PC2 of the sunspot number and the rest to other recurrent events in the Sun and solar wind. The first maximum of the aa-index (typical to odd cycles), during sunspot maximum, has been shown to be related to coronal mass ejections (CME), while the second maximum (typical to even cycles) in the cycle descending phase, is probably related to high-speed streams (HSS). The last events increase the activity level such that the minimum between even and odd cycle pairs is always higher than the minimum between succeeding odd and even cycle pairs.

Comparison of geomagnetic indices during even and odd solar cycles SC17-SC24: Signatures of Gnevyshev gap in geomagnetic activity

Jouni J. **Takalo**

Solar Phys. **296**, Article number: 19 (**2021**)

https://arxiv.org/pdf/2012.05061.pdf

https://link.springer.com/content/pdf/10.1007/s11207-021-01765-w.pdf

We show that the time series of sunspot group areas has a gap, so-called Gnevyshev gap (GG), between ascending and descending phases of the cycle and especially so for the even cycles. For the odd cycles this gap in less obvious, and is only a small decline after the maximum of the cycle. We resample the cycles to have same length of 3945 days (about 10.8 years), and show that the decline is between 1445-1567 days after the start of the cycle for the even cycles, and extending sometimes until 1725 days from the start of the cycle. For the odd cycles the gap is a little earlier 1332-1445 days after the start of the cycles with no extension. We analyze geomagnetic disturbances for solar cycles 17-24 using Dst-index, related Dxt- and Dcx-indices and Ap-index. In all of these time series there is a decline at the time or somewhat after the GG in the solar indices, and as deepest between 1567-1725. The declines are significant at 99 % level for both even and odd cycles of the Dst-index and for Dxt-, Dcx- and Ap-indices for even cycles. For odd cycles of Dxt-index the significance is 95 %, but insignificant for odd cycles of Dcx- and Ap indices. We, however, show that for the cycles 21 and 23, for which Dst exists, the GG is more intense than for the earlier odd cycles. The analyzes of OMNI2 data for 1964-2020 (SC20-SC24) show that these gaps during the maxima of the solar cycles can be seen also in the near-Earth solar wind velocity and IMF magnetic field intensity, and the energy function BV^2.

Temporal Distribution of Solar Cycle 24 Sunspot Groups: Comparison to Cycles 12-23

Jouni J. **Takalo**

ANNALS OF GEOPHYSICS **2020**

https://arxiv.org/ftp/arxiv/papers/2011/2011.12559.pdf

We analyze the temporal distribution of sunspot groups for even and odd cycles in the range SC12-SC24. It seems that cycle 24 is a characteristic even cycle, although with low amplitude. The number of large sunspot groups for cycle 24 is relatively smaller than for the average of both even and odd cycles SC12-SC23, and there is a deep decline of the large groups in the middle of the cycle. Temporal evolution of the sunspot groups of the even cycles is non-synchronous such that the northern hemisphere distribution of groups maximizes earlier that the southern hemisphere groups. This leads to a double-peak structure for the average even cycle. On the other hand, the distributions of the sunspot groups of odd cycles maximize simultaneously. We show that this double-peak structure intensifies the Gnevyshev gap (GG) for the even cycles, but is not its primary cause. On the contrary, we show that the GG exists for even and odd cycles, and separately on both hemispheres. We resample all cycles to have equal number of 3945 days and study the difference in the evolution of average total group area and average group area of the even and odd cycles separately. The analysis shows that there is a decline in both total area and average area in the even cycles 1445 days (about four years) after the beginning of the cycle, which is at least 99 % significant for both total and average area. The odd cycles do not have such a clear decline.

Comparison of the shape and temporal evolution of even and odd solar cycles

Jouni **Takalo** and Kalevi Mursula

A&A 636, A11 (**2020**)

https://www.aanda.org/articles/aa/pdf/2020/04/aa37488-20.pdf

https://arxiv.org/pdf/2004.03855.pdf

We study the difference in the shape of solar cycles for even and odd cycles using the Wolf sunspot numbers and group sunspot numbers of solar cycles 1−23. We furthermore analyse the data of sunspot area sizes for even and odd cycles SC12−SC23 and sunspot group data for even and odd cycles SC8−SC23 to compare the temporal evolution of even and odd cycles.

Methods. We applied the principal component analysis (PCA) to sunspot cycle data and studied the first two components, which describe the average cycle shape and cycle asymmetry. We used a distribution analysis to analyse the temporal evolution of the even and odd cycles and determined the skewness and kurtosis for even and odd cycles of sunspot group data.

Results. The PCA confirms the existence of the Gnevyshev gap (GG) for solar cycles at about 40% from the start of the cycle. The temporal evolution of sunspot area data for even cycles shows that the GG exists at least at the 95% confidence level for all sizes of sunspots. On the other hand, the GG is shorter and statistically insignificant for the odd cycles of aerial sunspot data. Furthermore, the analysis of sunspot area sizes for even and odd cycles of SC12−SC23 shows that the greatest difference is at 4.2−4.6 years, where even cycles have a far smaller total area than odd cycles. The average area of the individual sunspots of even cycles is also smaller in this interval. The statistical analysis of the temporal evolution shows that northern sunspot groups maximise earlier than southern groups for even cycles, but are concurrent for odd cycles. Furthermore, the temporal distributions of odd cycles are slightly more leptokurtic than distributions of even cycles. The skewnesses are 0.37 and 0.49 and the kurtoses 2.79 and 2.94 for even and odd cycles, respectively. The correlation coefficient between skewness and kurtosis for even cycles is 0.69, and for odd cycles, it is 0.90.

Conclusions. The separate PCAs for even and odd sunspot cycles show that odd cycles are more inhomogeneous than even cycles, especially in GSN data. Even cycles, however, have two anomalous cycles: SC4 and SC6. The variation in the shape of the early sunspot cycles suggests that there are too few and/or inaccurate measurements before SC8. According to the analysis of the sunspot area size data, the GG is more distinct in even than odd cycles. This may be partly due to sunspot groups maximizing earlier in the northern than in the southern hemisphere for even cycles. We also present another Waldmeier-type rule, that is, we find a correlation between skewness and kurtosis of the sunspot group cycles.

Comparison of Latitude Distribution and Evolution of Even and Odd Sunspot Cycles

Jouni **Takalo**

Solar Physics volume 295, Article number: 49 (**2020**)

https://link.springer.com/content/pdf/10.1007/s11207-020-01615-1.pdf

https://arxiv.org/pdf/2003.14262.pdf

We study the latitudinal distribution and evolution of sunspot areas of Solar Cycles 12 – 23 (SC12–23) and sunspot groups of Solar Cycles 8 – 23 (SC8–23) for even and odd cycles. The Rician distribution is the best-fit function for both even and odd sunspots group latitudinal occurrence. The mean and variance for even northern/southern butterfly wing sunspots are 14.94/14.76 and 58.62/56.08, respectively, and the mean and variance for odd northern/southern wing sunspots are 15.52/15.58 and 61.77/58.00, respectively. Sunspot groups of even cycle wings

are thus at somewhat lower latitudes on average than sunspot groups of the odd cycle wings, i.e. about 0.6 degrees for northern hemisphere wings and 0.8 degrees for southern hemisphere wings.
The spatial analysis of sunspot areas between SC12–23 shows that the small sunspots are at lower solar latitudes of the Sun than the large sunspots for both odd and even cycles, and also for both hemispheres.
Temporal evolution of sunspot areas shows a lack of large sunspots after four years (exactly between 4.2 – 4.5 years), i.e. about 40% after the start of the cycle, especially for even cycles. This is related to the Gnevyshev gap and is occurring at the time when the evolution of the average sunspot latitudes crosses about 15 degrees. The gap is, however, clearer for even cycles than odd ones. Gnevyshev gap divides the cycle into two disparate parts: the ascending phase/cycle maximum and the declining phase of the sunspot cycle.

Principal component analysis of sunspot cycle shape

Jouni **Takalo**, Kalevi Mursula
A&A 620, A100 **2018**
https://arxiv.org/pdf/1810.08583.pdf
We study the shape of sunspot cycles using the Wolf sunspot numbers and group sunspot numbers of solar cycles 1-23. We determine the most typical "model" cycles and the most asymmetric cycles, and test the validity of the two Waldmeier rules: the anti-correlation between cycle height and the length of its ascending phase (rule 1), and between cycle height and the length of the preceding cycle (rule 2). We applied the principal component analysis to sunspot cycles and studied the first two components, which describe the average cycle shape and cycle asymmetry, respectively. We also calculated their autocorrelation in order to study their recurrence properties. The best model cycles for Wolf numbers are SC12, SC14, and SC16, the successive even cycles from a long period of rather low overall solar activity. We find that the model cycles in eight different analyses using both sunspot series are almost exclusively even cycles. Correspondingly, the most asymmetric cycles are odd cycles. We find that both Waldmeier rules are valid for the whole Wolf number series of 23 cycles. Waldmeier rule 2 is also valid for group number series although its significance is weaker. Waldmeier rule 1 is not significant for the original group number series, but becomes significant for the proxy series. For separate centuries, Waldmeier rules are not always valid for Wolf numbers and very rarely for group numbers. Our results also offer a new interpretation for the Gnevyshev gap. In addition to being a local depression of solar activity, the Gnevyshev gap is a separatrix that divides cycles into two parts whose relative intensities determine the cycle asymmetry. The Gnevyshev gap is the zero value time of PC2, located approximately 33-42% into the cycle after its start.

Measurement of Solar Differential Rotation by Absolutely Calibrated Iodine-Cell Spectroscopy

Yoichi **Takeda**
Solar Phys. **2024**
https://arxiv.org/pdf/2406.18271
The iodine-cell technique, which is known to be efficient in precisely establishing Doppler velocity shifts, was once applied by the author to measuring the solar differential rotation based on full-disk spectroscopic observations (Takeda and Ueno, Sol. Phys. 270, 447, 2011). However, the data reduction procedure (in simple analogy with the stellar case) adopted therein was not necessarily adequate, because specific characteristic involved with the disk-resolved Sun (i.e., center-limb variation of line strengths) was not properly taken into consideration. Therefore, this problem is revisited based on the same data but with an application to theoretical spectrum fitting, which can yield absolute heliocentric radial velocities (v_obs) in a consistent manner as shown in the study of solar gravitational redshift (Takeda and Ueno, Sol. Phys. 281, 551, 2012). Likewise, instead of converting v_obs into omega (angular velocity) at each disk point, which suffers considerable errors especially near the central meridian, omega was derived this time by applying the least squares analysis to a dataset comprising v_obs values at many points. This new analysis resulted in omega (deg/day) = 13.92 (+/- 0.03) -1.69(+/- 0.34)(sin psi)^2 -2.37(+/- 0.62) (sin psi)^4 (psi: the heliographic latitude) along with the gravitational redshift of 675 m/s, which are favorably compared with previous publications. In addition, how the distribution of observing points on the disk affects the result is also examined, which reveals that rotation parameters may suffer appreciable errors depending on cases.

How Solar Soft X-Ray Irradiance Is Affected by the Size of Field of View

Aki **Takeda**1 and Shannon Boland2
2024 ApJ 960 91
https://iopscience.iop.org/article/10.3847/1538-4357/acf9f3/pdf
Soft X-ray images of the Sun obtained with multiple broadband filters provide a simple and useful method to calculate averaged coronal temperature and emission measure, from which we can further calculate solar X-ray irradiance in physical units, e.g., watts per square meter. However, X-ray telescopes are often designed for pursuing high spatial resolution, and thus the field of view (FOV) of full-Sun images is often limited over the limb, extending to only ~1.3 R⊙. This indicates that the irradiance obtained from the limited FOV may underestimate the true full-Sun irradiance by failing to count the contribution from outside the FOV. This work uses Hinode/X-Ray Telescope

(XRT) coronal images observed up to 1.7 R⊙ to investigate the fraction of irradiance excluded from the FOVs limited in size. The analysis indicates that the irradiance obtained within 1.1 R⊙, which is used for XRT irradiance study, excludes ~3.5%/~7% of irradiance relative to the value within 1.2/1.7 R⊙, respectively, for the active corona observed in 2022 July. In contrast, the excluded fraction increases to ~7%/~13%, respectively, for the minimum corona observed in 2009 August. To further investigate the dependence of exclusion fraction on the Sun's activity level, we process mission long Yohkoh/Soft X-ray Telescope full-Sun images to compare the irradiance within 1.1 and 0.9 R⊙ with that obtained from the maximum FOV of 1.2 R⊙. We confirm that the exclusion fraction is the largest in the period around solar minimum. We also find that the average value of exclusion fraction is slightly but measurably larger in the rising phase than the declining phase of the solar cycle.

Center--limb variation of solar photospheric microturbulence

Yoichi **Takeda**

Solar Phys. **297**, Article number: 4 **2022**

https://arxiv.org/pdf/2112.01142.pdf
https://link.springer.com/content/pdf/10.1007/s11207-021-01931-0.pdf
https://doi.org/10.1007/s11207-021-01931-0

Microturbulence (\xi) is a key parameter introduced in stellar spectroscopy to explain the strength of saturated lines by formally incorporating an additional thermal broadening term in the line opacity profile. Although our Sun can serve as an important testing bench to check the usual assumption of constant \xi, the detailed behavior of how \xi varies from the disk center through the limb seems to have never been investigated so far. In order to fill this gap, local \xi values on the solar disk were determined from the equivalent widths of 46 Fe I lines at 32 points from the center to the limb by requiring the consistency between the abundances derived from lines of various strengths. The run of \xi with \theta (angle between line of sight and the surface normal) was found to be only gradual from ~1.0km/s (at sin\theta = 0: disk center) to ~1.3km/s (at sin\theta ~ 0.7: two-thirds of radial distance); but thereafter increasing more steeply up to ~2km/s (at sin\theta = 0.97: limb). This result further suggests that the microturbulence derived from the flux spectrum of the disk-integrated Sun is by ~20% larger than that of the disk-center value, which is almost consistent with the prediction from 3D hydrodynamical model atmospheres.
Table 1. Literature data of solar microturbulence (after 1976)

Solar Cycle Variation of Coronal Temperature, Emission Measure, and Soft X-ray Irradiance Observed with Yohkoh Soft X-ray Telescope

Aki **Takeda**,1 Loren Acton,1 and Nicole Albanese2

ApJ **887** 225 **2019**

http://ylstone.physics.montana.edu/ylegacy/documents/publication/draft_takeda2019.pdf
https://doi.org/10.3847/1538-4357/ab53e3

This paper presents the solar soft X-ray irradiance (0.3-3.0nm) obtained from the mission-long fullSun X-ray images observed with the Soft X-ray Telescope(SXT) of the Yohkoh mission (1991-2001). The irradiance was calculated using filter-ratio temperatures and emission measures from the full-Sun integrated X-ray signals employing a coronal spectrum synthesized with CHIANTI atomic database version 8.0. Dependence of the results on the assumption of elemental abundances is investigated. The SXT irradiance for a shorter wavelength range was also calculated and compared with the low energy flux (0.1-0.8nm) of the X-Ray Sensor(XRS) aboard the GOES satellite. To incorporate the spatial information of the observed corona, we tried the alternative method to derive irradiance by applying the filter ratio method to the images of Northern hemispheric corona instead of spatially integrated signals from there. The emission-measure weighted average of the spatially resolved temperatures turned out to be generally 20 to 30% lower than those derived from the integrated signals, while the total of spatially resolved emission measures are accordingly 1.5 to 2 times higher. This trend is enhanced when solar activity is the lowest in early 1996. The irradiance obtained from the alternative method does not significantly vary from the result from the integrated signals. This provides some validation for the simpler full-Sun integrated method. The temporal variation of the emission measures of cool(2.5MK) components indicates that the ratio of the hot component relative to the medium component is higher in the ascending phase (mid 1998-2001) than the descending phase (1992-1995) of the solar activity cycle.

Solar Center--Limb Variation of the Strengths of Spectral Lines: Classification and Interpretation of Observed Trends

Y. **Takeda**, S. UeNo

Solar Phys. 294:63 **2019**

https://arxiv.org/pdf/1905.02306.pdf

The equivalent widths (W) of 565 spectral lines in the wavelength range of 4690--6870A were evaluated at 31 consecutive points from the solar disk center (mu=cos(theta)=1) to near the limb (mu=0.25) by applying the synthetic spectrum-fitting technique, in order to clarify the nature of their center--limb variations, especially the observed slope differing from line to line and its interpretation in terms of line properties. We found that the

distribution of the gradient beta (= -dlog W/dlog mu) well correlates with that of dlog W/dlog T index, which means that the center-to-limb variation of W is determined mainly by the T-sensitivity of individual lines because the line-forming region shifts towards upper layers of lower T as we go toward the limb. Further, the key to understanding the behavior of dlog W/dlog T (depending on the temperature sensitivity of number population) is whether the considered species is in minor population stage or major population stage, by which the distribution of beta is explained in terms of differences in excitation potential and line strengths. All the center--limb data of equivalent widths (as well as line-of-sight turbulent velocity dispersions, elemental abundances, and mean line-formation depths derived as by-products) along with the solar spectra used for our analysis are made available as on-line materials.

Toward Spectroscopically Detecting the Global Latitudinal Temperature Variation on the Solar Surface

Y. **Takeda**, S. UeNo

Solar Physics September **2017**, 292:123

A very slight rotation-induced latitudinal temperature variation (presumably on the order of several kelvin) on the solar surface is theoretically expected. While recent high-precision solar brightness observations reported its detection, confirmation by an alternative approach using the strengths of spectral lines is desirable, for which reducing the noise due to random fluctuation caused by atmospheric inhomogeneity is critical. Toward this difficult task, we carried out a pilot study of spectroscopically investigating the relative variation of temperature (TT) at a number of points in the solar circumference region near to the limb (where latitude dependence should be detectable, if any exists) based on the equivalent widths (WW) of 28 selected lines in the 5367 – 5393 Å and 6075 – 6100 Å regions. We paid special attention to i) clarifying which types of lines should be employed and ii) how much precision is attainable in practice. We found that lines with strong TT-sensitivity (|logW/logT||logf_0W/logf_0T|) should be used and that very weak lines should be avoided because they inevitably suffer strong relative fluctuations (ΔW/WΔW/W). Our analysis revealed that a precision of ΔT/T≈0.003ΔT/T≈0.003(corresponding to ≈ 15 K) can be achieved at best by a spectral line with comparatively large |logW/logT||logf_0W/logf_0T|, although this can possibly be further improved When a number of lines are used all together. Accordingly, if many such favorable lines could be measured with subpercent precision of ΔW/WΔW/W and by averaging the resulting ΔT/TΔT/T from each line, the random noise would eventually be reduced to ≲ 1 K and detection of a very subtle amount of global TT-gradient might be possible.

The Hinode/XRT Full-Sun Image Corrections and the Improved Synoptic Composite Image Archive

Aki **Takeda**, Keiji Yoshimura, Steven H. Saar

Solar Phys. Volume 291, Issue 1, pp 317-333 **2016**

http://solar.physics.montana.edu/takeda/xrt_synoptics/xrt_scia_final.pdf

The XRT Synoptic Composite Image Archive (SCIA) is a storage and gallery of X-ray full-Sun images obtained through the synoptic program of the X-Ray Telescope (XRT) onboard theHinode satellite. The archived images provide a quick history of solar activity through the daily and monthly layout pages and long-term data for morphological and quantitative studies of the X-ray corona. This article serves as an introduction to the SCIA, i.e., to the structure of the archive and specification of the data products included therein. We also describe a number of techniques used to improve the quality of the archived images: preparation of composite images to increase intensity dynamic range, removal of dark spots that are due to contaminants on the CCD, and correction of the visible stray light contamination that has been detected on the Ti-poly and C-poly filter images since May 2012.

Solar rotation inferred from radial velocities of the sun-as-a-star during the 2012 May 21 eclipse

Yoichi **Takeda**, Osamu Ohshima, Eiji Kambe, Hiroyuki Toda, Hisashi Koyano, Bun'ei Sato, Yasuhisa Nakamura, Norio Narita, Takashi Sekii

Publ. Astron. Soc. Japan, **2014**

http://arxiv.org/pdf/1411.1481v1.pdf

With an aim to examine how much information of solar rotation can be obtained purely spectroscopically by observing the sun-as-a-star during the **2012 May 21** eclipse at Okayama Astrophysical Observatory, we studied the variation of radial velocities (V_r), which were derived by using the iodine-cell technique based on a set of 184 high-dispersion spectra consecutively obtained over the time span of ~4 hours. The resulting V_r(t) was confirmed to show the characteristic variation (Rossiter-McLaughlin effect) caused by time-varying visibility of the solar disk. By comparing the observed V_r(t) curve with the theoretical ones, which were simulated with the latitude (psi) dependent solar rotation law omega(psi) = A + B sin^2(psi) (deg/day), we found that the relation B = -5.5 A + 77 gives the best fit, though separate determinations of A and B were not possible. Since this relationship is consistent with the real values known for the sun (A = 14.5, B = -2.8), we may state that our analysis yielded satisfactory

results. This consequence may provide a prospect of getting useful information on stellar rotation of eclipsing binaries from radial-velocity studies during eclipse, if many spectra of sufficiently high time-resolution are available.

The role of observable nonlinearities in solar cycle modulation

M. **Talafha**, M. Nagy, A. Lemerle, K. Petrovay
A&A 660, A92 **2022**
https://arxiv.org/pdf/2112.14465
https://www.aanda.org/articles/aa/pdf/2022/04/aa42572-21.pdf
Context. Two candidate mechanisms have recently been considered for the nonlinear modulation of solar cycle amplitudes. Tilt quenching (TQ) is a negative feedback between cycle amplitude and the mean tilt angle of bipolar active regions relative to the azimuthal direction; latitude quenching (LQ) consists in a positive correlation between cycle amplitude and average emergence latitude of active regions. Aims. Here we explore the relative importance of and the determining factors behind the LQ and TQ effects. Methods. The degree of nonlinearity induced by TQ, LQ and their combination is systematically probed in a grid of surface flux transport (SFT) models. The role of TQ and LQ is also explored in the successful 2x2D dynamo model optimized to reproduce the statistical behaviour of real solar cycles. Results. The relative importance of LQ vs TQ is found to correlate with the ratio u 0 /{\eta} in the SFT model grid, where u 0 is the meridional flow amplitude and {\eta} is diffusivity. An analytical interpretation of this result is given, further showing that the main underlying parameter is the dynamo effectivity range {\lambda} R which in turn is determined by the ratio of equatorial flow divergence to diffusivity. The relative importance of LQ vs TQ is shown to scale as C 1 +C 2 /{\lambda} 2 R . The presence of a latitude quenching is demonstrated in the 2x2D dynamo, contributing to the nonlinear modulation by an amount comparable to TQ. For other dynamo and SFT models considered in the literature the contribution of LQ to the modulation covers a broad range from being insignificant to being the dominant form of feedback. On the other hand, the contribution of a TQ effect (with the usually assumed amplitude) is never negligible.

Coronal heating in multiple magnetic threads

K. V. **Tam**1,2, A. W. Hood1, P. K. Browning3 and P. J. Cargill
A&A 580, A122 (**2015**)
http://www.aanda.org/articles/aa/pdf/2015/08/aa25995-15.pdf
Context. Heating the solar corona to several million degrees requires the conversion of magnetic energy into thermal energy. In this paper, we investigate whether an unstable magnetic thread within a coronal loop can destabilise a neighbouring magnetic thread.
Aims. By running a series of simulations, we aim to understand under what conditions the destabilisation of a single magnetic thread can also trigger a release of energy in a nearby thread.
Methods. The 3D magnetohydrodynamics code, Lare3d, is used to simulate the temporal evolution of coronal magnetic fields during a kink instability and the subsequent relaxation process. We assume that a coronal magnetic loop consists of non-potential magnetic threads that are initially in an equilibrium state.
Results. The non-linear kink instability in one magnetic thread forms a helical current sheet and initiates magnetic reconnection. The current sheet fragments, and magnetic energy is released throughout that thread. We find that, under certain conditions, this event can destabilise a nearby thread, which is a necessary requirement for starting an avalanche of energy release in magnetic threads.
Conclusions. It is possible to initiate an energy release in a nearby, non-potential magnetic thread, because the energy released from one unstable magnetic thread can trigger energy release in nearby threads, provided that the nearby structures are close to marginal stability.

The Characteristics of Valley Phase as Predictor of the Forthcoming Solar Cycle

Baolin **Tan**
Adv Space Res 63 (**2019**) 617–625
https://arxiv.org/pdf/1808.01417.pdf
Is Solar Cycle 24 anomalous? How do we predict the main features of a forthcoming cycle? In order to reply such questions, this work partitions quantitatively each cycle into valley, ascend, peak, and descend phases, statistically investigate the correlations between valley phase and the forthcoming cycle. We find that the preceding valley phase may dominate and can be predictor of the forthcoming cycle: (1) The growth rate in ascend phase strongly negatively correlates to valley length and strongly positively correlates to cycle maximum. (2) The cycle maximum strongly negatively correlates to valley length, and strongly positively correlates to cycle minimum. (3) The cycle period strongly negatively correlates to the valley variation. Based on these correlations, we conclude that the solar cycle 24 is a relatively weak and long cycle which is obviously weaker than Cycle 23. The similarity analysis also presents the similar result. The Cycle 25 is also inferred possibly to be a weak cycle. These results can help us understanding the physical processes of solar cycles.

Coronal Heating Driven by Magnetic-gradient Pumping Mechanism in Solar Plasmas

Baolin **Tan**

ApJ, **2014**

http://arxiv.org/pdf/1409.6418v1.pdf

The solar coronal heating is a longstanding mystery in astrophysics. Considering that the solar magnetic field is spatially inhomogeneous with considerable magnetic gradient from solar surface to the corona, this work proposes a magnetic gradient pumping (MGP) mechanism and try to explain the formation of hot plasma upflows, such as the hot type II spicules and hot plasma ejections, etc. In MGP mechanism, the magnetic gradients drive the energetic particles to move upwards from the underlying solar atmosphere and form hot upflows. These upflow energetic particles deposit in corona and make it becoming very hot. Roughly estimations indicate that the solar corona can be heated to above 1 million degrees, and the upflow velocity is about 40 km/s in chromosphere and about 130 km/s in the corona. The solar magnetic flux tubes act as pumpers to extract energetic particles from the underlying thermal photosphere, convey them and deposit in the corona. The deposition of energetic particles will make the corona become hot, and their escaping from the photosphere will make the underlying photosphere a bit cold. This mechanism present a natural explanation to the mystery of solar coronal heating.

Changing Relationships Between Sunspot Number, Total Sunspot Area and F10.7 in Cycles 23 and 24

Ken **Tapping**, Carly Morgan

Solar Phys. (**2017**) 292: 73. doi:10.1007/s11207-017-1111-6

This article is an update of a study (Tapping and Valdès in Solar Phys.272, 337, 2011) made in the early part of Cycle 24 using an intercomparison of various solar activity indices (including sunspot number and the 10.7 cm solar radio flux), in which it was concluded that a change in the relationship between photospheric and chromospheric/coronal activity took place just after the maximum of Cycle 23 and continued into Cycle 24. Precursors (short-term variations) were detected in Cycles 21 and 22. Since then the sunspot number index data have been substantially revised. This study is intended to be an update of the earlier study and to assess the impact of the revision of the sunspot number data upon those conclusions. This study compares original and revised sunspot number, total sunspot area, and 10.7 cm solar radio flux. The conclusion is that the transient changes in Cycles 21 and 22, and the more substantial change in Cycle 23, remain evident. Cycle 24 shows indications that the deviation was probably another short-term one.

The Formation and Dissipation of Current Sheets and Shocks due to Compressive Waves in a Stratified Atmosphere Containing a Magnetic Null

Lucas A. **Tarr**1,3,4 and Mark Linton

2019 ApJ 879 127

sci-hub.se/10.3847/1538-4357/ab27c5

We study the propagation and dissipation of magnetohydrodynamic waves in a set of numerical models that each includes a solar-like stratified atmosphere and a magnetic field with a null point. All simulations have the same magnetic field configuration but different transition region heights. Compressive wave packets introduced in the photospheric portion of the simulations refract toward the null and collapse it into a current sheet, which then undergoes reconnection. The collapsed null forms a current sheet owing to a strong magnetic pressure gradient caused by the inability of magnetic perturbations to cross the null. Although the null current sheet undergoes multiple reconnection episodes owing to repeated reflections off the lower boundary, we find no evidence of oscillatory reconnection arising from the dynamics of the null itself. Wave mode conversion around the null generates a series of slow-mode shocks localized near each separatrix. The shock strength is asymmetric across each separatrix, and subsequent shock damping therefore creates a tangential discontinuity across each separatrix, with long-lived current densities. A parameter study of the injected wave energy to reach the null confirms our previous Wentzel–Kramers–Brillouin estimates. Finally, using current estimates of the photospheric acoustic power, we estimate that the shock and ohmic heating we describe may account for ≈1%–10% of the radiative losses from coronal bright points with similar topologies and are similarly insufficient to account for losses from larger structures such as ephemeral regions. At the same time, the dynamics are comparable to proposed mechanisms for generating type II spicules.

On excited frequencies for Alfvén waves in a coronal arcade

Lucas A **Tarr**

ApJ **2017**

https://arxiv.org/pdf/1709.03446.pdf

The normal modes of oscillation for a magnetic arcade are used to analytically solve an initial value problem and estimate the power spectra of wave frequencies generated by a reconnection event in the solar corona. Over a realistic range of parameters, I find that such a disturbance generates a peak power at ∼10smHzfrequencies, but still substantial power up to ∼4Hz. The cadence and sensitivity of current instrumentation does not allow observations of oscillations at these frequencies, but in the near future, new instrumentation will be able to probe this regime, and observationally determine its energetic importance.

Magnetoacoustic Waves in a Stratified Atmosphere with a Magnetic Null Point

Lucas A. **Tarr**, Mark Linton, James Leake
ApJ 837:94 **2017**
https://arxiv.org/pdf/1611.06106v1.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/aa5e4e/pdf
We perform nonlinear MHD simulations to study the propagation of magnetoacoustic waves from the photosphere to the low corona. We focus on a 2D system with a gravitationally stratified atmosphere and three photospheric concentrations of magnetic flux that give rise to a magnetic null point with a magnetic dome topology. We find that a single wavepacket introduced at the lower boundary splits into multiple secondary wavepackets. A portion of the packet refracts towards the null due to the varying Alfv\'en speed. Waves incident on the equipartition contour surrounding the null, where the sound and Alfv\'en speeds coincide, partially transmit, reflect, and mode convert between branches of the local dispersion relation. Approximately 15.5% of the wavepacket's initial energy (Einput) converges on the null, mostly as a fast magnetoacoustic wave. Conversion is very efficient: 70% of the energy incident on the null is converted to slow modes propagating away from the null, 7% leaves as a fast wave, and the remaining 23% (0.036Einput) is locally dissipated. The acoustic energy leaving the null is strongly concentrated along field lines near each of the null's four separatrices. The portion of the wavepacket that refracts towards the null, and the amount of current accumulation, depends on the vertical and horizontal wavenumbers and the centroid position of the wavepacket as it crosses the photosphere. Regions that refract towards or away from the null do not simply coincide with regions of open versus closed magnetic field or the local field orientation. We also modeled wavepacket propagation using a WKB method and found that it agrees qualitatively, though not quantitatively, with the results of the numerical simulation.

Dynamics of Explosive Events Observed by the Interface Region Imaging Spectrograph

E. **Tavabi**, S. Zeighami & M. Heydari
Solar Physics volume 297, Article number: 76 (**2022**)
https://doi.org/10.1007/s11207-022-01990-x
In this research, we investigate Explosive Events (EEs) in the off-limb solar atmosphere, with simultaneous observations from the Si IV, Mg II k, and slit-jaw images (SJI) of the Interface Region Imaging Spectrograph (IRIS), on **17 August 2014, and 19 February**. IRIS data can be investigated to observe the motion of matter, fluctuations, energy absorption, and heat transition of the solar atmosphere. Mechanisms responsible for solar large-scale structures, such as flares and coronal mass ejections, might originate from these small-scale energetic events. Therefore, the study of these events can be helpful for understanding mechanisms in mass and energy transport from the chromosphere toward the transition region and corona. We obtain intensity profiles from spectra in two altitudes, i.e., at the solar limb and 5 arcsec distance from solar limb, and then analyze the EE fluctuations at these two altitudes along the slit. We find that some spectral line profiles show enhancements in blue and red wings indicating upward and downward flows, and some profiles have opposite EEs in both wings. The amplitude of the Doppler velocity in the two data sets of different altitudes was approximated to be about 50 km s−1. We calculated the phase velocity of the oscillations using a technique based on cross-correlation. The phase velocity is obtained as about 220 km s−1. According to the periodic red and blue enhancements in EEs, we suggest that the fluctuations in the EEs with one side enhancement indicate a swaying motions of spicules about their axes, and those EEs observed in both wings indicate a rotational motions of spicules. The swaying and rotational motions are indicative of kink and torsional waves, respectively.

Chromospheric peculiar off-limb dynamical events from IRIS observations

E. **Tavabi**, S. Koutchmy
ApJ **883** 41 **2019**
https://arxiv.org/ftp/arxiv/papers/1907/1907.10960.pdf
https://doi.org/10.3847/1538-4357/ab3730
To study motions and oscillations in the solar chromosphere and at the transition region (TR) level we analyze some extreme Doppler shifts observed off-limb with the Interface Region Imaging Spectrograph (IRIS). Raster scans and slit-jaw imaging observations performed in the near-ultraviolet (NUV) channels were used. Large transverse oscillations are revealed by the far wings profiles after accurately removing the bulk average line profiles of each sequence. Different regions around the Sun are considered. Accordingly, the cool material of spicules is observed in Mg II lines rather dispersed up to coronal heights. In the quiet Sun and especially in a polar coronal hole, we study

dynamical properties of the dispersed spicules-material off-limb using a high spectral, temporal and spatial resolutions IRIS observations. We suggest that numerous small-scale jet-like spicules show rapid twisting and swaying motions evidenced by the large distortion and dispersion of the line profiles, including impressive periodic Doppler shifts. Most of these events repeatedly appear in red- and blue-shifts above the limb throughout the whole interval of the observation datasets with an average swaying speed of order +/-35 kms-1 reaching a maximum value of 50 km s-1 in the polar coronal hole region, well above the 2.2 Mm heights. We identified for the 1st time waves with a short period of order of 100 sec and less and transverse amplitudes of order of +/- 20 to 30 km s-1 with the definite signature of Alfven waves. No correlation exists between brightness and Doppler shift variations; the phase speed of the wave is very large and cannot definitely be determined from the spectral features seen along the quasi-radial features. Even shorter periods waves are evidenced, although their contrast is greatly attenuated by the overlapping effects along the line of sight.

Polar Coronal Plumes as Tornado-like Jets

E. **Tavabi**1,2, S. Koutchmy3, and L. Golub
2018 ApJ 866 35
https://iopscience.iop.org/article/10.3847/1538-4357/aadc64/pdf
We examine the dynamical behavior of white-light polar-plume structures in the inner corona that are observed from the ground during total solar eclipses, based on their extreme ultraviolet (EUV) hot and cool emission line counterparts observed from space. EUV observations from Solar Dynamics Observatory/Atmospheric Imaging Assembly (SDO/AIA) of a sequence of rapidly varying coronal hole structures are analyzed. Evidence of events showing acceleration in the 1.25 Mk line of Fe xii at 193 Å is given. The structures along the plume show an outward velocity of about 140 km s−1that can be interpreted as an upward propagating wave in the 304 Å and 171 Å lines; higher speeds are seen in 193 Å (up to 1000 km s−1). The ejection of the cold He ii plasma is delayed by about 4 minutes in the lowest layer and is delayed more than 12 minutes in the highest level compared to the hot 193 Å behavior. A study of the dynamics using time-slice diagrams reveals that a large amount of fast ejected material originates from below the plume, at the footpoints. The release of plasma material appears to come from a cylinder with quasi-parallel edge-enhanced walls. After the initial phase of a longitudinal acceleration, the speed substantially reduces, and the ejecta disperse into the environment. Finally, the detailed temporal and spatial relationships between the cool and hot components were studied with simultaneous multiwavelength observations, using more AIA data. The outward-propagating perturbation of the presumably magnetic walls of polar plumes supports the suggestion that Alfvén waves propagate outwardly along these radially extended walls. **2010 July 10-11**

Analysis of a Failed Eclipse Plasma Ejection Using EUV Observations

E. **Tavabi**, S. Koutchmy, C. Bazin
Solar Phys. **2018**
https://arxiv.org/ftp/arxiv/papers/1801/1801.09222.pdf
The photometry of eclipse white-light (W-L) images showing a moving blob is interpreted for the first time together with observations from space with the PRoject for On Board Autonomy (PROBA-2) mission (ESA). An off-limb event seen with great details in W-L was analyzed with the SWAP imager (Sun Watcher using Active pixel system detector and image Processing) working in the EUV near 174 A. It is an elongated plasma blob structure of 25 Mm diameter moving above the E-limb with coronal loops under. Summed and co-aligned SWAP images are evaluated using a 20 hours sequence, in addition to the **July 11, 2010** eclipse W-L images taken from several sites. The Atmospheric Imaging Assembly (AIA) instruments on board the Solar Dynamical Observatory (SDO) recorded the event suggesting a magnetic reconnection near a high neutral point; accordingly, we also call it a magnetic plasmoid. The measured proper motion of the blob shows a velocity up to 12 km s^-1. Electron densities of the isolated condensation (cloud or blob or plasmoid) is photometrically evaluated. The typical value is 10^8 cm^-3 at r=1.7 R, superposed on a background corona of 10^7 cm^-3 density. The mass of the cloud near its maximum brightness is found to be 1.6x10^13 gr which is typically 0.6x10^-4 of the overall mass of the corona. From the extrapolated magnetic field the cloud evolves inside a rather broad open region but decelerates, after reaching its maximum brightness. The influence of such small events for supplying material to the ubiquitous slow wind is noticed. A precise evaluation of the EUV photometric data after accurately removing the stray light, suggests an interpretation of the weak 174 A radiation of the cloud as due to resonance scattering in the Fe IX/X lines.

Spicules Intensity Oscillations in SOT/HINODE Observations

E. **Tavabi**, A. Ajabshirizadeh, A. R. Ahangarzadeh Maralani, S. Zeighami
JOAA **2015**
Aims. We study the coherency of solar spicules intensity oscillations with increasing height above the solar limb in quiet Sun, active Sun and active region using observations from HINODE/SOT. Existence of coherency up to

transition region strengthens the theory of the coronal heating and solar wind through energy transport and photospheric oscillations.
Methods. Using time sequences from the HINODE/SOT in Ca II H line, we investigate oscillations found in intensity profiles at different heights above the solar limb. We use the Fourier and wavelet analysis to measure dominant frequency peaks of intensity at the heights, and phase difference between oscillations at two certain heights, to find evidence for the coherency of the oscillations. Finally, we can calculate the energy and the mass transported by spicules providing energy equilibrium, according to density values of spicules at different heights. To extend this work, we can also consider coherent oscillations at different latitudes and suggest to study of oscillations which may be obtained from observations of other satellites.

Alfvenic waves in polar spicules

E. **Tavabi**, S. Koutchmy, A. Ajabshirizadeh, A. R. Ahangarzadeh Maralani, S. Zeighami
A&A, 573, A4, **2015**
http://arxiv.org/pdf/1409.7654v2.pdf
Context. For investigating spicules from the photosphere to coronal heights, the new Hinode/SOT long series of high resolution observations from Space taken in CaII H line emission offers an improved way to look at their remarkable dynamical behavior using images free of seeing effects. They should be put in the context of the huge amount of already accumulated material from ground-based instruments, including high- resolution spectra of off-limb spicules. Results. The surge-like behavior of solar polar region spicules supports the untwisting multi-component interpretation of spicules exhibiting helical dynamics. Several tall spicules are found with (i) upward and downward flows similar at lower and middle-levels, the rate of upward motion being slightly higher at high levels; (ii) the left and right-hand velocities are also increasing with height; (iii) a large number of multi-component spicules show shearing motion of both left-handed and right-handed senses occurring simultaneously, which might be understood as twisting (or untwisting) threads. The number of turns depends on the overall diameter of the structure made of components and changes from at least one turn for the smallest structure to at most two or three turns for surge-like broad structures; the curvature along the spicule corresponds to a low turn number similar to a transverse kink mode oscillation along the threads.

Temporal Variations in Solar Irradiance Since 1947

A. **Tebabal**, B. Damtie, M. Nigussie,E. Yizengaw
Solar Physics August **2017**, 292:112
The study of variations in total solar irradiance (TSI) and spectral irradiance is important for understanding how the Sun affects the Earth's climate. A data-driven approach is used in this article to analyze and model the temporal variation of the TSI and Mg II index back to 1947. In both cases, observed data in the time interval of the satellite era, 1978 – 2013, were used for neural network (NN) model-design and testing. For this particular purpose, the evolution of the solar magnetic field is assumed to be the main driver for the day-to-day irradiance variability. First, we design a model for the Mg II index data from F10.7 cm solar radio-flux using the NN approach in the time span of 1978 through 2013. Results of Mg II index model were tested using various numbers of hidden nodes. The predicted values of the hidden layer with five nodes correspond well to the composite Mg II values. The model reproduces 94% of the variability in the composite Mg II index, including the secular decline between the 1996 and 2008 solar cycle minima. Finally, the extrapolation of the Mg II index was performed using the developed model from F10.7 cm back to 1947. Similarly, the NN model was designed for TSI variability study over the time span of the satellite era using data from the Physikalisch-Meteorologisches Observatorium Davos (PMOD) as a target, and solar activity indices as model inputs. This model was able to reproduce the daily irradiance variations with a correlation coefficient of 0.937 from sunspot and facular measurements in the time span of 1978 – 2013. Finally, the temporal variation of the TSI was analyzed using the designed NN model back to 1947 from the Photometric Sunspot Index (PSI) and the extrapolated Mg IIindex. The extrapolated TSI result indicates that the amplitudes of Solar Cycles 19 and 21 are closely comparable to each other, and Solar Cycle 20 appears to be of lower irradiance during its maximum.

Coronal Heating Rate in the Slow Solar Wind

Daniele **Telloni**1, Marco Romoli2, Marco Velli3, Gary P. Zank4,5, Laxman Adhikari4 +++
2023 ApJL 955 L4
https://iopscience.iop.org/article/10.3847/2041-8213/ace112/pdf
This Letter reports the first observational estimate of the heating rate in the slowly expanding solar corona. The analysis exploits the simultaneous remote and local observations of the same coronal plasma volume, with the Solar Orbiter/Metis and the Parker Solar Probe instruments, respectively, and relies on the basic solar wind magnetohydrodynamic equations. As expected, energy losses are a minor fraction of the solar wind energy flux, since most of the energy dissipation that feeds the heating and acceleration of the coronal flow occurs much closer

to the Sun than the heights probed in the present study, which range from 6.3 to 13.3 R⊙. The energy deposited to the supersonic wind is then used to explain the observed slight residual wind acceleration and to maintain the plasma in a nonadiabatic state. As derived in the Wentzel–Kramers–Brillouin limit, the present energy transfer rate estimates provide a lower limit, which can be very useful in refining the turbulence-based modeling of coronal heating and subsequent solar wind acceleration.

Energy Budget in the Solar Corona

Daniele **Telloni**1, Marco Romoli2,3, Marco Velli4, Gary P. Zank5,6, Laxman Adhikari5 +++
2023 ApJ 954 108
https://iopscience.iop.org/article/10.3847/1538-4357/aceb64/pdf
This paper addresses the first direct investigation of the energy budget in the solar corona. Exploiting joint observations of the same coronal plasma by Parker Solar Probe and the Metis coronagraph aboard Solar Orbiter and the conserved equations for mass, magnetic flux, and wave action, we estimate the values of all terms comprising the total energy flux of the proton component of the slow solar wind from 6.3 to 13.3 R⊙. For distances from the Sun to less than 7 R⊙, we find that the primary source of solar wind energy is magnetic fluctuations including Alfvén waves. As the plasma flows away from the low corona, magnetic energy is gradually converted into kinetic energy, which dominates the total energy flux at heights above 7 R⊙. It is found too that the electric potential energy flux plays an important role in accelerating the solar wind only at altitudes below 6 R⊙, while enthalpy and heat fluxes only become important at even lower heights. The results finally show that energy equipartition does not exist in the solar corona.

Does Turbulence along the Coronal Current Sheet Drive Ion Cyclotron Waves?

Daniele **Telloni**1, Gary P. Zank2,3, Laxman Adhikari2, Lingling Zhao2 et al./
2023 ApJ 944 227
https://iopscience.iop.org/article/10.3847/1538-4357/acb693/pdf
Evidence for the presence of ion cyclotron waves (ICWs), driven by turbulence, at the boundaries of the current sheet is reported in this paper. By exploiting the full potential of the joint observations performed by Parker Solar Probe and the Metis coronagraph on board Solar Orbiter, local measurements of the solar wind can be linked with the large-scale structures of the solar corona. The results suggest that the dynamics of the current sheet layers generates turbulence, which in turn creates a sufficiently strong temperature anisotropy to make the solar-wind plasma unstable to anisotropy-driven instabilities such as the Alfvén ion cyclotron, mirror-mode, and firehose instabilities. The study of the polarization state of high-frequency magnetic fluctuations reveals that ICWs are indeed present along the current sheet, thus linking the magnetic topology of the remotely imaged coronal source regions with the wave bursts observed in situ. The present results may allow improvement of state-of-the-art models based on the ion cyclotron mechanism, providing new insights into the processes involved in coronal heating.

When the Earth's atmosphere becomes dynamic…

Manuela **Temmer** · Sandro Krauss and Astrid Veronig
RHESSI Science Nugget No. 267 Feb **2016**
http://sprg.ssl.berkeley.edu/~tohban/wiki/index.php/When_the_Earth's_atmosphere_becomes_dynamic…
The results clearly show that the majority of CMEs is able to cause a distinct density enhancement in the thermosphere, with an increase up to a factor of 8 compared to the pre-event level. The highest correlations are derived for the CME Bz component with values greater than 10nT, while the correlation with the CME impact speed is somewhat smaller (see Figure 2). We also find that the density enhancement in the thermosphere is highly correlated to the Dst index (see Figure 3), a standard measure of geomagnetic activity that displays magnetic storms well.

Periodic Appearance of Coronal Holes and the Related Variation of SolarWind Parameters

Manuela **Temmer** · Bojan Vršnak · Astrid M. Veronig
Solar Phys (**2007**) 241: 371–383; **File**
http://www.springerlink.com/content/4764048141351573/fulltext.pdf
Abstract We compared the variability of coronal hole (CH) areas (determined from daily GOES/SXI images) with solar wind (daily ACE data) and geomagnetic parameters for the time span 25 January 2005 until 11 September 2005 (late declining phase of solar cycle 23). Applying wavelet spectral analysis, a clear 9-day period is found in the CH time series.

The GOES/SXI image sequence suggests that this periodic variation is caused by a mutual triangular distribution of CHs ~120° apart in longitude. From solar wind parameters a 9-day periodicity was obtained as well, simultaneously with the 9-day period in the CH area time series. These findings provide strong evidence that the 9-day period in solar wind parameters, showing up as higher harmonic of the solar rotation frequency, is caused by the "periodic" longitudinal distribution of CHs on the Sun recurring for several solar rotations. The shape of the wavelet spectrum from the *Dst* index matches only weakly with that from the CH areas and is more similar to the wavelet spectrum of the solar wind magnetic field magnitude. The distinct 9-day period does not show up in sunspot group areas which gives further evidence that the solar wind modulation is strongly related to CH areas but not to active region complexes. The wavelet power spectra for the whole ACE data range (~1998 – 2006) suggest that the 9-day period is not a singular phenomenon occurring only during a specific time range close to solar minimum but is occasionally also present during the maximum and decay phase of solar cycle 23. The main periods correspond to the solar rotation (27d) as well as to the second (13.5d) and third (9d) harmonic.

Three-dimensional solar active region magnetohydrostatic models and their stability using Euler potentials

Jaume **Terradas**, Thomas Neukirch
A&A **2022**
https://arxiv.org/pdf/2212.04735
Active regions (ARs) are typical magnetic structures found in the solar atmosphere. We calculate several magnetohydrostatic (MHS) equilibrium models that include the effect of a finite plasma-β and gravity and that are representative of these structures in three dimensions. The construction of the models is based on the use of two Euler potentials, α and β, that represent the magnetic field as $B=\nabla\alpha\times\nabla\beta$. The ideal MHS nonlinear partial differential equations are solved numerically using finite elements in a fixed 3D rectangular domain. The boundary conditions are initially chosen to correspond to a potential magnetic field (current-free) with known analytical expressions for the corresponding Euler potentials. The distinctive feature is that we incorporate the effect of shear by progressively deforming the initial potential magnetic field. This procedure is quite generic and allows us to generate a vast variety of MHS models. The thermal structure of the ARs is incorporated through the dependence of gas pressure and temperature on the Euler potentials. Using this method we achieve the characteristic hot and over-dense plasma found in ARs, but we demonstrate that the method can also be applied to study configurations with open magnetic field lines. Furthermore, we investigate basic topologies that include neutral lines. Our focus is on the force balance of the structures and we do not consider the energy balance in the constructed models. In addition, we address the difficult question of the stability of the calculated 3D models. We find that if the plasma is convectively stable, then the system is not prone in general to develop magnetic Rayleigh-Taylor instabilities.

Temporal and Spatial Scales for Coronal Heating by Alfvén Wave Dissipation in Transverse Loop Oscillations

Jaume **Terradas**1,2 and Iñigo Arregui
2018 Res. Notes AAS 2 196
http://iopscience.iop.org/article/10.3847/2515-5172/aaeb26
We address the temporal and spatial scales involved in the process of resonant absorption of magnetohydrodynamic (MHD) waves and their possible role in heating the solar corona by Alfvén wave dissipation.

Effect of Magnetic Twist on Nonlinear Transverse Kink Oscillations of Line-tied Magnetic Flux Tubes

J. **Terradas**1,2, N. Magyar3, and T. Van Doorsselaere3
2018 ApJ 853 35
http://sci-hub.tw/http://iopscience.iop.org/0004-637X/853/1/35/
Magnetic twist is thought to play an important role in many structures of the solar atmosphere. One of the effects of twist is to modify the properties of the eigenmodes of magnetic tubes. In the linear regime standing kink solutions are characterized by a change in polarization of the transverse displacement along the twisted tube. In the nonlinear regime, magnetic twist affects the development of shear instabilities that appear at the tube boundary when it is oscillating laterally. These Kelvin–Helmholtz instabilities (KHI) are produced either by the jump in the azimuthal component of the velocity at the edge of the sharp boundary between the internal and external part of the tube or by the continuous small length scales produced by phase mixing when there is a smooth inhomogeneous layer. In this work the effect of twist is consistently investigated by solving the time-dependent problem including the process of energy transfer to the inhomogeneous layer. It is found that twist always delays the appearance of the shear instability, but for tubes with thin inhomogeneous layers the effect is relatively small for moderate values of twist. On the contrary, for tubes with thick layers, the effect of twist is much stronger. This can have some important implications regarding observations of transverse kink modes and the KHI itself.

Ray Tracing of MHD Rossby waves in the Solar tachocline: meridional propagation and implications for the solar magnetic activity

André **Teruya**, Breno Raphaldini, and Carlos Raupp
Front. Astron. Space Sci. 9:856912 **2022**
https://doi.org/10.3389/fspas.2022.856912
https://www.frontiersin.org/articles/10.3389/fspas.2022.856912/full
Rossby waves have been recently recognised for their role in the large-scale spatio-temporal organisation of the solar magnetic activity. Here, we study the propagation of magnetohydrodynamic Rossby waves in a thin layer, representing the solar tachocline. We consider the waves embedded in a meridionally varying background state characterised by a mean zonal flow, which mimics the differential rotation profile of the Sun, and a toroidal magnetic field. Two anti-symmetric toroidal magnetic fields are utilised: one having a global structure with the maximum at around 50o and the other characterised by a narrow band centered at around 20o. We show that for a global structure toroidal magnetic field, the MHD Rossby modes undergo significant meridional propagation, either equatorward or poleward. In addition, the latitude where the waves exhibit a stationary behaviour is sensitive to the strength of the background magnetic field. On the other hand, a narrow band toroidal magnetic field is shown to work as a waveguide for the fast branch of MHD Rossby waves.

High Resolution Observations of the Low Atmospheric Response to Small Coronal Heating Events in an Active Region Core

Paola **Testa** (1), Helle Bakke (2,3), Luc Rouppe van der Voort (2,3), Bart De Pontieu
ApJ **956** 85 **2023**
https://arxiv.org/pdf/2308.15417.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/acf4f1/pdf
High resolution spectral observations of the lower solar atmosphere (chromosphere and transition region) during coronal heating events, in combination with predictions from models of impulsively heated loops, provide powerful diagnostics of the properties of the heating in active region cores. Here we analyze the first coordinated observations of such events with the Interface Region Imaging Spectrograph (IRIS) and the CHROMospheric Imaging Spectrometer (CHROMIS), at the Swedish 1-m Solar Telescope (SST), which provided extremely high spatial resolution and revealed chromospheric brightenings with spatial dimensions down to ~150km. We use machine learning methods (k-means clustering) and find significant coherence in the spatial and temporal properties of the chromospheric spectra, suggesting, in turn, coherence in the spatial and temporal distribution of the coronal heating. The comparison of IRIS and CHROMIS spectra with simulations suggest that both non-thermal electrons with low energy (low-energy cutoff ~5keV) and direct heating in the corona transported by thermal conduction contribute to the heating of the low atmosphere. This is consistent with growing evidence that non-thermal electrons are not uncommon in small heating events (nano- to micro-flares), and that their properties can be constrained by chromospheric and transition region spectral observations. **2016-09-04**

Coronal Abundances in an Active Region: Evolution and Underlying Chromospheric and Transition Region Properties

Paola **Testa**1, Juan Martínez-Sykora2,3,4,5, and Bart De Pontieu2,4,5
2023 ApJ 944 117
https://iopscience.iop.org/article/10.3847/1538-4357/acb343/pdf
The element abundances in the solar corona and solar wind are often different from those of the solar photosphere, typically with a relative enrichment of elements with low first ionization potential (FIP effect). Here, we study the spatial distribution and temporal evolution of the coronal chemical composition in an active region (AR) over about 10 days, using Hinode/EIS spectra, and we also analyze coordinated IRIS observations of the chromospheric and transition region emission to investigate any evidence of the footprints of the FIP effect in the lower atmosphere. To derive the coronal abundances, we use a spectral inversion method recently developed for the MUSE investigation. We find that, in the studied active region (AR 12738), the coronal FIP bias, as diagnosed by the Si/S abundance ratio, presents significant spatial variations, with its highest values (∼2.5–3.5) in the outflow regions at the boundary of the AR, but typically modest temporal variability. Some moss regions and some regions around the AR sunspot show enhanced FIP bias (∼2–2.5) with respect to the AR core, which has only a small FIP bias of ∼1.5. The FIP bias appears most variable in these moss regions. The IRIS observations reveal that the chromospheric turbulence, as derived from IRIS2 inversions of the Mg ii spectra, is enhanced in the outflow regions characterized by the high FIP bias, providing significant new constraints to both models aimed at explaining the formation of AR outflows and models of chemical fractionation.

The Solar X-ray Corona **Review**

Paola **Testa**, Fabio Reale

Book chapter. To appear in Springer's "Handbook of X-ray and Gamma-ray Astrophysics" (eds. A. Santangelo and C. Bambi), Section "The Sun, Stars & Planets" (eds. G. Micela & B. Stelzer) **2022**
https://arxiv.org/pdf/2206.03530.pdf
The X-ray emission from the Sun reveals a very dynamic hot atmosphere, the corona, which is characterized by a complex morphology and broad range of timescales of variability and spatial structuring. The solar magnetic fields play a fundamental role in the heating and structuring of the solar corona. Increasingly higher quality X-ray solar observations with high spatial (down to subarcsec) and temporal resolution provide fundamental information to refine our understanding of the solar magnetic activity and of the underlying physical processes leading to the heating of the solar outer atmosphere. Here we provide a brief historical overview of X-ray solar observations and we summarize recent progress in our understanding of the solar corona as made possible by state-of-the-art current X-ray observations. **13 January 1992, 8 June 2000, September 13 2011, November 9 2013**

IRIS Observations of Short-term Variability in Moss Associated with Transient Hot Coronal Loops

Testa, Paola ; Polito, Vanessa ; De Pontieu, Bart
The Astrophysical Journal, Volume 889, Issue 2, id.124, 23 pp. (**2020**)
https://iopscience.iop.org/article/10.3847/1538-4357/ab63cf/pdf
We observed rapid variability (≲60 s) at the footpoints of transient, hot (∼8-10 MK) coronal loops in active region cores, with the Interface Region Imaging Spectrograph (IRIS). The high spatial (∼0"33) and temporal (≲5-10 s) resolution of IRIS is often crucial for the detection of this variability. We show how, in combination with 1D RADYN loop modeling, these IRIS spectral observations of the transition region (TR) and chromosphere provide powerful diagnostics of the properties of coronal heating and energy transport (thermal conduction or nonthermal electrons, NTEs). Our simulations of nanoflare-heated loops indicate that emission in the Mg II triplet can be used as a sensitive diagnostic for nonthermal particles. In our events, we observe a large variety of IRIS spectral properties (intensity, Doppler shifts, broadening, chromospheric/TR line ratios, Mg II triplet emission) even for different footpoints of the same coronal events. In several events, we find spectroscopic evidence for NTEs (e.g., TR blueshifts and Mg II triplet emission), suggesting that particle acceleration can occur even for very small magnetic reconnection events, which are generally below the detection threshold of hard X-ray instruments that provide direct detection of emission of nonthermal particles.

High spatial resolution FeXII observations of solar active region

Paola **Testa** (1), Bart De Pontieu (2,3), Viggo Hansteen (3), ((1) Harvard-Smithonian Center for Astrophysics, (2) Lockheed-Martin Solar and Astrophysics Laboratory, (3) Institute of Theoretical Astrophysics, University of Oslo)
ApJ **2016**
http://arxiv.org/pdf/1606.04603v1.pdf
We use UV spectral observations of active regions with the Interface Region Imaging Spectrograph (IRIS) to investigate the properties of the coronal FeXII 1349.4A emission at unprecedented high spatial resolution (~0.33"). We find that by using appropriate observational strategies (i.e., long exposures, lossless compression), FeXII

emission can be studied with IRIS at high spatial and spectral resolution, at least for high density plasma (e.g., post-flare loops, and active region moss). We find that upper transition region (moss) FeXII emission shows very small average Doppler redshifts (v_Dop ~3 km/s), as well as modest non-thermal velocities (with an average ~24 km/s, and the peak of the distribution at ~15 km/s). The observed distribution of Doppler shifts appears to be compatible with advanced 3D radiative MHD simulations in which impulsive heating is concentrated at the transition region footpoints of a hot corona. While the non-thermal broadening of FeXII 1349.4A peaks at similar values as lower resolution simultaneous Hinode/EIS measurements of FeXII 195A, IRIS observations show a previously undetected tail of increased non-thermal broadening that might be suggestive of the presence of subarcsecond heating events. We find that IRIS and EIS non-thermal line broadening measurements are affected by instrumental effects that can only be removed through careful analysis. Our results also reveal an unexplained discrepancy between observed 195.1/1349.4A FeXII intensity ratios and those predicted by the CHIANTI atomic database.

Stellar activity and coronal heating: an overview of recent results **Review**

Testa,P., Saar, S. H., & Drake, J. J.

2015, Royal Society of London Philosophical Transactions Series A, 373, p. 20140259

http://sci-hub.tw/10.1098/rsta.2014.0259

http://arxiv.org/pdf/1502.07401v1.pdf

Observations of the coronae of the Sun and of solar-like stars provide complementary information to advance our understanding of stellar magnetic activity, and of the processes leading to the heating of their outer atmospheres. While solar observations allow us to study the corona at high spatial and temporal resolution, the study of stellar coronae allows us to probe stellar activity over a wide range of ages and stellar parameters. Stellar studies therefore provide us with additional tools for understanding coronal heating processes, as well as the long-term evolution of solar X-ray activity. We discuss how recent studies of stellar magnetic fields and coronae contribute to our understanding of the phenomenon of activity and coronal heating in late-type stars.

Inflows towards Bipolar Magnetic Active Regions and Their Nonlinear Impact on a Three-Dimensional Babcock-Leighton Solar Dynamo Model

Kinfe **Teweldebirhan**, Mark Miesch, Sarah Gibson

Solar Phys. **299**, 42 (**2024**)

The changing magnetic fields of the Sun are generated and maintained by a solar dynamo, the exact nature of which remains an unsolved fundamental problem in solar physics. Our objective in this paper is to investigate the role and impact of converging flows toward Bipolar Magnetic Regions (BMR inflows) on the Sun's global solar dynamo. These flows are large scale physical phenomena that have been observed and so should be included in any comprehensive solar dynamo model. We have augmented the Surface flux Transport And Babcock LEighton (STABLE) dynamo model to study the nonlinear feedback effect of BMR inflows with magnitudes varying with surface magnetic fields. This fully 3D realistic dynamo model produces the sunspot butterfly diagram and allows a study of the relative roles of dynamo saturation mechanisms such as tilt angle quenching and BMR inflows. The results of our STABLE simulations show that magnetic field dependent BMR inflows significantly affect the evolution of the BMRs themselves and result in a reduced buildup of the global poloidal field due to local flux cancellation within the BMRs, to an extent that is sufficient to saturate the dynamo. As a consequence, for the first time, we have achieved fully 3D solar dynamo solutions in which BMR inflows alone regulate the amplitudes and periods of the magnetic cycles.

Small-scale dynamos on the solar surface: dependence on magnetic Prandtl number

I. **Thaler**, H.C. Spruit

A&A 578, A54 **2015**

The question of possible small-scale dynamo action in the surface layers of the Sun is revisited with realistic 3D MHD simulations. As in other MHD problems, dynamo action is found to be a sensitive function of the magnetic Prandtl number Pm=ν/η; it disappears below a critical value Pc which is a function of the numerical resolution. At a grid spacing of 3.5 km, Pc based on the hyperdiffusivities implemented in the code (STAGGER) is ≈1, increasing with increasing grid spacing. As in other settings, it remains uncertain whether small scale dynamo action is present in the astrophysical limit where Pm<<1 and magnetic Reynolds number Rm≫1. The question is discussed in the context of the strong effect that external stray fields are observed to have in generating and maintaining dynamo action in other numerical and laboratory systems, and in connection with the type-II hypertransient behavior of dynamo action observed in the absence of such external fields.

Magnetic Helicity Estimations in Models and Observations of the Solar Magnetic Field. IV. Application to Solar Observations

J. K. **Thalmann**1, M. K. Georgoulis2, Y. Liu3, E. Pariat4,5, G. Valori6, S. Anfinogentov7, F. Chen8, Y. Guo8, K. Moraitis9, S. Yang10Show full author list

2021 ApJ 922 41
https://doi.org/10.3847/1538-4357/ac1f93
https://arxiv.org/pdf/2108.08525.pdf
In this ISSI-supported series of studies on magnetic helicity in the Sun, we systematically implement different magnetic helicity calculation methods on high-quality solar magnetogram observations. We apply finite-volume, discrete flux tube (in particular, connectivity-based) and flux-integration methods to data from Hinode's Solar Optical Telescope. The target is NOAA Active Region 10930 during a 1.5-day interval in 2006 December that included a major eruptive flare (SOL**2006-12-13**T02:14X3.4). Finite-volume and connectivity-based methods yield instantaneous budgets of the coronal magnetic helicity, while the flux-integration methods allow an estimate of the accumulated helicity injected through the photosphere. The objectives of our work are twofold: a cross-validation of methods, as well as an interpretation of the complex events leading to the eruption. To the first objective, we find (i) strong agreement among the finite-volume methods, (ii) a moderate agreement between the connectivity-based and finite-volume methods, (iii) an excellent agreement between the flux-integration methods, and (iv) an overall agreement between finite-volume- and flux-integration-based estimates regarding the predominant sign and magnitude of the helicity. To the second objective, we are confident that the photospheric helicity flux significantly contributed to the coronal helicity budget and that a right-handed structure erupted from a predominantly left-handed corona during the X-class flare. Overall, we find that the use of different methods to estimate the (accumulated) coronal helicity may be necessary in order to draw a complete picture of an active region corona, given the careful handling of identified data (preparation) issues, which otherwise would mislead the event analysis and interpretation.

Magnetic helicity budget of solar active regions prolific of eruptive and confined flares

J. K. **Thalmann**, K. Moraitis, L. Linan, E. Pariat, G. Valori, K. Dalmasse
ApJ **2019**
https://arxiv.org/pdf/1910.06563.pdf
We compare the coronal magnetic energy and helicity of two solar active regions (ARs), prolific in major eruptive (AR~11158) and confined (AR~12192) flaring, and analyze the potential of deduced proxies to forecast upcoming flares. Based on nonlinear force-free (NLFF) coronal magnetic field models with a high degree of solenoidality, and applying three different computational methods to investigate the coronal magnetic helicity, we are able to draw conclusions with a high level of confidence. Based on real observations of two solar ARs we checked trends regarding the potential eruptivity of the active-region corona, as suggested earlier in works that were based on numerical simulations, or solar observations. Our results support that the ratio of current-carrying to total helicity, |HJ|/|HV|, shows a strong ability to indicate the eruptive potential of a solar AR. However, |HJ|/|HV| seems not to be indicative for the magnitude or type of an upcoming flare (confined or eruptive). Interpreted in context with earlier observational studies, our findings furthermore support that the total relative helicity normalized to the magnetic flux at the NLFF model's lower boundary, HV/ϕ2, represents no indicator for the eruptivity. **2011 February 14, 2014 October 24**

Solar Photospheric Network Properties and Their Cycle Variation

K. **Thibault**, P. Charbonneau, and M. Béland
2014 ApJ 796 19
We present a numerical simulation of the formation and evolution of the solar photospheric magnetic network over a full solar cycle. The model exhibits realistic behavior as it produces large, unipolar concentrations of flux in the polar caps, a power-law flux distribution with index –1.69, a flux replacement timescale of 19.3 hr, and supergranule diameters of 20 Mm. The polar behavior is especially telling of model accuracy, as it results from lower-latitude activity, and accumulates the residues of any potential modeling inaccuracy and oversimplification. In this case, the main oversimplification is the absence of a polar sink for the flux, causing an amount of polar cap unsigned flux larger than expected by almost one order of magnitude. Nonetheless, our simulated polar caps carry the proper signed flux and dipole moment, and also show a spatial distribution of flux in good qualitative agreement with recent high-latitude magnetographic observations by Hinode. After the last cycle emergence, the simulation is extended until the network has recovered its quiet Sun initial condition. This permits an estimate of the network relaxation time toward the baseline state characterizing extended periods of suppressed activity, such as the Maunder Grand Minimum. Our simulation results indicate a network relaxation time of 2.9 yr, setting 2011 October as the soonest the time after which the last solar activity minimum could have qualified as a Maunder-type Minimum. This suggests that photospheric magnetism did not reach its baseline state during the recent extended minimum between cycles 23 and 24.

The GOES-R EUVS Model for EUV Irradiance Variability

E. M. B. **Thiemann**, F. G. Eparvier, D. Woodraska, P. C. Chamberlin, J. Machol, T. Eden, A. R. Jones, R. Meisner, S. Mueller, M. Snow, R. Viereck, T. N. Woods

Journal of Space Weather and Space Climate **9**, A43 **2019**
https://arxiv.org/pdf/1911.09181.pdf
https://www.swsc-journal.org/articles/swsc/pdf/2019/01/swsc190022.pdf
The Geostationary Operational Environmental Satellite R (GOES-R) series of four satellites are the next generation NOAA GOES satellites. Once on orbit and commissioned, they are renamed GOES 16-19, making critical terrestrial and space weather measurements through 2035. GOES 16 and 17 are currently on orbit, having been launched in 2016 and 2018, respectively. The GOES-R satellites include the EUV and X-ray Irradiance Sensors (EXIS) instrument suite, which measures calibrated solar irradiance in 8 lines or bands between 25 and 285 nm with the Extreme Ultraviolet Sensors (EUVS) instrument. EXIS also includes the X-Ray Sensor (XRS) instrument, which measures solar soft X-ray irradiance at the legacy GOES bands. The EUVS measurements are used as inputs to the EUVS Model, a solar spectral irradiance model for space weather operations that predicts irradiance in twenty-two 5 nm wide intervals from 5 nm to 115 nm, and one 10 nm wide interval from 117 to 127 nm at 30 second cadence. Once fully operational, NOAA will distribute the EUVS Model irradiance with 1 minute latency as a primary space weather data product, ushering in a new era of rapid dissemination and measurement continuity of EUV irradiance spectra. This paper describes the EUVS Model algorithms, data sources, calibration methods and associated uncertainties. Typical model (relative) uncertainties are less than ∼5\% for variability at time-scales longer than 6 hours, and are ∼25\% for solar flare induced variability. The absolute uncertainties, originating from the instruments used to calibrate the EUVS Model, are ∼10\%. Examples of model results are presented at both sub-daily and multi-year timescales to demonstrate the model's capabilities and limitations. Example solar flare irradiances are also modeled.

The spectral impact of magnetic activity on disk-integrated HARPS-N solar observations: exploring new activity indicators

A. P. G. **Thompson**, C. A. Watson, R. D. Haywood, J. C. Costes, ….
MNRAS **2020**
https://arxiv.org/pdf/2004.09830.pdf
Stellar activity is the major roadblock on the path to finding true Earth-analogue planets with the Doppler technique. Thus, identifying new indicators that better trace magnetic activity (i.e. faculae and spots) is crucial to aid in disentangling these signals from that of a planet's Doppler wobble. In this work, we investigate activity related features as seen in disk-integrated spectra from the HARPS-N solar telescope. We divide high-activity spectral echelle orders by low-activity master templates (as defined using both log R'HK and images from the Solar Dynamics Observatory, SDO), creating "relative spectra". With resolved images of the surface of the Sun (via SDO), the faculae and spot filling factors can be calculated, giving a measure of activity independent of, and in addition to, log R'HK. We find pseudo-emission (and pseudo-absorption) features in the relative spectra that are similar to those reported in our previous work on alpha Cen B. In alpha Cen B, the features are shown to correlate better to changes in faculae filling factor than spot filling factor. In this work we more confidently identify changes in faculae coverage of the visible hemisphere of the Sun as the source of features produced in the relative spectra. Finally, we produce trailed spectra to observe the RV component of the features, which show that the features move in a redward direction as one would expect when tracking active regions rotating on the surface of a star.

Current STEREO Status on the Far Side of the Sun

Thompson, William T.; Gurman, Joseph; Ossing, Daniel; Luhmann, Janet; Curtis, David; Schroeder, Peter; Mewaldt, Richard; Davis, Andrew; Wortman, Kristin; Russell, Christopher; and 10 coauthors
Joint American Astronomical Society/American Geophysical Union Triennial Earth-Sun Summit, meeting #1, #402.05, 04/**2015**
The current positions of the two STEREO spacecraft on the opposite side of the Sun from Earth (superior solar conjunction) has forced some significant changes in the spacecraft and instrument operations. No communications are possible when the spacecraft is within 2 degrees of the Sun, requiring that the spacecraft be put into safe mode until communications can be restored. Unfortunately, communications were lost with the STEREO Behind spacecraft on October 1, 2014, during testing for superior solar conjunction operations. We will discuss what is known about the causes of loss of contact, the steps being taken to try to recover the Behind spacecraft, and what has been done to prevent a similar occurrence on STEREO Ahead.We will also discuss the effect of being on the far side of the Sun on the science operations of STEREO Ahead. Starting on August 20, 2014, the telemetry rate from the STEREO Ahead spacecraft has been tremendously reduced due to the need to keep the temperature of the feed horn on the high gain antenna below acceptable limits. However, the amount of telemetry that can be brought down has been highly reduced. Even so, significant science is still possible from STEREO's unique position on the solar far side. We will discuss the science and space weather products that are, or will be, available from each STEREO instrument, when those products will be available, and how they will be used. Some data, including the regular space weather beacon products, are brought down for an average of a few hours each day during the daily real-time passes, while the in situ and radio beacon data are being stored on the onboard recorder to provide a continuous 24-hour coverage for eventual downlink once the spacecraft is back to normal operations.

Grand Challenges in the Physics of the Sun and Sun-like Stars **Review**

Michael J. **Thompson**

2014, Frontiers in Stellar and Solar Physics

The study of stellar structure and evolution is one of the main building blocks of astrophysics, and the Sun has an importance both as the star that is most amenable to detailed study and as the star that has by far the biggest impact on the Earth and near-Earth environment through its radiative and particulate outputs. Over the past decades, studies of stars and of the Sun have become somewhat separate. But in recent years, the rapid advances in asteroseismology, as well as the quest to better understand solar and stellar dynamos, have emphasized once again the synergy between studies of the stars and the Sun. In this article I have selected two "grand challenges" both for their crucial importance and because I thnk that these two problems are tractable to significant progress in the next decade. They are (i) understanding how solar and stellar dynamos generate magnetic field, and (ii) improving the predictability of geo-effective space weather.

Coordinate systems for solar image data

W. T. **Thompson**

2005

http://secchi.nrl.navy.mil/wiki/uploads/Main/coordinates.pdf

A set of formal systems for describing the coordinates of solar image data is proposed. These systems build on current practice in applying coordinates to solar image data. Both heliographic and heliocentric coordinates are discussed. A distinction is also drawn between heliocentric and helioprojective coordinates, where the latter takes the observer's exact geometry into account. The extension of these coordinate systems to observations made from non-terrestial viewpoints is discussed, such as from the upcoming STEREO mission. A formal system for incorporation of these coordinates into FITS files, based on the FITS World Coordinate System, is described, together with examples.

Present day challenges in understanding the geomagnetic hazard to national power grids

A.W.P. **Thomson**, C.T. Gaunt, P. Cilliers, J.A. Wild, B. Opperman, L.-A. McKinnell, P. Kotze, C.M. Ngwira, S.I. Lotz

Adv. Space Res. Volume 45, Issue 9, Pages 1182-1190, **2010; File**

Power grids and pipeline networks at all latitudes are known to be at risk from the natural hazard of geomagnetically induced currents. At a recent workshop in South Africa, UK and South African scientists and engineers discussed the current understanding of this hazard, as it affects major power systems in Europe and Africa. They also summarised, to better inform the public and industry, what can be said with some certainty about the hazard and what research is yet required to develop useful tools for geomagnetic hazard mitigation.

Can Multi-threaded Flux Tubes in Coronal Arcades Support a Magnetohydrodynamic Avalanche?

J. **Threlfall**, J. Reid & A. W. Hood

Solar Physics volume 296, Article number: 120 (**2021**)

https://link.springer.com/content/pdf/10.1007/s11207-021-01865-7.pdf

https://doi.org/10.1007/s11207-021-01865-7

Magnetohydrodynamic (MHD) instabilities allow energy to be released from stressed magnetic fields, commonly modelled in cylindrical flux tubes linking parallel planes, but, more recently, also in curved arcades containing flux tubes with both footpoints in the same photospheric plane. Uncurved cylindrical flux tubes containing multiple individual threads have been shown to be capable of sustaining an MHD avalanche, whereby a single unstable thread can destabilise many. We examine the properties of multi-threaded coronal loops, wherein each thread is created by photospheric driving in a realistic, curved coronal arcade structure (with both footpoints of each thread in the same plane). We use three-dimensional MHD simulations to study the evolution of single- and multi-threaded coronal loops, which become unstable and reconnect, while varying the driving velocity of individual threads. Experiments containing a single thread destabilise in a manner indicative of an ideal MHD instability and consistent with previous examples in the literature. The introduction of additional threads modifies this picture, with aspects of the model geometry and relative driving speeds of individual threads affecting the ability of any thread to destabilise

others. In both single- and multi-threaded cases, continuous driving of the remnants of disrupted threads produces secondary, aperiodic bursts of energetic release.

Above the Noise: The Search for Periodicities in the Inner Heliosphere

James **Threlfall**, Ineke De Moortel, Thomas Conlon
Solar Physics November **2017**, 292:165
Remote sensing of coronal and heliospheric periodicities can provide vital insight into the local conditions and dynamics of the solar atmosphere. We seek to trace long (one hour or longer) periodic oscillatory signatures (previously identified above the limb in the corona by, e.g., Telloni et al. in Astrophys. J.767, 138, 2013) from their origin at the solar surface out into the heliosphere. To do this, we combined on-disk measurements taken by the Atmospheric Imaging Assembly (AIA) onboard the Solar Dynamics Observatory (SDO) and concurrent extreme ultra-violet (EUV) and coronagraph data from one of the Solar Terrestrial Relations Observatory(STEREO) spacecraft to study the evolution of two active regions in the vicinity of an equatorial coronal hole over several days in early 2011. Fourier and wavelet analysis of signals were performed. Applying white-noise-based confidence levels to the power spectra associated with detrended intensity time series yields detections of oscillatory signatures with periods from 6 – 13 hours in both AIA and STEREO data. As was found by Telloni et al. (2013), these signatures are aligned with local magnetic structures. However, typical spectral power densities all vary substantially as a function of period, indicating spectra dominated by red (rather than white) noise. Contrary to the white-noise-based results, applying global confidence levels based on a generic background-noise model (allowing a combination of white noise, red noise, and transients following Auchère et al. in Astrophys. J.825, 110, 2016) without detrending the time series uncovers only sporadic, spatially uncorrelated evidence of periodic signatures in either instrument. Automating this method to individual pixels in the STEREO/COR coronagraph field of view is non-trivial. Efforts to identify and implement a more robust automatic background noise model fitting procedure are needed.

Solar disc radius determined from observations made during eclipses with bolometric and photometric instruments on board the PICARD satellite

G. **Thuillier**1, P. Zhu2, A. I. Shapiro3, S. Sofia4, R. Tagirov1, M. van Ruymbeke2, J.-M. Perrin5, T. Sukhodolov1 and W. Schmutz1
A&A 603, A28 (**2017**)
Context. Despite the importance of having an accurate measurement of the solar disc radius, there are large uncertainties of its value due to the use of different measurement techniques and instrument calibration. An item of particular importance is to establish whether the value of the solar disc radius correlates with the solar activity level.
Aims. The main goal of this work is to measure the solar disc radius in the near-UV, visible, and near-IR regions of the solar spectrum.
Methods. Three instruments on board the PICARD spacecraft, namely the Bolometric Oscillations Sensor (BOS), the PREcision MOnitoring Sensor (PREMOS), and a solar sensor (SES), are used to derive the solar disc radius using the light curves produced when the Sun is occulted by the Moon. Nine eclipses, from 2010 to 2013, resulted in 17 occultations as viewed from the moving satellite. The calculation of the solar disc radius uses a simulation of the light curve taking into account the center-to-limb variation provided by the Non-local thermodynamic Equilibrium Spectral SYnthesis (NESSY) code.
Results. We derive individual values for the solar disc radius for each viewed eclipse. Tests for a systematic variation of the radius with the progression of the solar cycle yield no significant results during the three years of measurements within the uncertainty of our measurements. Therefore, we derive a more precise radius value by averaging these values. At one astronomical unit, we obtain 959.79 arcseconds (arcsec) from the bolometric experiment; from PREMOS measurements, we obtain 959.78 arcsec at 782 nm and 959.76 arcsec at 535 nm. We found 960.07 arcsec at 210 nm, which is a higher value than the other determinations given the photons at this wavelength originate from the upper photosphere and lower chromosphere. We also give a detailed comparison of our results with those previously published using measurements from space-based and ground-based instruments using the Moon angular radius reference, and different methods.
Conclusions. Our results, which use the Moon as an absolute calibration, clearly show the dependence of the solar disc radius with wavelength in UV, visible and near-IR. Beyond the metrological results, solar disc radius measurements will allow the accuracy of models of the solar atmosphere to be tested. Proposed systematic variations of the solar disc radius during the time of observation would be smaller than the uncertainty of our measurement, which amounts to less than 26 milliarcseconds.

The Infrared Solar Spectrum Measured by the SOLSPEC Spectrometer Onboard the International Space Station

G. **Thuillier**, J. W. Harder, A. Shapiro, T. N. Woods, J.-M. Perrin, M. Snow, T. Sukhodolov, W. Schmutz

Solar Phys., Volume 290, Issue 6, pp 1581-1600 **2015**
A solar spectrum extending from the extreme ultraviolet to the near-infrared is an important input for solar physics, climate research, and atmospheric physics. Ultraviolet measurements have been conducted since the beginning of the space age, but measurements throughout the contiguous visible and infrared (IR) regions are much more sparse. Ageing is a key problem throughout the entire spectral domain, but most of the effort extended to understand degradation was concentrated on the ultraviolet spectral region, and these mechanisms may not be appropriate in the IR. This problem is further complicated by the scarcity of long-term data sets. Onboard the International Space Station, the SOLSPEC spectrometer measured an IR solar spectral irradiance lower than the one given by ATLAS 3, e.g. by about 7 % at 1 700 nm. We here evaluate the consequences of the lower solar spectral irradiance measurements and present a re-analysis of the on-orbit calibration lamp and solar data trend, which lead to a revised spectrum.

Solar Spectral Irradiance Variability in November/December 2012: Comparison of Observations by Instruments on the International Space Station and Models

G. **Thuillier**, G. Schmidtke, C. Erhardt, B. Nikutowski, A. I. Shapiro, C. Bolduc, J. Lean, N. Krivova, P. Charbonneau, G. Cessateur, … show all 16
Solar Phys., **2014**
Onboard the International Space Station (ISS), two instruments are observing the solar spectral irradiance (SSI) at wavelengths from 16 to 2900 nm. Although the ISS platform orientation generally precludes pointing at the Sun more than 10 – 14 days per month, in November/December 2012 a continuous period of measurements was obtained by implementing an ISS 'bridging' maneuver. This enabled observations to be made of the solar spectral irradiance (SSI) during a complete solar rotation. We present these measurements, which quantify the impact of active regions on SSI, and compare them with data simultaneously gathered from other platforms, and with models of spectral irradiance variability. Our analysis demonstrates that the instruments onboard the ISS have the capability to measure SSI variations consistent with other instruments in space. A comparison among all available SSI measurements during November–December 2012 in absolute units with reconstructions using solar proxies and observed solar activity features is presented and discussed in terms of accuracy.

The Solar Irradiance Spectrum at Solar Activity Minimum Between Solar Cycles 23 and 24

G. **Thuillier**, D. Bolsée, G. Schmidtke, T. Foujols, B. Nikutowski, A. I. Shapiro, R. Brunner, M. Weber, C. Erhardt, M. Hersé, et al.
Solar Physics, June **2014**, Volume 289, Issue 6, pp 1931-1958
On 7 February 2008, the SOLAR payload was placed onboard the International Space Station. It is composed of three instruments, two spectrometers and a radiometer. The two spectrometers allow us to cover the 16 – 2900 nm spectral range. In this article, we first briefly present the instrumentation, its calibration and its performance in orbit. Second, the solar spectrum measured during the transition between Solar Cycles 23 to 24 at the time of the minimum is shown and compared with other data sets. Its accuracy is estimated as a function of wavelength and the solar atmosphere brightness-temperature is calculated and compared with those derived from two theoretical models.

On the periodicity of linear and nonlinear oscillatory reconnection

J.O. **Thurgood**, D.I. Pontin, J.A. McLaughlin
A&A 621, A106 (2019)
https://arxiv.org/pdf/1811.08831.pdf

(Abridged for ArXiv) An injection of energy towards a magnetic null point can drive reversals of current sheet polarity leading to time-dependent Oscillatory Reconnection, which is a possible explanation of how periodic phenomena can be generated when reconnection occurs in the solar atmosphere. However, the details of what controls the period of these oscillations is poorly understood, despite being crucial in assessing whether OR can account for observed periodic behaviour. This paper aims to highlight that different types of reconnection reversal are supported about null points, and that these are distinct from the oscillation on the closed-boundary, linear systems considered in the 1990s. In particular, we explore the features of a nonlinear oscillation local to the null point, and examine the effect of resistivity and perturbation energy on the period, contrasting it to the linear case. It is found that in the linear systems, the inverse Lundquist number dictates the period, provided the perturbation energy is small relative to the inverse Lundquist number defined on the boundary, regardless of the broadband structure of the initial perturbation. However, when the perturbation energy exceeds the threshold required for 'nonlinear' null collapse to occur, a complex oscillation of the magnetic field is produced which is, at best, only weakly-dependent on the resistivity. The resultant periodicity is strongly influenced by the amount of free energy, with more energetic perturbations producing higher-frequency oscillations. Crucially, with regards to typical solar-based and astrophysical-based input energies, we demonstrate that the majority far exceed the threshold for nonlinearity to develop. This substantially alters the properties and periodicity of both null collapse and subsequent OR. Therefore, nonlinear regimes of OR should be considered in solar and astrophysical contexts.

Analysis of Different Solar Spectral Irradiance Reconstructions and Their Impact on Solar Heating Rates

G. **Thuillier**, S. M. L. Melo, J. Lean, N. A. Krivova, C. Bolduc, V. I. Fomichev, P. Charbonneau, A. I. Shapiro, W. Schmutz, D. Bolsée

Solar Physics, April **2014**, Volume 289, Issue 4, pp 1115-1142

Proper numerical simulation of the Earth's climate change requires reliable knowledge of solar irradiance and its variability on different time scales, as well as the wavelength dependence of this variability. As new measurements of the solar spectral irradiance have become available, so too have new reconstructions of historical solar irradiance variations, based on different approaches. However, these various solar spectral irradiance reconstructions have not yet been compared in detail to quantify differences in their absolute values, variability, and implications for climate and atmospheric studies. In this paper we quantitatively compare five different reconstructions of solar spectral irradiance changes during the past four centuries, in order to document and analyze their differences. The impact on atmosphere and climate studies is discussed in terms of the calculation of short wave solar heating rates.

First direct measurements of transverse waves in solar polar plumes using SDO/AIA

J.O. **Thurgood**, R.J Morton, J.A. McLaughlin

2014 ApJ 790 L2

http://arxiv.org/pdf/1406.5348v1.pdf

There is intense interest in determining the precise contribution of Alfv\'enic waves propagating along solar structures to the problems of coronal heating and solar wind acceleration. Since the launch of SDO/AIA, it has been possible to resolve transverse oscillations in off-limb solar polar plumes and recently McIntosh et al. (2011, Nature, 475, 477) concluded that such waves are energetic enough to play a role in heating the corona and accelerating the fast solar wind. However, this result is based on comparisons to Monte Carlo simulations and confirmation via direct measurements is still outstanding. Thus, this letter reports on the first direct measurements of transverse wave motions in solar polar plumes. Over a 4 hour period, we measure the transverse displacements, periods and velocity amplitudes of 596 distinct oscillations observed in the 171 \AA channel of SDO/AIA. We find a broad range of non-uniformly distributed parameter values which are well described by log-normal distributions with peaks at 234 km, 121 s and 8 km s−1, and mean and standard deviations of 407±297 km, 173±118 s and 14±10 km s−1. Within standard deviations, our direct measurements are broadly consistent with previous results. However, accounting for the whole of our observed non-uniform parameter distribution we calculate an energy flux of 9−24 W m−2, which is 4−10 times below the energy requirement for solar wind acceleration. Hence, our results indicate that transverse MHD waves as resolved by SDO/AIA cannot be the dominant energy source for fast solar wind acceleration in the open-field corona.

Upflows in the upper solar atmosphere **Review**

Hui **Tian**, Louise Harra, Deborah Baker, David H. Brooks, Lidong Xia

Solar Phys. **296**, Article number: 47 **2021**

https://link.springer.com/content/pdf/10.1007/s11207-021-01792-7.pdf

https://arxiv.org/pdf/2102.02429.pdf

https://doi.org/10.1007/s11207-021-01792-7

Spectroscopic observations at extreme and far ultraviolet wavelengths have revealed systematic upflows in the solar transition region and corona. These upflows are best seen in the network structures of the quiet Sun and coronal

holes, boundaries of active regions, and dimming regions associated with coronal mass ejections. They have been intensively studied in the past two decades because they are highly likely to be closely related to the formation of the solar wind and heating of the upper solar atmosphere. We present an overview of the characteristics of these upflows, introduce their possible formation mechanisms, and discuss their potential roles in the mass and energy transport in the solar atmosphere. Though past investigations have greatly improved our understanding of these upflows, they have left us with several outstanding questions and unresolved issues that should be addressed in the future. New observations from the Solar Orbiter mission, the Daniel K. Inouye Solar Telescope and the Parker Solar Probe will likely provide critical information to advance our understanding of the generation, propagation and energization of these upflows.

4. Upflows from CME-induced dimmings

Are IRIS bombs connected to Ellerman bombs?

Hui **Tian**, Zhi Xu, Jiansen He, Chad Madsen

ApJ **824** 96 **2016**

http://arxiv.org/pdf/1604.05423v1.pdf

Recent observations by the Interface Region Imaging Spectrograph (IRIS) have revealed pockets of hot gas (~2--8 ×104 K) potentially resulting from magnetic reconnection in the partially ionized lower solar atmosphere (IRIS bombs; IBs). Using joint observations between IRIS and the Chinese New Vacuum Solar Telescope, we have identified ten IBs. We find that three are unambiguously and three others are possibly connected to Ellerman bombs (EBs), which show intense brightening of the extended Hα wings without leaving an obvious signature in the Hα core. These bombs generally reveal the following distinct properties: (1) The O~{\sc{iv}}~1401.156\AA{} and 1399.774\AA{} lines are absent or very weak; (2) The Mn~{\sc{i}}~2795.640\AA{} line manifests as an absorption feature superimposed on the greatly enhanced Mg~{\sc{ii}}~k line wing; (3) The Mg~{\sc{ii}}~k and h lines show intense brightening in the wings and no dramatic enhancement in the cores; (4) Chromospheric absorption lines such as Ni~{\sc{ii}}~1393.330\AA{} and 1335.203\AA{} are very strong; (5) The 1700\AA{} images obtained with the Atmospheric Imaging Assembly on board the Solar Dynamics Observatory reveal intense and compact brightenings. These properties support the formation of these bombs in the photosphere, demonstrating that EBs can be heated much more efficiently than previously thought. We also demonstrate that the Mg~{\sc{ii}}~k and h lines can be used to investigate EBs similarly to Hα, which opens a promising new window for EB studies. The remaining four IBs obviously have no connection to EBs and they do not have the properties mentioned above, suggesting a higher formation layer possibly in the chromosphere.

Numerical simulations of Kelvin-Helmholtz instability: a two-dimensional parametric study

Chunlin **Tian**, Yao Chen

ApJ **2016**

http://arxiv.org/pdf/1604.01546v1.pdf

Using two-dimensional simulations, we numerically explore the dependences of Kelvin-Helmholtz instability upon various physical parameters, including viscosity, width of sheared layer, flow speed, and magnetic field strength. In most cases, a multi-vortex phase exists between the initial growth phase and final single-vortex phase. The parametric study shows that the evolutionary properties, such as phase duration and vortex dynamics, are generally sensitive to these parameters except in certain regimes. An interesting result is that for supersonic flows, the phase durations and saturation of velocity growth approach constant values asymptotically as the sonic Mach number increases. We confirm that the linear coupling between magnetic field and Kelvin-Helmholtz modes is negligible if the magnetic field is weak enough. The morphological behaviour suggests that the multi-vortex coalescence might be driven by the underlying wave-wave interaction. Based on these results, we make a preliminary discussion about several events observed in the solar corona. The numerical models need to be further improved to make a practical diagnostic of the coronal plasma properties.

Quantifying Poynting Flux in the Quiet Sun Photosphere

Dennis **Tilipman**1,2, Maria Kazachenko1,2, Benoit Tremblay3, Ivan Milić4,5, Valentin Martínez Pillet1, and Matthias Rempel3

2023 ApJ 956 83

https://iopscience.iop.org/article/10.3847/1538-4357/ace621/pdf

Poynting flux is the flux of magnetic energy, which is responsible for chromospheric and coronal heating in the solar atmosphere. It is defined as a cross product of the electric and magnetic fields, and in ideal MHD conditions it can be expressed in terms of the magnetic field and plasma velocity. Poynting flux has been computed for active regions and plages, but estimating it in the quiet Sun (QS) remains challenging due to resolution effects and

polarimetric noise. However, with the upcoming DKIST capabilities, such estimations will become more feasible than ever before. Here, we study QS Poynting flux in SUNRISE/IMaX observations and MURaM simulations. We explore two methods for inferring transverse velocities from observations—FLCT and a neural network–based method DeepVel—and show DeepVel to be the more suitable method in the context of small-scale QS flows. We investigate the effect of azimuthal ambiguity on Poynting flux estimates, and we describe a new method for azimuth disambiguation. Finally, we use two methods for obtaining the electric field. The first method relies on an idealized Ohm's law, whereas the second is a state-of-the-art inductive electric field inversion method PDFI_SS. We compare the resulting Poynting flux values with theoretical estimates for chromospheric and coronal energy losses and find that some of the Poynting flux estimates are sufficient to match the losses. Using MURaM simulations, we show that photospheric Poynting fluxes vary significantly with optical depth, and that there is an observational bias that results in underestimated Poynting fluxes due to an unaccounted shear term contribution.

Dominance of Bursty over Steady Heating of the 4--8 MK Coronal Plasma in a Solar Active Region: Quantification using Maps of Minimum, Maximum, and Average Brightness

Sanjiv K. **Tiwari**, Lucy A. Wilkerson, Navdeep K. Panesar, Ronald L. Moore, Amy R. Winebarger

ApJ *ApJ* **942** 2 **2023**

https://arxiv.org/pdf/2211.09936.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/aca541/pdf

A challenge in characterizing active region (AR) coronal heating is in separating transient (bursty) loop heating from the diffuse background (steady) heating. We present a method of quantifying coronal heating's bursty and steady components in ARs, applying it to FeXVIII (hot94) emission of an AR observed by SDO/AIA. The maximum, minimum, and average brightness values for each pixel, over a 24 hour period, yield a maximum-brightness map, a minimum-brightness map, and an average-brightness map of the AR. Running sets of such three maps come from repeating this process for each time step of running windows of 20, 16, 12, 8, 5, 3, 1 and 0.5 hours. From each running window's set of three maps, we obtain the AR's three corresponding luminosity light curves. We find: (1) The time-averaged ratio of minimum-brightness-map luminosity to average-brightness-map luminosity increases as the time window decreases, and the time-averaged ratio of maximum-brightness-map luminosity to average-brightness-map luminosity decreases as the window decreases. (2) For the 24-hour window, the minimum-brightness map's luminosity is 5% of the average-brightness map's luminosity, indicating that at most 5% of the AR's hot94 luminosity is from heating that is steady for 24 hours. (3) This upper limit on the fraction of the hot94 luminosity from steady heating increases to 33% for the 30-minute running window. This requires that the heating of the 4--8 MK plasma in this AR is mostly in bursts lasting less than 30 minutes: at most a third of the heating is steady for 30 minutes. **May 29, 2018**

SolO/EUI Observations of Ubiquitous Fine-scale Bright Dots in an Emerging Flux Region: Comparison with a Bifrost MHD Simulation

Sanjiv K. **Tiwari**, Viggo H. Hansteen, Bart De Pontieu, Navdeep K. Panesar, David Berghmans

ApJ **2022**

https://arxiv.org/pdf/2203.06161.pdf

We report on the presence of numerous tiny bright dots in and around an emerging flux region (an X-ray/coronal bright point) observed with SolO's EUI/\hri\ in 174 Å. These dots are roundish, have a diameter of 675±300 km, a lifetime of 50±35 seconds, and an intensity enhancement of 30\% ±10\% above their immediate surroundings. About half of the dots remain isolated during their evolution and move randomly and slowly (<10 \kms). The other half show extensions, appearing as a small loop or surge/jet, with intensity propagations below 30\,\kms. Many of the bigger and brighter \hri\ dots are discernible in SDO/AIA 171 Å channel, have significant emissivity in the temperature range of 1--2 MK, and are often located at polarity inversion lines observed in HMI LOS magnetograms. Although not as pervasive as in observations, Bifrost MHD simulation of an emerging flux region do show dots in synthetic \fe\ images. These dots in simulation show distinct Doppler signatures -- blueshifts and redshifts coexist, or a redshift of the order of 10 \kms\ is followed by a blueshift of similar or higher magnitude. The synthetic images of \oxy\ and \siiv\ lines, which represent transition region radiation, also show the dots that are observed in \fe\ images, often expanded in size, or extended as a loop, and always with stronger Doppler velocities (up to 100 \kms) than that in \fe\ lines. Our observation and simulation results, together with the field geometry of dots in the simulation, suggest that most dots in emerging flux regions form in the lower solar atmosphere (at ≈1 Mm) by magnetic reconnection between emerging and pre-existing/emerged magnetic field. Some dots might be manifestations of magneto-acoustic shocks through the line formation region of \fe\ emission. **May 20, 2020**

Fine-scale explosive energy release at sites of prospective magnetic flux cancellation in the core of the solar active region observed by Hi-C 2.1, IRIS and SDO

Sanjiv K. **Tiwari**, Navdeep K. Panesar, Ronald L. Moore, Bart De Pontieu, Amy R. Winebarger, Leon Golub, Sabrina L. Savage, Laurel A. Rachmeler, Ken Kobayashi, Paola Testa, Harry P. Warren, David H. Brooks, Jonathan W. Cirtain, David E. McKenzie, Richard J. Morton, Hardi Peter, Robert W. Walsh

ApJ **887** 56 **2019**
https://arxiv.org/pdf/1911.01424.pdf
sci-hub.se/10.3847/1538-4357/ab54c1
The second Hi-C flight (Hi-C2.1) provided unprecedentedly-high spatial and temporal resolution (~250km, 4.4s) coronal EUV images of Fe IX/X emission at 172 Å, of AR 12712 on **29-May-2018**, during 18:56:21-19:01:56 UT. Three morphologically-different types (I: dot-like, II: loop-like, III: surge/jet-like) of fine-scale sudden-brightening events (tiny microflares) are seen within and at the ends of an arch filament system in the core of the AR. Although type Is (not reported before) resemble IRIS-bombs (in size, and brightness wrt surroundings), our dot-like events are apparently much hotter, and shorter in span (70s). We complement the 5-minute-duration Hi-C2.1 data with SDO/HMI magnetograms, SDO/AIA EUV images, and IRIS UV spectra and slit-jaw images to examine, at the sites of these events, brightenings and flows in the transition-region and corona and evolution of magnetic flux in the photosphere. Most, if not all, of the events are seated at sites of opposite-polarity magnetic flux convergence (sometimes driven by adjacent flux emergence), implying likely flux cancellation at the microflare's polarity inversion line. In the IRIS spectra and images, we find confirming evidence of field-aligned outflow from brightenings at the ends of loops of the arch filament system. In types I and II the explosion is confined, while in type III the explosion is ejective and drives jet-like outflow. The light-curves from Hi-C, AIA and IRIS peak nearly simultaneously for many of these events and none of the events display a systematic cooling sequence as seen in typical coronal flares, suggesting that these tiny brightening-events have chromospheric/transition-region origin.

Damping of Propagating Kink Waves in the Solar Corona

Ajay K. **Tiwari**, Richard J. Morton, Stephane Régnier, James A. McLaughlin
ApJ **876** 106 **2019**
https://arxiv.org/pdf/1904.08834.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ab164b/pdf
Alfvénic waves have gained renewed interest since the existence of ubiquitous propagating kink waves were discovered in the corona. {It has long been suggested that Alfvénic} waves play an important role in coronal heating and the acceleration of the solar wind. To this effect, it is imperative to understand the mechanisms that enable their energy to be transferred to the plasma. Mode conversion via resonant absorption is believed to be one of the main mechanisms for kink wave damping, and is considered to play a key role in the process of energy transfer. This study examines the damping of propagating kink waves in quiescent coronal loops using the Coronal Multi-channel Polarimeter (CoMP). A coherence-based method is used to track the Doppler velocity signal of the waves, enabling us to investigate the spatial evolution of velocity perturbations. The power ratio of outward to inward propagating waves is used to estimate the associated damping lengths and quality factors. To enable accurate estimates of these quantities, {we provide the first derivation of a likelihood function suitable for fitting models to the ratio of two power spectra obtained from discrete Fourier transforms. Maximum likelihood estimation is used to fit an exponential damping model to the observed variation in power ratio as a function of frequency.} We confirm earlier indications that propagating kink waves are undergoing frequency dependent damping. Additionally, we find that the rate of damping decreases, or equivalently the damping length increases, for longer coronal loops that reach higher in the corona.

New Evidence that Magnetoconvection Drives Solar–Stellar Coronal Heating

Sanjiv K. **Tiwari**1,2,3,4, Julia K. Thalmann5, Navdeep K. Panesar1, Ronald L. Moore1,2, and Amy R. Winebarger
2017 ApJL 843 L20
http://iopscience.iop.org.sci-hub.cc/2041-8205/843/2/L20/
How magnetic energy is injected and released in the solar corona, keeping it heated to several million degrees, remains elusive. Coronal heating generally increases with increasing magnetic field strength. From a comparison of a nonlinear force-free model of the three-dimensional active region coronal field to observed extreme-ultraviolet loops, we find that (1) umbra-to-umbra coronal loops, despite being rooted in the strongest magnetic flux, are invisible, and (2) the brightest loops have one foot in an umbra or penumbra and the other foot in another sunspot's penumbra or in unipolar or mixed-polarity plage. The invisibility of umbra-to-umbra loops is new evidence that magnetoconvection drives solar-stellar coronal heating: evidently, the strong umbral field at both ends quenches the magnetoconvection and hence the heating. Broadly, our results indicate that depending on the field strength in both feet, the photospheric feet of a coronal loop on any convective star can either engender or quench coronal heating in the loop's body. **2014 April 01/02, 2014 July 07**

Imaging Spectropolarimeter for the Multi-Application Solar Telescope at Udaipur Solar Observatory: Characterization of Polarimeter and Preliminary Observations

Alok Ranjan **Tiwary**, Shibu K. Mathew, A. Raja Bayanna, P. Venkatakrishnan…
Solar Physics April **2017**, 292:49
http://link.springer.com/article/10.1007/s11207-017-1076-5

The Multi-Application Solar Telescope (MAST) is a 50 cm off-axis Gregorian telescope that has recently become operational at the Udaipur Solar Observatory (USO). An imaging spectropolarimeter is being developed as one of the back-end instruments of MAST to gain a better understanding of the evolution and dynamics of solar magnetic and velocity fields. This system consists of a narrow-band filter and a polarimeter. The polarimeter includes a linear polarizer and two sets of liquid crystal variable retarders (LCVRs). The instrument is intended for simultaneous observations in the spectral lines 6173 Å and 8542 Å, which are formed in the photosphere and chromosphere, respectively. In this article, we present results from the characterization of the LCVRs for the spectral lines of interest and the response matrix of the polarimeter. We also present preliminary observations of an active region obtained using the spectropolarimeter. For verification purposes, we compare the Stokes observations of the active region obtained from the Helioseismic Magnetic Imager (HMI) onboard the Solar Dynamics Observatory (SDO) with that of MAST observations in the spectral line 6173 Å. We find good agreement between the two observations, considering the fact that MAST observations are limited by seeing.

Cosmic-Ray Propagation Around the Sun - Investigating the Influence of the Solar Magnetic Field on the Cosmic-Ray Sun Shadow

Julia Becker **Tjus**, Paolo Desiati, Niklas Döpper, Horst Fichtner, Jens Kleimann, Mike Kroll, Frederik Tenholt

A&A 633, A83 (2020)

https://doi.org/10.1051/0004-6361/201936306

https://arxiv.org/pdf/1903.12638.pdf

The cosmic-ray Sun shadow, which is caused by high-energy charged cosmic rays being blocked and deflected by the Sun and its magnetic field, has been observed by various experiments such as Argo-YBJ, HAWC, Tibet, and IceCube. Most notably, the shadow's size and depth was recently shown to correlate with the 11-year solar cycle. The interpretation of such measurements, which help to bridge the gap between solar physics and high-energy particle astrophysics, requires a solid theoretical understanding of cosmic-ray propagation in the coronal magnetic field. It is the aim of this paper to establish theoretical predictions for the cosmic-ray Sun shadow in order to identify observables that can be used to study this link in more detail. To determine the cosmic-ray Sun shadow, we numerically compute trajectories of charged cosmic rays in the energy range of 5 to 316 TeV for five different mass numbers. We present and analyse the resulting shadow images for protons and iron, as well as for typically measured cosmic-ray compositions. We confirm the observationally established correlation between the magnitude of the shadowing effect and both the mean sunspot number and the polarity of the magnetic field during the solar cycle. We also show that during low solar activity, the Sun's shadow behaves similarly to that of a dipole, for which we find a non-monotonous dependence on energy. In particular, the shadow can become significantly more pronounced than the geometrical disk expected for a totally unmagnetized Sun. For times of high solar activity, we instead predict the shadow to depend monotonously on energy, and to be generally weaker than the geometrical shadow for all tested energies. These effects should become visible in energy-resolved measurements of the Sun shadow, and may in the future become an independent measure for the level of disorder in the solar magnetic field.

Near-surface Azimuthal Magnetic Fields and Solar Activity Cycles

A. G. **Tlatov**

Solar Phys. Volume 298, article number 147 **2023**

https://arxiv.org/ftp/arxiv/papers/2309/2309.10381.pdf

https://doi.org/10.1007/s11207-023-02239-x

Variations of the azimuthal magnetic fields of the Sun in the 23-25 activity cycles of the activity cycles are considered. To identify azimuthal magnetic fields, the analysis of daily observations of LOS magnetic fields from the regions near the solar limb was performed. It is shown that with a sufficiently large averaging of the data, large-scale structures are distinguished that can be interpreted by horizontal magnetic fields directed along the East-West line. Azimuthal magnetic fields are visible both in the low-latitude zone and at high latitudes. Azimuthal fields at the same latitudes have opposite directions in the northern and southern hemispheres, and also change sign in even and odd cycles of activity. The mechanism of formation of global azimuthal magnetic fields and their role in the cycle of solar activity is discussed. The near-surface azimuthal magnetic field is closely related to the activity cycle. Apparently, the azimuthal field is formed from U-shaped flux tubes of active regions (AR). Due to the presence of the tilt angle AR during differential rotation, the subsurface magnetic fields are pulled in the azimuthal direction. The role of azimuthal magnetic fields in solar activity cycles is considered. A scheme for generating a magnetic field according to a scheme different from Babcock-Layton dynamo models is proposed.

Ground-based Solar Observations for Space Weather Forecasting

A.G. **Tlatov**, A.A. Pevtsov

2023

https://arxiv.org/ftp/arxiv/papers/2303/2303.01708.pdf

The possibilities of organizing an observation service for solar activity in order to provide space weather forecasting are considered. The most promising at this stage is the creation of a ground-based observation network. Such a network should include solar magnetographs that provide observation of large-scale magnetic fields of the Sun, and patrol optical telescopes designed to detect coronal mass ejections and solar flares. The data of magnetographic observations provide an assessment of recurrent solar winds. Patrol telescopes operating in continuous mode allow detecting the moments of eruption and determining the parameters of coronal mass ejections at the initial stage of acceleration. The network service can be supplemented with other types of observations in the radio and optical bands. The paper considers the composition of observational tools, as well as methods and models for forecasting.

Dark Dots on the Photosphere and Their Counting in the Sunspot Index

Andrey G. **Tlatov**
Solar Physics volume 297, Article number: 67 (**2022**)
https://doi.org/10.1007/s11207-022-02002-8
https://arxiv.org/pdf/2205.13142.pdf
A large number of small dark areas can be observed in the continuum with high-spatial resolution in recent satellite observations of the Sun, as well as in high-quality ground-based data. These regions have no penumbra, have a contrast of up to 20%20% and are similar to solar pores. The characteristic area of such structures is from 0.3 to 5 μhm or from 0.5 to 7 Mm typical diameter. The number of such points in one image can be several hundred. The nature of such formations remains unclear.
We have performed a selection of dark regions with a contrast of at least 3%3% of the level of the quiet Sun using data obtained with the Helioseismic and Magnetic Imager (HMI) on board the Solar Dynamcis Observatory (SDO) from 2010 to 2020. We have studied the properties of "dark dots", including their variation with the solar cycle, area distribution, and contrast. We also studied the intensity of the magnetic field of such structures. We found that the number of dark dots with an area of less than 5 μhm, in which the magnetic field is not significant and is less than |B|<30|B|<30 G, is from 60 to 80%80% of the total number of structures of this size. This means that they are not associated with magnetic activity. The existence of such structures can significantly affect the calculations of the sunspot index since they can be mistaken with pores.

The shape of sunspots and solar activity cycles

Andrey **Tlatov**
Solar Physics **volume 297**, Article number: 110
https://arxiv.org/pdf/2203.04722.pdf
https://doi.org/10.1007/s11207-022-02045-x
The paper presents the results of the analysis of the geometric characteristics of sunspots for the period of 19-24 cycles of activity. The shape of sunspots was studied on the basis of the method of normalization of images of sunspots to study the average profile of the spot. The deviation of the shape of sunspots from the axisymmetric configuration is investigated. It was found that the spots, as a rule, have an ellipsoid shape, and the major axis of the ellipse has a predominant inclination to the equator, opposite in the Northern and Southern hemispheres. The angle of inclination of the sunspot axis corresponds to the angle of inclination of the bipoles in the activity cycles. The relationship between the shape of sunspots in the current cycle and the amplitude of the next cycle of activity is found. The greater the elongation along the longitude of the current cycle of spots, the higher the next cycle of activity will be.

On the timing of the next great solar activity minimum

A.G.**Tlatov**. A.A.Pevtsov
Advances in Space Research Volume 60, Issue 5, 1 September **2017**, Pages 1108-1114
http://sci-hub.cc/10.1016/j.asr.2017.05.009
The long-term variations in solar activity are studied using the dataset comprised of sunspot number and 14C radioisotope timeseries. We use a novel S200 index to identify possible past Grand Minima (GM). The Maunder, Oort, Wolf and Spörer Minima fall in phase with the minimum of S200 index. We also show GM develop in clusters, with a separation of about 400–600 years between individual GM. Extending these found similarities to modern solar activity, it is predicted that next grand solar minimum may occur in about ∼2090±20.

Tilt Angles of Solar Filaments over the Period 1919-2014

A. G. **Tlatov**, K.M. Kuzanyan, V.V. Vasil'yeva
Solar Phys. Volume 291, Issue 4, pp 1115-1127 **2016**
http://arxiv.org/pdf/1601.02342v1.pdf
The spatial and temporal distributions of solar filaments were analyzed using data from the Meudon Observatory for the period 1919-2003 and the Kislovodsk Mountain Astronomical Station for the period 1979-2014. We scanned Hα solar synoptic charts on which the filaments were isolated and digitized. The data on each filament comprise its

location, length, area, and other geometrical characteristics. The temporal distributions of the number and total length of the filaments have been obtained. We also found latitudinal migration of filament locations with the solar cycle, and analyzed the longitudinal distribution and asymmetry of filaments in the northern and southern hemispheres, and other properties of their distribution. The tilt angles of filaments with respect the solar equator (τ) were analyzed. On average, the eastern tips of filaments are closer to the poles than the western ones ($\tau \sim 10^\circ$). On the other hand, the filaments in the polar regions ($\theta > 50^\circ$, where θ is the latitude) usually have negative tilts ($\tau < 0^\circ$). The tilt angles vary with the phases of the 11 year sunspot cycle and are at their highest values in the epoch of the activity maximum. In the century-long modulation of the solar activity (Gleissberg cycle), the mean tilt angles of filaments in the mid-latitude zone ($\theta \sim \pm 40^\circ$) were maximum in the middle of the 20th century in solar sunspot cycles 18-19. We hereby propose using the statistical properties of solar filaments as an additional coherent measure of manifestation of the solar cycle which covers all latitudes and for which almost a century long systematically calibrated data series is available.

The change of the solar cyclicity mode ☆

A.G. **Tlatov**

Advances in Space Research, Volume 55, Issue 3, 1 February **2015**, Pages 851–856

http://www.sciencedirect.com/science/article/pii/S027311771400386X

Our analysis of groups of sunspots since the year 1610 till indicates that the Gnevyshev–Ohl rule (GO) displays cycles of inversion with the period of 200 years. The latest inversion occurred in the Hale double cycle 22–23. Due to that, in several subsequent double cycles the odd cycles should be weaker than their preceding even cycles. Gleissberg cycles with the period of about 100 years and variations with the period of 200 years are manifested in variations of physical parameters of sunspots and are interconnected. We suggested that the secular minima of the solar activity occur in the vicinity of the extreme points of the 200-year cycles of inversion of the GO rule. The peak of the next secular minimum is expected between the years 2025÷20352025÷2035. We studied the variations of the physical parameters of sunspots in a Gleissberg cycle. At
the maximum phase of the Gleissberg cycle, the average area of groups and the average number of spots in a group reach their maximum. According to our forecast, the amplitude of the 25th solar activity cycle will be somewhat lower than that of the 24th.

Properties of sunspot umbrae of leading and trailing polarity in 1917–2013

Andrey Georgievich **Tlatov**, , , K.A. Tlatovaa, , V.V. Vasil'evaa, , A.A. Pevtsovb, , K. Mursula

Advances in Space Research, Volume 55, Issue 3, 1 February **2015**, Pages 835–842

http://www.sciencedirect.com/science/article/pii/S0273117714003408

Using the software developed by us, we produced a digitized (tabulated) database of sunspot umbrae and pores observed at Mount Wilson Observatory (MWO) in 1917–2013. The database includes the heliographic coordinates, areas and the polarity and strength of magnetic fields of umbrae and pores in the MWO sunspot drawings. Using this database we study here the properties and long-term variation of sunspot umbrae and pores, separately for leading and trailing polarity spots. We find that the leading sunspots have tendency for larger umbrae and stronger magnetic field strength than the trailing spots. The average field strength and area of sunspot umbrae vary with sunspot cycle. Furthermore, the mean magnetic field strength in sunspot umbrae exhibits a gradual increase from early 1960s to 1990s. The nature of this increase is discussed.

Applying an Automatic Image-Processing Method to Synoptic Observations

Andrey G. **Tlatov**, Valeria V. Vasil'eva, Valentina V. Makarova, Pavel A. Otkidychev

Solar Physics, April **2014**, Volume 289, Issue 4, pp 1403-1412

We used an automatic image-processing method to detect solar-activity features observed in white light at the Kislovodsk Solar Station. This technique was applied to automatically or semi-automatically detect sunspots and active regions. The results of this automated recognition were verified with statistical data available from other observatories and revealed a high detection accuracy. We also provide parameters of sunspot areas, of the umbra, and of faculae as observed in Solar Cycle 23 as well as the **magnetic flux** of these active elements, calculated at the Kislovodsk Solar Station, together with white-light images and magnetograms from the Michaelson Doppler Imager onboard the Solar and Heliospheric Observatory (SOHO/MDI). The ratio of umbral and total sunspot areas during Solar Cycle 23 is ≈ 0.19. The area of sunspots of the leading polarity was approximately 2.5 times the area of sunspots of the trailing polarity.

Bimodal Distribution of Magnetic Fields and Areas of Sunspots

Andrey G. **Tlatov**, Alexei A. Pevtsov

Solar Physics, April **2014**, Volume 289, Issue 4, pp 1143-1152

We applied automatic identification of sunspot umbrae and penumbrae to daily observations from the Helioseismic Magnetic Imager (HMI) on board the Solar Dynamics Observatory (SDO) to study their magnetic flux density (B) and area (A). The results confirm an already known logarithmic relationship between the area of sunspots and their

maximum flux density. In addition, we find that the relation between average magnetic flux density (Bavg) and sunspot area shows a bimodal distribution: for small sunspots and pores (A≤20 millionth of solar hemisphere, MSH), Bavg≈800 G (gauss), and for large sunspots (A≥100 MSH), Bavg is about 600 G. For intermediate sunspots, average flux density linearly decreases from about 800 G to 600 G. A similar bimodal distribution was found in several other integral parameters of sunspots. We show that this bimodality can be related to different stages of sunspot penumbra formation and can be explained by the difference in average inclination of magnetic fields at the periphery of small and large sunspots.

A new dynamo pattern revealed by the tilt angle of bipolar sunspot groups

A.**Tlatov**, E.Illarionov, D.Sokoloff, V.Pipin
E-print, April **2013**, MNRAS
We obtain the latitude-time distribution of the averaged tilt angle of solar bipoles. For large bipoles, which are mainly bipolar sunspot groups, the spatially averaged tilt angle is positive in the Northern solar hemisphere and negative in the Southern, with modest variations during course of the solar cycle. We consider the averaged tilt angle to be a tracer for a crucial element of the solar dynamo, i.e. the regeneration rate of poloidal large-scale magnetic field from toroidal. The value of the tilt obtained crudely corresponds to a regeneration factor corresponding to about 10% of r.m.s. velocity of solar convection. These results develop findings of Kosovichev and Stenflo (2012) concerning Joy's law, and agree with the usual expectations of solar dynamo theory. Quite surprisingly, we find a pronounced deviation from these properties for smaller bipoles, which are mainly solar ephemeral regions. They possess tilt angles of approximately the same absolute value, but of opposite sign compared to that of the large bipoles. Of course, the tilt data for small bipoles are less well determined than those for large bipoles; however they remain robust under various modifications of the data processing.

Tilt of sunspot bipoles in Solar Cycles 15 to 24

Ksenia **Tlatova**, Andrey Tlatov, Alexei Pevtsov, Kalevi Mursula, Valeria Vasil'eva, Elina Heikkinen, Luca Bertello, Alexander Pevtsov, Ilpo Virtanen, Nina Karachik
Solar Phys. 293:118 **2018**
https://arxiv.org/pdf/1807.07913.pdf
We use recently digitized sunspot drawings from Mount Wilson Observatory to investigate the latitudinal dependence of tilt angles of active regions and its change with solar cycle. The drawings cover the period from 1917 to present and contain information about polarity and strength of magnetic field in sunspots. We identify clusters of sunspots of same polarity, and used these clusters to form ``bipole pairs''. The orientation of these bipole pairs was used to measure their tilts. We find that the latitudinal profile of tilts does not monotonically increase with latitude as most previous studies assumed, but instead, it shows a clear maximum at about 25--30 degree latitudes. Functional dependence of tilt (γ) on latitude (φ) was found to be $\gamma=(0.20\pm0.08)\sin(2.80\varphi)+(-0.00\pm0.06)$. We also find that latitudinal dependence of tilts varies from one solar cycle to another, but larger tilts do not seem to result in stronger solar cycles. Finally, we find the presence of a systematic offset in tilt of active regions (non-zero tilts at the equator), with odd cycles exhibiting negative offset and even cycles showing the positive offset.

Understanding the Relationship between Solar Coronal Abundances and F10.7 cm Radio Emission

Andy S. H. **To**1, Alexander W. James1,2, T. S. Bastian3, Lidia van Driel-Gesztelyi1,4,5, David M. Long1,6, Deborah Baker1, David H. Brooks7, Samantha Lomuscio3, David Stansby1, and Gherardo Valori8
2023 ApJ 948 121
https://iopscience.iop.org/article/10.3847/1538-4357/acbc1b/pdf
Sun-as-a-star coronal plasma composition, derived from full-Sun spectra, and the F10.7 radio flux (2.8 GHz) have been shown to be highly correlated (r = 0.88) during solar cycle 24. However, this correlation becomes nonlinear during increased solar magnetic activity. Here we use cotemporal, high spatial resolution, multiwavelength images of the Sun to investigate the underlying causes of the nonlinearity between coronal composition (FIP bias) and F10.7 solar index correlation. Using the Karl G. Jansky Very Large Array, Hinode/EIS (EUV Imaging Spectrometer), and the Solar Dynamics Observatory, we observed a small active region, AR 12759, throughout the solar atmosphere from the photosphere to the corona. The results of this study show that the magnetic field strength (flux density) in active regions plays an important role in the variability of coronal abundances, and it is likely the main contributing factor to this nonlinearity during increased solar activity. Coronal abundances above cool sunspots are lower than in dispersed magnetic plage regions. Strong magnetic concentrations are associated with stronger F10.7 cm gyroresonance emission. Considering that as the solar cycle moves from minimum to maximum, the sizes of sunspots and their field strength increase with the gyroresonance component, the distinctly different tendencies of radio emission and coronal abundances in the vicinity of sunspots is the likely cause of saturation of Sun-as-a-star coronal abundances during solar maximum, while the F10.7 index remains well correlated with the sunspot number and other magnetic field proxies. **2020 April 3, 7**

Two-Station Interplanetary Scintillation Measurements of Solar Wind Speed near the Sun Using the X-band Radio Signal of the Nozomi Spacecraft

M. **Tokumaru**, S. Fujimaki, M. Higashiyama, A. Yokobe, T. Ohmi, K. Fujiki and M. Kojima
Solar Physics, Volume 276, Numbers 1-2, 315-336, **2012**

Interplanetary scintillation (IPS) measurements of the solar wind speed for the distance range between 13 and 37 R S were carried out during the solar conjunction of the Nozomi spacecraft in 2000–2001 using the X-band radio signal. Two large-aperture antennas were employed in this study, and the baseline between the two antennas was several times longer than the Fresnel scale for the X-band. We successfully detected a positive correlation of IPS from the cross-correlation analysis of received signal data during ingress, and estimated the solar wind speed from the time lag corresponding to the maximum correlation by assuming that the solar wind flows radially. The speed estimates range between 200 and 540 km s−1 with the majority below 400 km s−1. We examined the radial variation in the solar wind speed along the same streamline by comparing the Nozomi data with data obtained at larger distances. Here, we used solar wind speed data taken from 327 MHz IPS observations of the Solar-Terrestrial Environment Laboratory (STEL), Nagoya University, and in situ measurements by the Advanced Composition Explorer (ACE) for the comparison, and we considered the effect of the line-of-sight integration inherent to IPS observations for the comparison. As a result, Nozomi speed data were proven to belong to the slow component of the solar wind. Speed estimates within 30 R S were found to be systematically slower by 10–15 % than the terminal speeds, suggesting that the slow solar wind is accelerated between 13 and 30 R S.

Fluctuating Sunspot Numbers Exhibit A Non-Markovian Damped Stochastic Process

Reynan L. **Toledo**, Reinabelle Reyes, Christopher C. Bernido
2023
https://arxiv.org/ftp/arxiv/papers/2306/2306.14151.pdf

The rise and fall in the number of sunspots have served as a lynchpin in many investigations on solar dynamics. Arising from magnetic disturbances in the sun, variations in sunspot numbers have helped define a solar cycle of around eleven years which to date is yet to be fully understood. We model the fluctuation of sunspot numbers as a modulated Brownian motion characterized by a memory parameter {\mu} and a decay parameter \b{eta}. By matching the theoretical and empirical mean square deviation of the sunspot numbers, the values of {\mu} and \b{eta} are determined for each solar cycle. This allows us to obtain an exact form of a probability density function (PDF) which closely matches the dataset for sunspots. This novel PDF for sunspot numbers exhibit a memory behavior from which some insights could be obtained. In particular, the values of {\mu} indicate that consecutive sunspot numbers are negatively correlated for large times. The values of \b{eta}, on the other hand, when viewed as a time series from one solar cycle to another, indicate a positive trend towards increasing values which could possibly suggest a diminishing solar activity.

Evidence for a Time Lag in Solar Modulation of Galactic Cosmic Rays

Nicola **Tomassetti**1, Miguel Orcinha2, Fernando Barão2, and Bruna Bertucci1
2017 ApJL 849 L32
http://iopscience.iop.org/article/10.3847/2041-8213/aa9373/pdf

The solar modulation effect of cosmic rays in the heliosphere is an energy-, time-, and particle-dependent phenomenon that arises from a combination of basic particle transport processes such as diffusion, convection, adiabatic cooling, and drift motion. Making use of a large collection of time-resolved cosmic-ray data from recent space missions, we construct a simple predictive model of solar modulation that depends on direct solar-physics inputs: the number of solar sunspots and the tilt angle of the heliospheric current sheet. Under this framework, we present calculations of cosmic-ray proton spectra, positron/electron and antiproton/proton ratios, and their time dependence in connection with the evolving solar activity. We report evidence for a time lag $\Delta T = 8.1 \pm 1.2$ months, between solar-activity data and cosmic-ray flux measurements in space, which reflects the dynamics of the formation of the modulation region. This result enables us toforecast the cosmic-ray flux near Earth well in advance by monitoring solar activity.

Scientific objectives and capabilities of the Coronal Solar Magnetism Observatory†

S. **Tomczyk**, E. Landi, J. T. Burkepile, R. Casini, E. E. DeLuca, Y. Fan, S. E. Gibson, H. Lin, S. W. McIntosh, S. C. Solomon, G. de Toma, A. G. de Wijn, J. Zhang

DOI: 10.1002/2016JA022871

Magnetic influences increase in importance in the solar atmosphere from the photosphere out into the corona, yet our ability to routinely measure magnetic fields in the outer solar atmosphere is lacking. We describe the scientific objectives and capabilities of the **COronal Solar Magnetism Observatory** (**COSMO**), a proposed synoptic facility designed to measure magnetic fields and plasma properties in the large-scale solar atmosphere. COSMO comprises a suite of three instruments chosen to enable the study of the solar atmosphere as a coupled system: 1) a coronagraph with a 1.5-m aperture to measure the magnetic field, temperature, density and dynamics of the corona; 2) an instrument for diagnostics of chromospheric and prominence magnetic fields and plasma properties; and 3) a white-light K-coronagraph to measure the density structure and dynamics of the corona and coronal mass ejections. COSMO will provide a unique combination of magnetic field, density, temperature and velocity observations in the corona and chromosphere that have the potential to transform our understanding of fundamental physical processes in the solar atmosphere and their role in the origins of solar variability and space weather.

Prospects and Challenges for Helioseismology **Review**

J. **Toomre**, M. J. Thompson

Space Science Reviews Volume 196, Issue 1, pp 1-14 **2015**

Helioseismology has advanced considerably our knowledge of the interior of the Sun over the past three decades. Our understanding of the Sun's internal structure, its dynamics, rotation, convection and magnetism, have all been advanced. Yet there are challenges, areas where the results from helioseismology are tantalizing but inconclusive, and aspects where the interpretation of the data has still to be put on a firm footing. In this paper we shall focus on a number of those challenges and give our assessment of where progress needs to be made in the next decade.

Convective Magnetic Flux Emergence Simulations from the Deep Solar Interior to the Photosphere: Comprehensive Study of Flux Tube Twist

Shin **Toriumi**1, Hideyuki Hotta2, and Kanya Kusano2

2024 ApJ 975 209

https://iopscience.iop.org/article/10.3847/1538-4357/ad7e1d/pdf

The emergence of magnetic flux from the deep convection zone plays an important role in solar magnetism, such as the generation of active regions and triggering of various eruptive phenomena, including jets, flares, and coronal mass ejections. To investigate the effects of magnetic twist on flux emergence, we performed numerical simulations of flux tube emergence using the radiative magnetohydrodynamic code R2D2 and conducted a systematic survey on the initial twist. Specifically, we varied the twist of the initial tube both positively and negatively from zero to twice the critical value for kink instability. As a result, regardless of the initial twist, the flux tube was lifted by the convective upflow and reached the photosphere to create sunspots. However, when the twist was too weak, the photospheric flux was quickly diffused and not retained long as coherent sunspots. The degree of magnetic twist measured in the photosphere conserved the original twist relatively well and was comparable to actual solar observations. Even in the untwisted case, a finite amount of magnetic helicity was injected into the upper atmosphere because the background turbulence added helicity. However, when the initial twist exceeded the critical value for kink instability, the magnetic helicity normalized by the total magnetic flux was found to be unreasonably larger than the observations, indicating that the kink instability of the emerging flux tube may not be a likely scenario for the formation of flare-productive active regions.

Universal Scaling Laws for Solar and Stellar Atmospheric Heating: Catalog of Power-law Index between Solar Activity Proxies and Various Spectral Irradiances

Shin **Toriumi**, Vladimir S. Airapetian, Kosuke Namekata, Yuta Notsu

ApJ Supplement Series **262** 46 **2022**

https://arxiv.org/pdf/2208.10511.pdf

https://iopscience.iop.org/article/10.3847/1538-4365/ac8b15/pdf

The formation of extremely hot outer atmospheres is one of the most prominent manifestations of magnetic activity common to the late-type dwarf stars, including the Sun. It is widely believed that these atmospheric layers, the corona, transition region, and chromosphere, are heated by the dissipation of energy transported upwards from the stellar surface by the magnetic field. This is signified by the spectral line fluxes at various wavelengths, scaled with power-law relationships against the surface magnetic flux over a wide range of formation temperatures, which are universal to the Sun and Sun-like stars of different ages and activity levels. This study describes a catalog of power-law indices between solar activity proxies and various spectral line fluxes. Compared to previous studies, we expanded the number of proxies, which now includes the total magnetic flux, total sunspot number, total sunspot area, and the F10.7 cm radio flux, and further enhances the number of spectral lines by a factor of two. This provides the data to study in detail the flux-flux scaling laws from the regions specified by the temperatures of the corona (log(T/K)=6-7) to those of the chromosphere (log(T/K)~4), as well as the reconstruction of various spectral line fluxes of the Sun in the past, F-, G-, and K-type dwarfs, and the modeled stars.

Universal Scaling Laws for the Solar and Stellar Atmospheric Heating

Shin **Toriumi**, Vladimir S. Airapetian

ApJ **927** 179 **2022**

https://arxiv.org/pdf/2202.01232.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/ac5179/pdf

The Sun and sun-like stars commonly host the multi-million-Kelvin coronae and the 10,000-Kelvin chromospheres. These extremely hot gases generate X-ray and Extreme Ultraviolet emissions that may impact the erosion and chemistry of (exo)planetary atmospheres, influencing the climate and conditions of habitability. However, the mechanism of coronal and chromospheric heating is still poorly understood. While the magnetic field most probably plays a key role in driving and transporting energy from the stellar surface upwards, it is not clear if the atmospheric heating mechanisms of the Sun and active sun-like stars can be described in a unified manner. To this end, we report on a systematic survey of the responses of solar and stellar atmospheres to surface magnetic flux over a wide range of temperatures. By analyzing 10 years of multi-wavelength synoptic observations of the Sun, we reveal that the irradiance and magnetic flux show power-law relations with an exponent decreasing from above- to sub-unity as the temperature decreases from the corona to the chromosphere. Moreover, this trend indicating the efficiency of atmospheric heating can be extended to sun-like stars. We also discover that the power-law exponent has a solar cycle dependence, where it becomes smallest at activity maximum, probably due to the saturation of atmospheric heating. Our study provides observational evidence that the mechanism of atmospheric heating is universal among the Sun and sun-like stars, regardless of age or activity.

Sun-as-a-star Spectral Irradiance Observations of Transiting Active Regions

Shin **Toriumi**, Vladimir S. Airapetian, Hugh S. Hudson, Carolus J. Schrijver, Mark C.M. Cheung, Marc L. DeRosa

ApJ **902** 36 **2020**

https://arxiv.org/pdf/2008.04319.pdf

Major solar flares are prone to occur in active region atmospheres associated with large, complex, dynamically-evolving sunspots. This points to the importance of monitoring the evolution of starspots, not only in visible but also in ultra violet (UV) and X-rays, in understanding the origin and occurrence of stellar flares. To this end, we perform spectral irradiance analysis on different types of transiting solar active regions by using a variety of full-disk synoptic observations. The target events are an isolated sunspot, spotless plage, and emerging flux in prolonged quiet-Sun conditions selected from the past decade. We find that the visible continuum and total solar irradiance become darkened when the spot is at the central meridian, whereas it is bright near the solar limb; UV bands sensitive to the chromosphere correlate well with the variation of total unsigned magnetic flux in the photosphere; amplitudes of EUV and soft X-ray increase with the characteristic temperature, whose light curves are flat-topped due to their sensitivity to the optically thin corona; the transiting spotless plage does not show the darkening in the visible irradiance, while the emerging flux produces an asymmetry in all light curves about the central meridian. The multi-wavelength sun-as-a-star study described here indicates that such time lags between the coronal and photospheric light curves have the potential to probe the extent of coronal magnetic fields above the starspots. In addition, EUV wavelengths that are sensitive to the transition-region temperature sometimes show anti-phased variations, which may be used for diagnosing plasmas around starspots. **2018-Feb-01-11, 2018-Jul-04-14, 2019-Jan-14-24, 2019-Nov-27-Dec 07**

Analysis of Solar Diameter Measurements Made at the Basilica of San Petronio during and after the Maunder Minimum

I. **Tovar**1, A. J. P. Aparicio1,2, V. M. S. Carrasco1,2, M. C. Gallego1,2, and J. M. Vaquero2,3

2021 ApJ 912 122

https://doi.org/10.3847/1538-4357/abefdb

A series of measurements of the solar diameter taken in the meridian line of the Basilica of San Petronio (Bologna, Italy) between 1655 and 1736 has been analyzed. This series is of interest because the measurement period includes the Maunder Minimum (1645–1715; hereafter MM) when solar activity was abnormally low. Some authors have suggested an increase of the solar diameter during the MM. Trying to detect these changes, statistical analyses comparing measurements taken in San Petronio during the MM (1655–1715) and other ones taken in a subsequent period (1716–1736) have been performed. Mann–Whitney U tests and Student's t-tests indicate that there is no statistically significant difference in the medians and averages of the solar diameter in both periods. In fact, we have found differences around $0''.6$ in the medians and the averages, which are below the mean accuracy of the instrument. Therefore, we conclude that there is no difference between the solar diameter value measured during the MM (1655–1715) and that for the subsequent period 1716–1736. This implies that there has not been an increase in the solar diameter of several arcseconds during the MM as has been speculated by some authors.

The Dark Side of the Sun A Plea for a Next-Generation Opacity Calculation

Regner **Trampedach**
Proceedings of the second Workshop on Astrophysical Opacities (held in Kalamazoo, MI, 2017) **2018**
https://arxiv.org/pdf/1804.03746.pdf
Is the Sun likely to have a more opaque interior than previously thought? The solar oxygen (or abundance) problem can be solved with higher interior opacities, reconciling abundance analyses based on 3D convective atmospheres with the helioseismic structure of the solar interior. This has been known for more than a decade, but last year we learned that the absorption by just iron may contribute 7\% more to the solar opacity at the bottom of the convection zone than predicted by any opacity calculation so far, and by OP05 in particular. I find that artificial changes to the absorption (calibrated against the iron experiment) by other elements in a solar mixture give an opacity increase of a shape and magnitude that can restore agreement between modern abundance analysis and helioseismology. This suggests that improved opacity calculations will solve the solar oxygen problem.

Bayesian Methods for Reconstructing Sunspot Numbers Before and During the Maunder Minimum

Guido **Travaglini**
Solar Physics January **2017**, 292:23
The Maunder Minimum (MM) was an extended period of reduced solar activity in terms of yearly sunspot numbers (SSN) during 1610 – 1715. The reality of this "grand minimum" is generally accepted in the scientific community, but the statistics of the SSN record suggest a need for data reconstruction. The MM data show a nonstandard distribution compared with the entire SSN signal (1610 – 2014). The pattern does not satisfy the weakly stationary solar dynamo approximation, which characterizes many natural events spanning centuries or even millennia, including the Sun and the stars. Over the entire observation period (1610 – 2014), the reported SSN exhibits statistically significant regime switches, departures from autoregressive stationarity, and growing trends. Reconstruction of the SSN during the pre-MM and MM periods is performed using five novel statistical procedures in support of signal analysis. A Bayesian–Monte Carlo backcast technique is found to be most reliable and produces an SSN signal that meets the weak-stationarity requirement. The computed MM signal for this reconstruction does not show a "grand" minimum or even a "semi-grand" minimum.

Inferring depth-dependent plasma motions from surface observations using the DeepVel neural network

Benoit **Tremblay**1,2,3*, Jean-François Cossette3,4, Maria D. Kazachenko2,5, Paul Charbonneau3 and Alain Vincent3
J. Space Weather Space Clim. **2021**, 11, 9
https://www.swsc-journal.org/articles/swsc/pdf/2021/01/swsc200059.pdf
Coverage of plasma motions is limited to the line-of-sight component at the Sun's surface. Multiple tracking and inversion methods were developed to infer the transverse motions from observational data. Recently, the DeepVel neural network was trained with computations performed by numerical simulations of the solar photosphere to recover the missing transverse component at the surface and at two additional optical depths simultaneously from the surface white light intensity in the Quiet Sun. We argue that deep learning could provide additional spatial coverage to existing observations in the form of depth-dependent synthetic observations, i.e. estimates generated through the emulation of numerical simulations. We trained different versions of DeepVel using slices from numerical simulations of both the Quiet Sun and Active Region at various optical and geometrical depths in the solar atmosphere, photosphere and upper convection zone to establish the upper and lower limits at which the neural network can generate reliable synthetic observations of plasma motions from surface intensitygrams. Flow fields inferred in the photosphere and low chromosphere $\tau \in [0.1, 1)$ are comparable to inversions performed at the surface ($\tau \approx 1$) and are deemed to be suitable for use as synthetic estimates in data assimilation processes and data-driven simulations. This upper limit extends closer to the transition region ($\tau \approx 0.01$) in the Quiet Sun, but not for Active Regions. Subsurface flows inferred from surface intensitygrams fail to capture the small-scale features of turbulent convective motions as depth crosses a few hundred kilometers. We suggest that these reconstructions could be used as first estimates of a model's velocity vector in data assimilation processes to nowcast and forecast short term solar activity and space weather.

Inferring Plasma Flows at Granular and Supergranular Scales With a New Architecture for the DeepVel Neural Network

Benoit **Tremblay**, and Raphaël Attie
Front. Astron. Space Sci., **2020** |
https://doi.org/10.3389/fspas.2020.00025
The wealth of observational data available has been instrumental in investigating physical features relevant to solar granulation, supergranulation and Active Regions. Meanwhile, numerical models have attempted to bridge the gap between the physics of the solar interior and such observations. However, there are relevant physical quantities that can be modeled but that cannot be directly measured and must be inferred. For example, direct measurements of

plasma motions at the photosphere are limited to the line-of-sight component. Methods have consequently been developed to infer the transverse plasma motions from continuum images in the case of the Quiet Sun and magnetograms in the case of Active Regions. Correlation-based tracking methods calculate the optical flows by correlating series of images locally while other methods like “Coherent Structure Tracking” or “Balltracking” exploit the coherency of photospheric granules to track them and use the group motions of the granules as a proxy of the average plasma flows advecting them. Recently, neural network computing has been used in conjunction with numerical models of the Sun to be able to recover the full velocity vector in photospheric plasma from continuum images. We experiment with a new architecture for the DeepVel neural network which takes inspiration from the U-Net architecture. Simulation data of the Quiet Sun and Active Regions are then used to evaluate the response at granular and supergranular scales of the aforementioned method.

Reconstruction of Horizontal Plasma Motions at the Photosphere from Intensitygrams: A Comparison Between DeepVel, LCT, FLCT, and CST

Benoit **Tremblay**, Thierry Roudier, Michel Rieutord, Alain Vincent
Solar Physics April **2018**, 293:57
https://link.springer.com/content/pdf/10.1007%2Fs11207-018-1276-7.pdf
Direct measurements of plasma motions in the photosphere are limited to the line-of-sight component of the velocity. Several algorithms have therefore been developed to reconstruct the transverse components from observed continuum images or magnetograms. We compare the space and time averages of horizontal velocity fields in the photosphere inferred from pairs of consecutive intensitygrams by the LCT, FLCT, and CST methods and the DeepVel neural network in order to identify the method that is best suited for generating synthetic observations to be used for data assimilation. The Stein and Nordlund (Astrophys. J. Lett.753, L13, 2012) magnetoconvection simulation is used to generate synthetic SDO/HMI intensitygrams and reference flows to train DeepVel. Inferred velocity fields show that DeepVel performs best at subgranular and granular scales and is second only to FLCT at mesogranular and supergranular scales.

Sensitivity of Global Oscillation Frequencies to Solar Activity on Short Timescales

Sushanta C. **Tripathy**1 and Kiran Jain1
2024 Res. Notes AAS 8 264
https://iopscience.iop.org/article/10.3847/2515-5172/ad85e8
Sun's oscillations frequencies vary with the changing magnetic activity and hold a strong positive correlation. While most of the analysis for global modes have been carried out using time series longer than a solar rotation, only a few studies are available showing their variation on shorter timescales. Using Doppler observations from Global Oscillation Network Group during the period 1995–2024, we analyze oscillation frequencies computed on a timescale of nine days and compare them with those obtained from 108 days. We also study their sensitivity in cycles 23 and 24 to the change in solar activity as represented by the 10.7 cm radio flux.

Probing the Sun's Near Surface Shear Layer using HMI Spherical Harmonic Coefficients

Sushanta C. **Tripathy**, Kiran Jain, Shukurijon Kholikov, Rudolf Komm
Proceedings of the IAU Symposium 365 - Dynamics of Solar and Stellar Convection Zones and Atmospheres, 2023 August 21-25, Yerevan, Armenia **2023**
https://arxiv.org/pdf/2312.11699.pdf
We have measured zonal and meridional components of subsurface flows up to a depth of 30 Mm below the solar surface by applying the technique of ring diagram on Dopplergrams which are constructed from the spherical harmonic (SH) coefficients. The SH coefficients are obtained from the Helioseismic and Magnetic Imager (HMI) full-disk Dopplergrams. We find a good agreement and some differences between the flows obtained in this study with those from the traditional methods using direct Dopplergrams.

Improving the Understanding of Subsurface Structure and Dynamics of Solar Active Regions

S. C. **Tripathy**, K. Jain, D. Braun, P. Cally, M. Dikpati, T. Felipe, R. Jain, S. Kholikov, E. Khomenko, R. Komm, J. Leibacher, V. Martinez-Pillet, A. Pevtsov, S.P. Rajaguru, M. Roth, H. Uitenbroek, J. Zhao
A white paper submitted to the decadal survey for solar and space Physics (Heliophysics) -- SSPH 2024-2033 **2023**
https://arxiv.org/ftp/arxiv/papers/2305/2305.07585.pdf
The goal of helioseismology is to provide accurate information about the Sun's interior from the observations of the wave field at its surface. In the last three decades, both global and local helioseismology studies have made significant advances and breakthroughs in solar physics. However, 3-d mapping of the structure and dynamics of sunspots and active regions below the surface has been a challenging task and are among the longest standing and intriguing puzzles of solar physics due to the complexity of the turbulent and dynamic nature of sunspots. Thus the key problems that need to be addressed during the next decade are: (i) Understanding the wave excitation

mechanisms in the quiet Sun and magnetic regions, (ii) Characterizing the wave propagation and transformation in strong and inclined magnetic field regions and understanding the magnetic portals in the chromosphere, (iii) Improving helioseismology techniques and investigating the whole life cycle of active regions, from magnetic flux emergence to dissipation, and (iv) Detecting helioseismic signature of the magnetic flux of active regions before it becomes visible on the surface so as to provide warnings several days before the emergence. For a transformative progress on these problems require full disk, simultaneous Doppler and vector magnetic field measurements of the photosphere up to the chromosphere with a spatial resolution of about 2 arc-sec as well as large-scale radiative MHD simulations of the plasma dynamics from the sub-photosphere to the chromosphere.

Seismology of Active Regions: Current Status and Perspectives **Review**

Sushanta **Tripathy**

Front. Astron. Space Sci. 10: 1091777 **2023**.

doi: 10.3389/fspas.2023.1091777

https://www.frontiersin.org/articles/10.3389/fspas.2023.1091777/pdf

The goal of helioseismology is to provide accurate information about the Sun's interior from the observations of the wave field at its surface. In the last three decades, both global and local helioseismology studies have made significant advances and breakthroughs in solar physics. However, 3-d mapping of the structure and dynamics of sunspots and active regions below the surface has been a challenging task and is among the long standing and intriguing puzzles in solar physics due to the complexity of the turbulent and dynamic nature of magnetized regions. In this review, I present some of the recent results relevant for helioseismology of sunspots and active regions obtained from high resolution observations, forward modeling and numerical simulations.

Identification of Inertial Modes in the Solar Convection Zone

Santiago A. **Triana**1, Gustavo Guerrero2,3, Ankit Barik4, and Jérémy Rekier1,5

2022 ApJL 934 L4

https://iopscience.iop.org/article/10.3847/2041-8213/ac7dac/pdf

The observation of global acoustic waves (p modes) in the Sun has been key to unveiling its internal structure and dynamics. A different kind of wave, known as sectoral Rossby modes, has been observed and identified, which potentially opens the door to probing internal processes that are inaccessible through p-mode helioseismology. Yet another set of waves, appearing as retrograde-propagating, equatorially antisymmetric vorticity waves, has also been observed but their identification remained elusive. Here, through a numerical model implemented as an eigenvalue problem, we provide evidence supporting the identification of those waves as a class of inertial eigenmodes, distinct from the Rossby-mode class, with radial velocities comparable to the horizontal ones deep in the convective zone but still small compared to the horizontal velocities toward the surface. We also suggest that the signature of tesseral-like Rossby modes might be present in recent observational data.

The Aditya-L1 mission of ISRO

Durgesh **Tripathi**, D. Chakrabarty, B. Raghvendra Prasad, A. Nandi, A. N. Ramaprakash, Nigar Shaji, K. Sankarasubramanian, R. Satheesh Thampi, V. K. Yadav

The Era of Multi-Messenger Solar Physics Proceedings IAU Symposium No. 372, **2022** G. Cauzzi & A. Tritschler, eds.

https://arxiv.org/pdf/2212.13046.pdf

The Aditya-L1 is the first space-based solar observatory of the Indian Space Research Organization (ISRO). The spacecraft will carry seven payloads providing uninterrupted observations of the Sun from the first Lagrangian point. Aditya-L1 comprises four remote sensing instruments, {\it viz.} a coronagraph observing in visible and infrared, a full disk imager in Near Ultra-Violet (NUV), and two full-sun integrated spectrometers in soft X-ray and hard X-ray. In addition, there are three instruments for in-situ measurements, including a magnetometer, to study the magnetic field variations during energetic events. Aditya-L1 is truly a mission for multi-messenger solar astronomy from space that will provide comprehensive observations of the Sun across the electromagnetic spectrum and in-situ measurements in a broad range of energy, including magnetic field measurements at L1.

Coronal heating and solar wind formation in quiet Sun and coronal holes: a unified scenario

Durgesh **Tripathi**, V. N. Nived, Sami K Solanki

ApJ **908** 28 **2021**

https://arxiv.org/pdf/2011.09803.pdf

https://doi.org/10.3847/1538-4357/abcc6b

Coronal holes (CHs) are darker than quiet Sun (QS) when observed in coronal channels. This study aims to understand the similarities and differences between CHs and QS in the transition region using the

\ion{Si}{4}~1394~Å line recorded by the Interface Region Imaging Spectrograph (IRIS) by considering the distribution of magnetic field measured by the Helioseismic and Magnetic Imager (HMI) onboard the Solar Dynamics Observatory (SDO). We find that \ion{Si}{4} intensities obtained in CHs are lower than those obtained in QS for regions with identical magnetic flux densities. Moreover, the difference in intensities between CHs and QS increases with increasing magnetic flux. For the regions with equal magnetic flux density, QS line profiles are more redshifted than those measured in CHs. Moreover, the blue shifts measured in CHs show an increase with increasing magnetic flux density unlike in the QS. The non-thermal velocities in QS, as well as in CHs, show an increase with increasing magnetic flux. However, no significant difference was observed in QS and CHs, albeit a small deviation at small flux densities. Using these results, we propose a unified model for the heating of the corona in the QS and in CHs and the formation of the solar wind. **2014/07/24, 2014/07/26, 2015/10/14**

On the ratios of \ion{Si}{4} lines (λ1394/λ1403) in an emerging flux region

Durgesh **Tripathi**, V. N. Nived, Hiroaki Isobe, J.G. Doyle
ApJ **894** 128 **2020**
https://arxiv.org/pdf/2004.04530.pdf
https://doi.org/10.3847/1538-4357/ab8558
The resonance lines of \ion{Si}{4} formed at λ1394 and 1403 Å are the most critical for the diagnostics of the solar transition region in the observations of the Interface Region Imaging Spectrograph (IRIS). Studying the intensity ratios of these lines (1394Å/1403Å), which under optically thin condition is predicted to be two, helps us to diagnose the optical thickness of the plasma being observed. Here we study the evolution of the distribution of intensity ratios in 31 IRIS rasters recorded for four days during the emergence of an active region. We found that during the early phase of the development, the majority of the pixels show intensity ratios smaller than two. However, as the active region evolves, more and more pixels show the ratios closer to two. Besides, there are a substantial number of pixels with ratio values larger than 2. At the evolved stage of the active region, the pixels with ratios smaller than two were located on the periphery, whereas those with values larger than 2 were in the core. However, for quiet Sun regions, the obtained intensity ratios were close to two irrespective of the location on the disk. Our findings suggest that the \ion{Si}{4} lines observed in active regions are affected by the opacity during the early phase of the flux emergence. The results obtained here could have important implications for the modelling of the solar atmosphere, including the initial stage of the emergence of an active region as well as quiet Sun. **2018 May 22-25**

A Study of Acoustic Halos in Active Region NOAA 11330 using Multi-Height SDO Observations

S. C. **Tripathy**, K. Jain, S. Kholikov, F. Hill, S. P. Rajaguru, P. S. Cally
Advances in Space Research Volume 61, Issue 2, 15 January **2018**, Pages 691-704
https://arxiv.org/pdf/1711.01259.pdf
We analyze data from the Helioseismic Magnetic Imager (HMI) and the Atmospheric Imaging Assembly (AIA) instruments on board the Solar Dynamics Observatory (SDO) to characterize the spatio-temporal acoustic power distribution in active regions as a function of the height in the solar atmosphere. For this, we use Doppler velocity and continuum intensity observed using the magnetically sensitive line at 6173 \AA\ as well as intensity at 1600 \AA\ and 1700 \AA. We focus on the power enhancements seen around AR 11330 as a function of wave frequency, magnetic field strength, field inclination and observation height. We find that acoustic halos occur above the acoustic cutoff frequency and extends up to 10 mHz in HMI Doppler and AIA 1700 \AA\ observations. Halos are also found to be strong functions of magnetic field and their inclination angle. We further calculate and examine the spatially averaged relative phases and cross-coherence spectra and find different wave characteristics at different heights. **27-28 October 2011**

Variations in High Degree Acoustic Mode Frequencies of the Sun during Solar Cycle 23 and 24

S.C. **Tripathy**, K. Jain, F. Hill
ApJ **2015**
http://arxiv.org/pdf/1509.05474v1.pdf
We examine continuous measurements of the high-degree acoustic mode frequencies of the Sun covering the period from 2001 July to June 2014. These are obtained through the ring-diagram technique applied to the full-disk Doppler observations made by the Global Oscillation Network Group (GONG). The frequency shifts in the degree range of 180-1200 are correlated with different proxies of solar activity e.g. 10.7 cm radio flux, the International Sunspot Number and the strength of the local magnetic field. In general, a good agreement is found between the shifts and activity indices, and the correlation coefficients are found to be comparable with intermediate degree mode frequencies. Analyzing the frequency shifts separately for the two cycles, we find that cycle 24 is weaker than cycle 23. Since the magnetic activity is known to be different in the two hemisphere, for the first time, we compute the frequency shifts over the two hemispheres separately and find that the shifts also display hemispheric

asymmetry; the amplitude of shifts in the northern hemisphere peaked during late 2011, more than two years earlier than the south. We further correlate the hemispheric frequency shifts with the hemispheric sunspot number and mean magnetic activity index. Since the frequency shifts and the hemispheric activity indices are found to be significantly correlated, we suggest that the shifts be used as an indicator of hemispheric activity since not many indices are measured over the two hemispheres separately. We also investigate the variation at different latitudinal bands and conclude that the shifts in active latitudes correlate well with the local magnetic activity index.

On the Reflection of Torsional Alfvén Waves from the Solar Transition Region

Yuriy **Tsap** & Yulia Kopylova
Solar Physics volume 296, Article number: 5 (**2021**)
https://link.springer.com/content/pdf/10.1007/s11207-020-01753-6.pdf
On the basis of the two-layer model, we investigate the reflection of linear torsional Alfvén waves propagating in a thin magnetic flux tube from the solar transition region. As distinguished from Hollweg (Astrophys. J. 277, 392, 1984), the density jump across the transition region modeled by a sharp boundary is taken into account. A new expression for the determination of the reflection coefficient is proposed. Weakly damping Alfvén modes with periods from a few tens of seconds to a few minutes can quite effectively penetrate from the chromosphere to the corona and vice versa.

On the Description of Transverse Wave Propagation Along Thin Magnetic Flux Tubes

Yu.T.**Tsap**, A.V.Stepanov, Yu.G.Kopylova
Geomagnetism and Aeronomy, **2018**, V.58, N7, pp.942-946
https://arxiv.org/pdf/1904.03619.pdf
Two approaches are used for description of linear transverse (kink) modes excited in a vertical thin magnetic flux tube. First one is based on the elastic thread model (Spruit, 1981). The second one follows from the the Taylor and Laurent series expansions of wave variables with respect to the tube radius inside and outside of the magnetic flux tube (Lopin and Nagorny, 2013). It has been shown that the main reason of the discrepancy of these approaches is related to the phenomenological equation of plasma motion used in the former case. This suggests that results obtained on the basis of this equation should be revised.

Stratified Solar Photosphere: Hinode Observations and Phase Relationships

Y. T. **Tsap**, A. V. Stepanov, Y. G. Kopylova
Solar Phys. Volume 291, Issue 11, pp 3349–3356 **2016**
Based on the linearized magnetohydrodynamic (MHD) equations within the framework of the thin flux tube approximation, the phase relationships between the disturbed quantities of evanescent acoustic and slow sausage MHD modes excited in the adiabatically stratified solar atmosphere are considered. It has been shown that the sign of the phase differences (equal to \(\pm\pi/2\)) between the velocity and other disturbed quantities such as pressure, density, magnetic field, and temperature, depends on the wave frequency \(\omega\). The obtained phase relationships agree well with SOT/Hinode observations obtained by Fujimura and Tsuneta (Astrophys. J.702, 1443, 2009) when \(\omega\approx\omega_{\mathrm{c}}\), where \(\omega_{\mathrm{c}}\) is the cutoff frequency. The role of various modes excited in the solar atmosphere in the light of the chromospheric and coronal heating problems are discussed.

Frozen-In Magnetic Field Lines and Alfvén Wave Generation in Weakly Ionized Plasma

Y. T. **Tsap**, A. V. Stepanov, Y. G. Kopylova
Solar Phys. Volume 290, Issue 7, pp 1923-1929 **2015**
On the basis of the three-fluid approximation, we consider the generation of linear Alfvén waves with periods $\gtrsim 10^{-3}$ s in the collisional partially ionized plasma of the solar photosphere. The results obtained in previous work (Tsap, Stepanov, and Kopylova in Solar Phys. 270, 205, 2011) are generalized for the case of the arbitrary ratio between the initial velocities of ions and neutral atoms. We find that the ponderomotive force plays an important role during Alfvén wave excitation and propagation. Furthermore, the energy flux of Alfvén waves does not depend on the degree of the plasma ionization if the magnetic field lines are frozen into the charged particles. These modes can be effectively generated in the weakly ionized plasma of the solar photosphere.

Spectral Analysis of Solar and Geomagnetic Parameters in Relation to Cosmic-ray Intensity for the Time Period 1965 – 2018

M. **Tsichla** M. Gerontidou H. Mavromichalaki
Solar Physics January **2019**, 294:15
sci-hub.tw/10.1007/s11207-019-1403-0

https://link.springer.com/content/pdf/10.1007%2Fs11207-019-1403-0.pdf
Spectral analysis of solar and geomagnetic parameters as well as of cosmic-ray intensity was performed aiming to identify possible new periodicities and confirm the well-known ones. Specifically, short-, mid-, and long-term periodicities of these parameters such as sunspot number, Bz-component of the interplanetary magnetic field, geomagnetic Ap index, and cosmic-ray intensity over the time period 1965 – 2018, covering five solar cycles from Cycles 20 to 24, are presented. For this purpose, two different techniques, fast Fourier transformation and wavelet analysis, have been used in order to ensure accuracy in the frequency values and also their localization in the time series. The periodicities resulting from our comprehensive study, including the well-known 11-year and 27-day periods, the harmonics of the 5.5-year and of the 6-, 9-, and 13.9-day periods, respectively, and the ≈ 1.3-year and 1.7-year periods, were found in all of the above parameters except for the Bz-component of the interplanetary magnetic field. New periodicities such as the ≈ 10-month period for sunspot number and cosmic-ray intensity and the ≈ 3-year period for sunspot number, Ap index, and cosmic-ray intensity, were also determined. Furthermore, the newly introduced splitting of the 27-day periodicity into two adjacent peaks was confirmed in the Fourier spectra of the interplanetary magnetic field and the geomagnetic Ap index. It was concluded that several common periodicities appear in solar activity: the Ap index, and the cosmic-ray intensity. This result, in association with the fact that the spectral behavior of geomagnetic-activity parameters, provides invaluable information about the physical processes involved, and indicates that the Ap index might be used as a suitable index for space-weather forecasting.

Electron plasma wake field acceleration in solar coronal and chromospheric plasmas

David **Tsiklauri**
Phys. Plasmas **2017**
https://arxiv.org/pdf/1706.05265.pdf
Three dimensional, particle-in-cell, fully electromagnetic simulations of electron plasma wake field acceleration applicable to solar atmosphere are presented. It is established that injecting driving and trailing electron bunches into solar coronal and chromospheric plasmas, results in electric fields (-(20-5)?106 V/m), leading to acceleration of the trailing bunch up to 52 MeV, starting from initial 36 MeV. The results provide one of potentially important mechanisms for the extreme energetic solar flare electrons, invoking plasma wake field acceleration.

Alfvén wave phase mixing in flows -- why over-dense solar coronal open magnetic field structures are cool?

D. **Tsiklauri**
MNRAS **2015**
http://arxiv.org/pdf/1507.05293v1.pdf
Our magnetohydrodynamic (MHD) simulations and analytical calculations show that, when a background flow is present, mathematical expressions for the Alfv\'en wave (AW) damping via phase mixing are modified by a following substitution C′A(x)→C′A(x)+V′0(x), where CA and V0 are AW phase and the flow speeds and prime denotes derivative in the direction across the background magnetic field. In uniform magnetic field and over-dense plasma structures, in which CA is smaller compared to surrounding plasma, the flow, that is confined to the structure, in the same direction as the AW, reduces the effect of phase mixing, because on the edges of the structure C′A and V′0 have opposite sign. Thus, the wave damps via phase mixing {\it slower} compared to the case without the flow. This is the consequence of the co-directional flow reducing the wave front stretching in the transverse direction. Although, the result is generic and is applicable to different laboratory or astrophysical plasma systems, we apply our finding to address the question why over-dense solar coronal open magnetic field structures (OMFS) are cooler than the background plasma. Observations show that the over-dense OMFS (e.g. solar coronal polar plumes) are cooler than surrounding plasma and that in these structures Doppler broadening of lines is consistent with bulk plasma motions, such as Alfv\'en waves (AW). If over-dense solar coronal OMFS are heated by AW damping via phase mixing, we conjecture that, co-directional with AW, plasma flow in them, reduces the phase mixing induced heating, thus providing an explanation why they appear cooler than the background.

Solar Fine-Scale Structures. I. Spicules and Other Small-Scale, Jet-Like Events at the Chromospheric Level: Observations and Physical Parameters **Review**

G. **Tsiropoula**, K. Tziotziou, I. Kontogiannis, M. S. Madjarska, J. G. Doyle and Y. Suematsu
Space Science Reviews, Volume 169, Numbers 1-4 (**2012**), 181-244,
Over the last two decades the uninterrupted, high resolution observations of the Sun, from the excellent range of telescopes aboard many spacecraft complemented with observations from sophisticated ground-based telescopes have opened up a new world producing significantly more complete information on the physical conditions of the solar atmosphere than before. The interface between the lower solar atmosphere where energy is generated by

subsurface convection and the corona comprises the chromosphere, which is dominated by jet-like, dynamic structures, called mottles when found in quiet regions, fibrils when found in active regions and spicules when observed at the solar limb. Recently, space observations with Hinode have led to the suggestion that there should exist two different types of spicules called Type I and Type II which have different properties. Ground-based observations in the Ca ii H and K filtergrams reveal the existence of long, thin emission features called straws in observations close to the limb, and a class of short-lived events called rapid blue-shifted excursions characterized by large Doppler shifts that appear only in the blue wing of the Ca ii infrared line. It has been suggested that the key to understanding how the solar plasma is accelerated and heated may well be found in the studies of these jet-like, dynamic events. However, while these structures are observed and studied for more than 130 years in the visible, but also in the UV and EUV emission lines and continua, there are still many questions to be answered. Thus, despite their importance and a multitude of observations performed and theoretical models proposed, questions regarding their origin, how they are formed, their physical parameters, their association with the underlying photospheric magnetic field, how they appear in the different spectral lines, and the interrelationship between structures observed in quiet and active regions on the disk and at the limb, as well as their role in global processes has not yet received definitive answers. In addition, how they affect the coronal heating and solar wind need to be further explored. In this review we present observations and physical properties of small-scale jet-like chromospheric events observed in active and quiet regions, on the disk and at the limb and discuss their interrelationship.

IEEE TRANSACTIONS ON PLASMA SCIENCE, VOL. 51, NO. 7, JULY **2023**

https://ieeexplore.ieee.org/stamp/stamp.jsp

Owing to the ever-present solar wind, our vast solar system is full of plasmas. The turbulent solar wind, together with sporadic solar eruptions, introduces various space plasma processes and phenomena in the solar atmosphere all the way to Earth's ionosphere and atmosphere and outward to interact with the interstellar media to form the heliopause and termination shock. Remarkable progress has been made in space plasma physics in the last 65 years, mainly due to sophisticated in situ measurements of plasmas, plasma waves, neutral particles, energetic particles, and dust via space-borne satellite instrumentation. Additionally, high-technology groundbased instrumentation has led to new and greater knowledge of solar and auroral features. As a result, a new branch of space physics, i.e., space weather, has emerged since many of the space physics processes have a direct or indirect influence on humankind. After briefly reviewing the major space physics discoveries before rockets and satellites (Section I), we aim to review all our updated understanding on coronal holes, solar flares, and coronal mass ejections, which are central to space weather events at Earth (Section II), solar wind (Section III), storms and substorms (Section IV), magnetotail and substorms, emphasizing the role of the magnetotail in substorm dynamics (Section V), radiation belts/energetic magnetospheric particles (Section VI), structures and space weather dynamics in the ionosphere (Section VII), plasma waves, instabilities, and waveparticle interactions (Section VIII), long-period geomagnetic pulsations (Section IX), auroras (Section X), geomagnetically induced currents (GICs, Section XI), planetary magnetospheres and solar/stellar wind interactions with comets, moons and asteroids (Section XII), interplanetary discontinuities, shocks and waves (Section XIII), interplanetary dust (Section XIV), space dusty plasmas (Section XV), and solar energetic particles and shocks, including the heliospheric termination shock (Section XVI). This article is aimed to provide a panoramic view of space physics and space weather.

A Study of Alfvén Wave Propagation and Heating the Chromosphere

Jiannan **Tu** and Paul Song

2013 ApJ 777 53

Alfvén wave propagation, reflection, and heating of the chromosphere are studied for a one-dimensional solar atmosphere by self-consistently solving plasma, neutral fluid, and Maxwell's equations with incorporation of the Hall effect and strong electron-neutral, electron-ion, and ion-neutral collisions. We have developed a numerical model based on an implicit backward difference formula of second-order accuracy both in time and space to solve stiff governing equations resulting from strong inter-species collisions. A non-reflecting boundary condition is applied to the top boundary so that the wave reflection within the simulation domain can be unambiguously determined. It is shown that due to the density gradient the Alfvén waves are partially reflected throughout the chromosphere and more strongly at higher altitudes with the strongest reflection at the transition region. The waves are damped in the lower chromosphere dominantly through Joule dissipation, producing heating strong enough to balance the radiative loss for the quiet chromosphere without invoking anomalous processes or turbulences. The heating rates are larger for weaker background magnetic fields below ~500 km with higher-frequency waves subject to heavier damping. There is an upper cutoff frequency, depending on the background magnetic field, above which the waves are completely damped. At the frequencies below which the waves are not strongly damped, the

interaction of reflected waves with the upward propagating waves produces power at their double frequencies, which leads to more damping. The wave energy flux transmitted to the corona is one order of magnitude smaller than that of the driving source.

Solar neutrinos, helioseismology and the solar internal dynamics REVIEW

Sylvaine **Turck-Chièze**1 and Sébastien Couvidat

2011 Rep. Prog. Phys. 74 086901 doi:10.1088/0034-4885/74/8/086901

Neutrinos are fundamental particles ubiquitous in the Universe and whose properties remain elusive despite more than 50 years of intense research activity. This review illustrates the importance of solar neutrinos in astrophysics, nuclear physics and particle physics. After a description of the historical context, we remind the reader of the noticeable properties of these particles and of the stakes of the solar neutrino puzzle. The standard solar model triggered persistent efforts in fundamental physics to predict the solar neutrino fluxes, and its constantly evolving predictions have been regularly compared with the detected neutrino signals. Anticipating that this standard model could not reproduce the internal solar dynamics, a seismic solar model was developed which enriched theoretical neutrino flux predictions with in situ observation of acoustic and gravity waves propagating in the Sun. This seismic model contributed to the stabilization of the neutrino flux predictions. This review recalls the main historical steps, from the pioneering Homestake mine experiment and the GALLEX-SAGE experiments capturing the first proton–proton neutrinos. It emphasizes the importance of the SuperKamiokande and SNO detectors. Both experiments demonstrated that the solar-emitted electron neutrinos are partially transformed into other neutrino flavors before reaching the Earth. This sustained experimental effort opens the door to neutrino astronomy, with long-base lines and underground detectors. The success of BOREXINO in detecting the 7Be neutrino signal alone instills confidence in physicists' ability to detect each neutrino source separately. It justifies the building of a new generation of detectors to measure the entire solar neutrino spectrum in greater detail, as well as supernova neutrinos. A coherent picture has emerged from neutrino physics and helioseismology. Today, new paradigms take shape in these two fields: neutrinos are massive particles, but their masses are still unknown, and the research on the solar interior focuses on the dynamical aspects and on the signature of dark matter. The magnetic moment of the neutrino begins to be an actor in stellar evolution. The third part of the review is dedicated to this prospect. The understanding of the crucial role of both rotation and magnetism in solar physics benefits from SoHO, SDO and PICARD space observations, and from a new prototype, GOLF-NG. The magnetohydrodynamical view of the solar interior is a new way of understanding the impact of the Sun on the Earth's environment and climate. For now, the particle and stellar challenges seem decoupled, but this is only a superficial appearance. The development of asteroseismology—with the COROT and KEPLER spacecraft—and of neutrino physics will both contribute to improvements in our understanding of, for instance, supernova explosions. This shows the far-reaching impact of neutrino and stellar astronomy.

Stochastic Modelling, Analysis, and Simulations of the Solar Cycle Dynamic Process

Douglas C. **Turner**1 and Gangaram S. Ladde2

2018 ApJ 855 108

http://iopscience.iop.org/article/10.3847/1538-4357/aaaf1c

Analytical solutions, discretization schemes and simulation results are presented for the time delay deterministic differential equation model of the solar dynamo presented by Wilmot-Smith et al. In addition, this model is extended under stochastic Gaussian white noise parametric fluctuations. The introduction of stochastic fluctuations incorporates variables affecting the dynamo process in the solar interior, estimation error of parameters, and uncertainty of the α-effect mechanism. Simulation results are presented and analyzed to exhibit the effects of stochastic parametric volatility-dependent perturbations. The results generalize and extend the work of Hazra et al. In fact, some of these results exhibit the oscillatory dynamic behavior generated by the stochastic parametric additative perturbations in the absence of time delay. In addition, the simulation results of the modified stochastic models influence the change in behavior of the very recently developed stochastic model of Hazra et al.

Solar Cycle Slow to Get Going: What Does It Mean for Space Weather?

Turner, Ronald

Space Weather, Vol. 9, No. 4, S04004, **2011**

If you have the sense that the current solar cycle has been slow to build up, maybe it is more than just the “watched pot” failing to boil. A comparison with previous sunspot cycles shows that the current cycle is among the slowest-growing cycles characterized with good historical data. Figure 1 shows the smoothed sunspot number for the period from 2 years before the minimum to 2 years after it for the 24 numbered solar cycles (cycle 1 started in 1755; we are just now entering cycle 24). It illustrates the historically slow increase of the current cycle (shown in red) as of February 2011. Three of the four cycles with slower increases (shown in blue) were during the Dalton Minimum in the early nineteenth century. The fourth is the period leading into cycle 1. The red dots in the figure are cycle 24 monthly average sunspot numbers; these data are too recent to be adjusted by the smoothing algorithm that includes

the influence of monthly averages within 6 months of the smoothed value. Also shown, at the bottom of the figure, for context, are the sunspot data for the first 23 cycles, which also identify the Dalton Minimum.

Vortex Motions in the Solar Atmosphere **Review**

Definitions, Theory, Observations, and Modelling

K. **Tziotziou**, E. Scullion, S. Shelyag, O. Steiner, E. Khomenko, +++

Space Science Reviews volume 219, Article number: 1 (**2023**)

https://link.springer.com/content/pdf/10.1007/s11214-022-00946-8.pdf

Vortex flows, related to solar convective turbulent dynamics at granular scales and their interplay with magnetic fields within intergranular lanes, occur abundantly on the solar surface and in the atmosphere above. Their presence is revealed in high-resolution and high-cadence solar observations from the ground and from space and with state-of-the-art magnetoconvection simulations. Vortical flows exhibit complex characteristics and dynamics, excite a wide range of different waves, and couple different layers of the solar atmosphere, which facilitates the channeling and transfer of mass, momentum and energy from the solar surface up to the low corona. Here we provide a comprehensive review of documented research and new developments in theory, observations, and modelling of vortices over the past couple of decades after their observational discovery, including recent observations in Hα, innovative detection techniques, diverse hydrostatic modelling of waves and forefront magnetohydrodynamic simulations incorporating effects of a non-ideal plasma. It is the first systematic overview of solar vortex flows at granular scales, a field with a plethora of names for phenomena that exhibit similarities and differences and often interconnect and rely on the same physics. With the advent of the 4-m Daniel K. Inouye Solar Telescope and the forthcoming European Solar Telescope, the ongoing Solar Orbiter mission, and the development of cutting-edge simulations, this review timely addresses the state-of-the-art on vortex flows and outlines both theoretical and observational future research directions.

A persistent quiet-Sun small-scale tornado III. Waves

Kostas **Tziotziou**, Georgia Tsiropoula, Ioannis Kontogiannis

A&A 643, A166 **2020**

https://arxiv.org/pdf/2010.06327.pdf

https://doi.org/10.1051/0004-6361/202038951

Vortex flows can foster a variety of wave modes. A recent oscillatory analysis of a persistent 1.7 h vortex flow with a significant substructure has suggested the existence of various types of waves within it. We investigate the nature and characteristics of waves within this quiet-Sun vortex flow to better understand its physics and dynamics. We used a cross-wavelet spectral analysis between pairs of Ha and Ca II 8542 intensity time series at different wavelengths and, hence, atmospheric heights, acquired with CRISP/SST, as well as the derived Ha Doppler velocity and full width at half maximum (FWHM) time series. We constructed halftone frequency-phase difference plots and investigated the existence and propagation characteristics of different wave modes. Our analysis suggests the existence of upwards propagating Alfvenic type waves with phase speeds of ~20-30 km/s. The dominant wave mode seems to be the fast kink wave mode; however, our analysis also suggests the existence of localised Alfvenic torsional waves related to the dynamics of individual chromospheric swirls that characterise the substructure of the vortex flow. The Ha V-I phase difference analysis seems to imply the existence of a standing wave pattern possibly arising from the interference of upwards propagating kink waves with downwards propagating ones that are reflected at the transition region or the corona. Moreover, the results provide further evidence that the central chromospheric swirl drives the dynamics of the vortex flow. This is the first exhaustive phase difference analysis within a vortex flow that explores the nature and dynamics of different wave modes within it. The questions, however, of whether, and how, the dissipation of the derived wave modes occurs and if vortex flows ultimately play a role in the energy budget of the upper layers of the solar atmosphere remain open.

A persistent quiet-Sun small-scale tornado. II. Oscillations

K. **Tziotziou**, G. Tsiropoula, I. Kontogiannis

A&A 623, A160 **2019**

https://arxiv.org/pdf/1903.04796.pdf

https://www.aanda.org/articles/aa/pdf/2019/03/aa34679-18.pdf

Recently, the characteristics, and dynamics of a persistent 1.7 h vortex flow, resembling a small-scale tornado, have been investigated with ground-base and space-based observations and for the first time in the Ha line centre. The vortex flow showed significant substructure in the form of several intermittent chromospheric swirls.

We investigate the oscillatory behaviour of various physical parameters in the vortex area, with a 2D wavelet analysis performed within the vortex flow area and in a quiet-Sun region (for comparison), using the same high spatial and temporal resolution Ha and Ca II 8542 CRISP observations, as well as Doppler velocities and FWHM derived from the Ha line profiles.

The vortex flow shows significant oscillatory power in the 3-5 min range that peaks around 4 min and behaves

differently than the reference quiet-Sun region. Oscillations reflect the cumulative action of different components such as swaying motions, rotation, and waves. The derived swaying motion periods are in the range of 200-220 s, and the rotation periods are ~270 s for Ha and ~215 s for Ca II. Periods increase with atmospheric height and seem to decrease with radial distance from the vortex centre, suggesting a deviation from a rigid rotation. The behaviour of power within the vortex flow as a function of period and height implies the existence of evanescent waves and the excitation of different types of waves, such as magnetoacoustic (e.g. kink) or Alfven waves.
The vortex flow seems to be dominated by two motions: a transverse (swaying) motion, and a rotational motion while oscillations point to the propagation of waves within it. Nearby fibril-like flows could play an important role in the rotational modulation of the vortex flow. Indirect evidence exists that the structure is magnetically supported while the central swirl seems to be acting as a "central engine" to the vortex flow. **June 7, 2014**

A persistent quiet-Sun small-scale tornado
I. Characteristics and dynamics⋆

K. **Tziotziou**1, G. Tsiropoula1, I. Kontogiannis2, E. Scullion3 and J. G. Doyle
A&A 618, A51 (**2018**)
https://www.aanda.org/articles/aa/pdf/2018/10/aa33101-18.pdf
Context. Vortex flows have been extensively observed over a wide range of spatial and temporal scales in different spectral lines, and thus layers of the solar atmosphere, and have been widely found in numerical simulations. However, signatures of vortex flows have only recently been reported in the wings of the Hα, but never so far in the Hα line centre.
Aims. We investigate the appearance, characteristics, substructure, and dynamics of a 1.7 h persistent vortex flow observed from the ground and from space in a quiet-Sun region in several lines/channels covering all atmospheric layers from the photosphere up to the low corona.
Methods. We use high spatial and temporal resolution CRisp Imaging SpectroPolarimeter (CRISP) observations in several wavelengths along the Hα and Ca II 8542 Å line profiles, simultaneous Atmospheric Imaging Assembly (AIA) observations in several Ultraviolet (UV) and Extreme ultraviolet (EUV) channels and Helioseismic and Magnetic Imager (HMI) magnetograms to study a persistent vortex flow located at the south solar hemisphere. Doppler velocities were derived from the Hα line profiles. Our analysis involves visual inspection and comparison of all available simultaneous/near-simultaneous observations and detailed investigation of the vortex appearance, characteristics and dynamics using time slices along linear and circular slits.
Results. The most important characteristic of the analysed clockwise rotating vortex flow is its long duration (at least 1.7 h) and its large radius (~3″). The vortex flow shows different behaviours in the different wavelengths along the Hα and Ca II 8542 Å profiles reflecting the different formation heights and mechanisms of the two lines. Ground-based observations combined with AIA observations reveal the existence of a funnel-like structure expanding with height, possibly rotating rigidly or quasi-rigidly. However, there is no clear evidence that the flow is magnetically driven as no associated magnetic bright points have been observed in the photosphere. Hα and Ca II 8542 Å observations also reveal significant substructure within the flow, manifested as several individual intermittent chromospheric swirls with typical sizes and durations. They also exhibit a wide range of morphological patterns, appearing as dark absorbing features, associated mostly with mean upwards velocities around 3 km s−1 and up to 8 km s−1, and occupying on average ~25% of the total vortex area. The radial expansion of the spiral flow occurs with a mean velocity of ~3 km s−1, while its dynamics can be related to the dynamics of a clockwise rigidly rotating logarithmic spiral with a swinging motion that is, however, highly perturbed by nearby flows associated with fibril-like structures. A first rough estimate of the rotational period of the vortex falls in the range of 200–300 s.
Conclusions. The vortex flow resembles a small-scale tornado in contrast to previously reported short-lived swirls and in analogy to persistent giant tornadoes. It is unclear whether the observed substructure is indeed due to the physical presence of individual intermittent, recurring swirls or a manifestation of wave-related instabilities within a large vortex flow. Moreover, we cannot conclusively demonstrate that the long duration of the observed vortex is the result of a central swirl acting as an “engine” for the vortex flow, although there is significant supporting evidence inferred from its dynamics. It also cannot be excluded that this persistent vortex results from the combined action of several individual smaller swirls further assisted by nearby flows or that this is a new case in the literature of a hydrodynamically driven vortex flow**. June 7, 2014**

SITCoM: SiRGraF Integrated Tool for Coronal dynaMics

Purvi **Udhwani**, Arpit Kumar Shrivastav, Ritesh Patel
Frontiers in Astronomy and Space Sciences 10:1227872 **2023**
https://arxiv.org/pdf/2308.04647.pdf
https://www.frontiersin.org/articles/10.3389/fspas.2023.1227872/pdf
SiRGraF Integrated Tool for Coronal dynaMics (SITCoM) is based on Simple Radial Gradient Filter (SiRGraF) used to filter the radial gradient in the white-light coronagraph images and bring out dynamic structures. SITCoM has been developed in **Python** and integrated with SunPy and can be installed by users with the command pip install sitcom. This enables the user to pass the white-light coronagraph data to the tool and generate radially filtered output with an option to save in various formats as required. We have implemented the functionality of tracking the

transients such as coronal mass ejections (CMEs), outflows, plasma blobs, etc., using height-time plots and deriving their kinematics. In addition, SITCoM also supports oscillation and waves studies such as for streamer waves. This is done by creating a distance-time plot at a user-defined location (artificial slice) and fitting a sinusoidal function to derive the properties of waves, such as time period, amplitude, and damping time (if any). We provide the provision to manually or automatically select the data points to be used for fitting. SITCoM is a tool to analyze some properties of coronal dynamics quickly. We present an overview of the SITCoM with the applications for deriving coronal dynamics' kinematics and oscillation properties. We discuss the limitations of this tool along with prospects for future improvement. **2001-01-07, 06 July 2004, 2005-10-12, 2010-08-01, 2017-09-10, 29 August 2022**

The Magnetic Properties of Heating Events on High-Temperature Active Region Loops

Ignacio **Ugarte-Urra**, Nicholas A. Crump, Harry P. Warren, Thomas Wiegelmann
ApJ **2019**
https://arxiv.org/pdf/1904.11976.pdf
Understanding the relationship between the magnetic field and coronal heating is one of the central problems of solar physics. However, studies of the magnetic properties of impulsively heated loops have been rare. We present results from a study of 34 evolving coronal loops observed in the Fe XVIII line component of AIA/SDO 94 A filter images from three active regions with different magnetic conditions. We show that the peak intensity per unit cross-section of the loops depends on their individual magnetic and geometric properties. The intensity scales proportionally to the average field strength along the loop (Bavg) and inversely with the loop length (L) for a combined dependence of (Bavg/L)0.52±0.13. These loop properties are inferred from magnetic extrapolations of the photospheric HMI/SDO line-of-sight and vector magnetic field in three approximations: potential and two Non Linear Force-Free (NLFF) methods. Through hydrodynamic modeling (EBTEL model) we show that this behavior is compatible with impulsively heated loops with a volumetric heating rate that scales as $\epsilon H \sim B0.3\pm0.2 avg/L0.2\pm0.20.1$. **2011/02/12, 2011/04/15, 2011/11/08**

Modeling Coronal Response in Decaying Active Regions with Magnetic Flux Transport and Steady Heating

Ignacio **Ugarte-Urra**, Harry P. Warren, Lisa A. Upton, Peter R. Young
ApJ **846** 165 **2017**
https://arxiv.org/pdf/1708.04324.pdf
We present new measurements of the dependence of the Extreme Ultraviolet radiance on the total magnetic flux in active regions as obtained from the Atmospheric Imaging Assembly (AIA) and the Helioseismic and Magnetic Imager on board the Solar Dynamics Observatory (SDO). Using observations of nine active regions tracked along different stages of evolution, we extend the known radiance - magnetic flux power-law relationship ($I \propto \Phi\alpha$) to the AIA 335 \AA\ passband, and the Fe XVIII 93.93 \AA\ spectral line in the 94 \AA\ passband. We find that the total unsigned magnetic flux divided by the polarity separation (Φ/D) is a better indicator of radiance for the Fe XVIII line with a slope of $\alpha=3.22\pm0.03$. We then use these results to test our current understanding of magnetic flux evolution and coronal heating. We use magnetograms from the simulated decay of these active regions produced by the Advective Flux Transport (AFT) model as boundary conditions for potential extrapolations of the magnetic field in the corona. We then model the hydrodynamics of each individual field line with the Enthalpy-based Thermal Evolution of Loops (EBTEL) model with steady heating scaled as the ratio of the average field strength and the length ($\bar{B}/L$) and render the Fe XVIII and 335 \AA\ emission. We find that steady heating is able to partially reproduce the magnitudes and slopes of the EUV radiance - magnetic flux relationships and discuss how impulsive heating can help reconcile the discrepancies. This study demonstrates that combined models of magnetic flux transport, magnetic topology and heating can yield realistic estimates for the decay of active region radiances with time. **2013/05-12 – 06-10**

Full Sun monochromatic images

Ignacio **Ugarte-Urra** and Harry Warren
Hinode EIS science nugget 28 Feb **2011**
http://msslxr.mssl.ucl.ac.uk:8080/SolarB/eisnuggets.jsp
While X-ray and EUV imagers take images at a cadence close to the characteristic evolutionary timescales of solar phenomena, narrow slit spectroscopy is better suited for many plasma diagnostics. This improvement in our ability to measure the properties of solar plasmas, however, is often achieved at the expense of longer exposure times and a slower cadence. Wide slit spectroscopy ("overlapograms") is a compromise between both worlds as it produces images of over a relatively large field-of-view in bands as narrow as a single spectral line.

Photospheric Velocities Measured at Mt. Wilson Show Zonal and Sectoral Flows Compose the Torsional Oscillations

Roger K. **Ulrich**, Tham Tran, John Boyden
Solar Phys. 298, Article number: 123 **2023**
https://arxiv.org/pdf/2307.06387
https://link.springer.com/content/pdf/10.1007/s11207-023-02215-5.pdf
The methods for reducing the observations from the 150-foot Tower Telescope on Mt.~Wilson are reviewed and a new method for determining the North/South (sectoral) and the East/West (zonal) velocity components is described and applied. Due to a calibration problem with the data prior to 1983, only observations between 1983 and 2013 are presented at this time. After subtraction of latitude dependent averages over the 30-year period of observation the residual deviations in the sectoral and zonal flow velocities are well synchronized and correspond to what is widely recognized as the Torsional Oscillations. Both flow components need to be included in any model that replicates the Torsional Oscillations.

Heating and dynamics of the Solar atmosphere **Thesis**

Vishal **Upendran**
Thesis presented to IUCAA and JNU **2023**.
https://arxiv.org/pdf/2304.01553
The solar atmosphere shows anomalous variation in temperature, starting from the 5500 K photosphere to the million-degree Kelvin corona. The corona itself expands into the interstellar medium as the free streaming solar wind, which modulates and impacts the near-Earth space weather. The precise source regions of different structures in the solar wind, their formation height, and the heating of the solar atmosphere are inextricably linked and unsolved problems in astrophysics. Observations suggest correlations between Coronal holes (CHs), which are cool, intensity deficit structures in the solar corona, with structures in the solar wind. Observations also suggest the local plasma heating in the corona through power-law distributed impulsive events. In this thesis, we use narrowband photometric, spectroscopic, and disc-integrated emission of the solar atmosphere ranging from Near Ultraviolet to X-rays along with in-situ solar wind measurements to understand (i). the source regions of the solar wind, (ii). the underlying mechanism of solar coronal heating, and (iii). the differentiation in dynamics of CHs with the background Quiet Sun (QS) regions, which do not show any significant signature of the solar wind. We leverage machine learning and numerical modeling tools to develop solar wind forecasting codes using interpretable AI, inversion codes to infer the properties of impulsive events and to understand the differences in the thermodynamics of CHs and QS regions. We finally present a unified scenario of solar wind emergence and heating in the solar atmosphere and discuss the implications of inferences from this thesis.

Nanoflare Heating of the Solar Corona Observed in X-rays

Vishal **Upendran**, Durgesh Tripathi, N.P.S. Mithun, Santosh Vadawale, Anil Bhardwaj
ApJ Letters **940** L38 **2022**
https://arxiv.org/pdf/2211.02324.pdf
https://iopscience.iop.org/article/10.3847/2041-8213/aca078/pdf
The existence of the million-degree corona above the cooler photosphere is an unsolved problem in astrophysics. Detailed study of quiescent corona that exists regardless of the phase of the solar cycle may provide fruitful hints towards resolving this conundrum. However, the properties of heating mechanisms can be obtained only statistically in these regions due to their unresolved nature. Here, we develop a two-step inversion scheme based on the machine learning scheme of Upendran & Tripathi (2021a) for the empirical impulsive heating model of Pauluhn & Solanki (2007), and apply it to disk integrated flux measurements of the quiet corona as measured by the X-ray solar monitor (XSM) onboard Chandrayaan - 2. We use data in three energy passbands, viz., 1 - 1.3 keV, 1.3 - 2.3 keV, and 1 - 2.3 keV, and estimate the typical impulsive event frequencies, timescales, amplitudes, and the distribution of amplitudes. We find that the impulsive events occur at a frequency of ≈25 events per minute with a typical lifetime of ≈10 minutes. They are characterized by a power law distribution with a slope $\alpha \leq 2.0$. The typical amplitudes of these events lie in an energy range of 1021 - 1024 ergs, with a typical radiative loss of about ≈103 erg cm−2 s−1 in the energy range of 1 - 2.3 keV. These results provide further constraints on the properties of sub-pixel impulsive events in maintaining the quiet solar corona.

On the formation of solar wind & switchbacks, and quiet Sun heating

Vishal **Upendran** (1), Durgesh Tripathi (1)
ApJ **2021**
https://arxiv.org/pdf/2111.11668.pdf
The solar coronal heating in quiet Sun (QS) and coronal holes (CH), including solar wind formation, are intimately tied by magnetic field dynamics. Thus, a detailed comparative study of these regions is needed to understand the underlying physical processes. CHs are known to have subdued intensity and larger blueshifts in the corona. This

work investigates the similarities and differences between CHs and QS in the chromosphere using the Mg II h & k, C II lines, and transition region using Si IV line, for regions with identical absolute magnetic flux density (|B|). We find CHs to have subdued intensity in all the ines, with the difference increasing with line formation height and |B|. The chromospheric lines show excess upflows and downflows in CH, while Si IV shows excess upflows (downflows) in CHs (QS), where the flows increase with |B|. We further demonstrate that the upflows (downflows) in Si IV are correlated with both upflows and downflows (only downflows) in the chromospheric lines. CHs (QS) show larger Si IV upflows (downflows) for similar flows in the chromosphere, suggesting a common origin to these flows. These observations may be explained due to impulsive heating via interchange (closed-loop) reconnection in CHs (QS), resulting in bidirectional flows at different heights, due to differences in magnetic field topologies. Finally, the kinked field lines from interchange reconnection may be carried away as magnetic field rotations and observed as switchbacks. Thus, our results suggest a unified picture of solar wind emergence, coronal heating, and near-Sun switchback formation.

On the Impulsive Heating of Quiet Solar Corona

Vishal **Upendran** (IUCAA, Pune), Durgesh Tripathi (IUCAA, Pune)

ApJ **916** 59 **2021**

https://arxiv.org/pdf/2103.16824.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/abf65a/pdf
https://doi.org/10.3847/1538-4357/abf65a

The solar corona consists of a million-degree Kelvin plasma. A complete understanding of this phenomenon demands the study of Quiet Sun (QS) regions. In this work, we study QS regions in the 171 Å, 193 Å and 211 Å passbands of the Atmospheric Imaging Assembly (AIA) on board the Solar Dynamics Observatory (SDO), by combining the empirical impulsive heating forward model of Pauluhn & Solanki (2007) with a machine-learning inversion model that allows uncertainty quantification. We find that there are {\approx} 2--3 impulsive events per min, with a lifetime of about 10--20 min. Moreover, for all the three passbands, the distribution of power law slope {\alpha} peaks above 2. Our exploration of correlations among the frequency of impulsive events and their timescales and peak energy suggests that conduction losses dominate over radiative cooling losses. All these finding suggest that impulsive heating is a viable heating mechanism in QS corona. **2011-08-14, 2019-05-02**

Solar Cycle Precursors and the Outlook for Cycle 25

Lisa A. **Upton**, David H. Hathaway

JGR **2023**

https://arxiv.org/pdf/2305.06516.pdf

Sunspot Cycle 25 is now over 3 years past the cycle minimum of December 2019. At this point in the cycle, curve-fitting to the activity becomes reliable and now consistently indicates a maximum sunspot number of 135 +/- 10 - slightly larger than Cycle 24's maximum of 116.4, but well below the average of 179. A geomagnetic precursor, the minimum in the aa-index, and the Sun's magnetic precursors, the Sun's polar field strength and its axial dipole moment at the time of minimum, are often used to predict the amplitude of the cycle at (or before) the onset of the cycle. We examine Cycle 25 predictions produced by these precursors. The geomagnetic precursor indicated a Cycle 25 slightly stronger that Cycle 24, with a maximum of 132 +/- 8. The Sun's magnetic precursors indicated that Cycle 25 would be more similar to Cycle 24, with a maximum sunspot number of 120 +/- 10 or 114 +/- 15. Combining the curve-fitting results with the precursor predictions, we conclude that Cycle 25 will have a maximum smoothed sunspot number of 134 +/- 8 with maximum occurring late in the fall of 2024. Models for predicting the Sun's magnetic field ahead of minimum, were generally successful at predicting the polar precursors years in advance. The fact that Sun's magnetic precursors at cycle minimum were successfully predicted years before minimum and that the precursors are consistent with the size of Cycle 25 suggests that we can now reliably predict the solar cycle.

An Updated Solar Cycle 25 Prediction with AFT: The Modern Minimum

Lisa A. **Upton**, David H. Hathaway

Geophysical Research Letters **2018**

https://arxiv.org/pdf/1808.04868.pdf

Over the last decade there has been mounting evidence that the strength of the Sun's polar magnetic fields during a solar cycle minimum is the best predictor of the amplitude of the next solar cycle. Surface flux transport models can be used to extend these predictions by evolving the Sun's surface magnetic field to obtain an earlier prediction for the strength of the polar fields, and thus the amplitude of the next cycle. In 2016, our Advective Flux Transport (AFT) model was used to do this, producing an early prediction for Solar Cycle 25. At that time, AFT predicted that Cycle 25 will be similar in strength to the Cycle 24, with an uncertainty of about 15% . AFT also predicted that the polar fields in the southern hemisphere would weaken in late 2016 and into 2017 before recovering. That AFT prediction was based on the magnetic field configuration at the end of January 2016. We now have 2 more years of observations. We examine the accuracy of the 2016 AFT prediction and find that the new observations track well

with AFT's predictions for the last two years. We show that the southern relapse did in fact occur, though the timing was off by several months. We propose a possible cause for the southern relapse and discuss the reason for the offset in timing. Finally, we provide an updated AFT prediction for Solar Cycle 25 which includes solar observations through January of 2018.

Effects of Meridional Flow Variations on Solar Cycles 23 and 24

Lisa **Upton**, David H. Hathaway
ApJ, ApJ 792 142., **2014**
http://arxiv.org/pdf/1408.0035v1.pdf
The faster meridional flow that preceded the solar cycle 23/24 minimum is thought to have led to weaker polar field strengths, producing the extended solar minimum and the unusually weak cycle 24. To determine the impact of meridional flow variations on the sunspot cycle, we have simulated the Sun's surface magnetic field evolution with our newly developed surface flux transport model. We investigate three different cases: a constant average meridional flow, the observed time-varying meridional flow, and a time-varying meridional flow in which the observed variations from the average have been doubled. Comparison of these simulations shows that the variations in the meridional flow over cycle 23 have a significant impact (~20%) on the polar fields. However, the variations produced polar fields that were stronger than they would have been otherwise. We propose that the primary cause of the extended cycle 23/24 minimum and weak cycle 24 was the weakness of cycle 23 itself - with fewer sunspots, there was insufficient flux to build a big cycle. We also find that any polar counter-cells in the meridional flow (equatorward flow at high latitudes) produce flux concentrations at mid-to-high latitudes that are not consistent with observations.

Are coronal loops projection effects?

Vadim M. **Uritsky**, James A. Klimchuk
ApJ **2023**
https://arxiv.org/pdf/2310.07102.pdf
We report results of an in-depth numerical investigation of three-dimensional projection effects which could influence the observed loop-like structures in an optically thin solar corona. Several archetypal emitting geometries are tested, including collections of luminous structures with circular cross-sections of fixed and random size, light-emitting structures with highly anisotropic cross-sections, as well as two-dimensional stochastic current density structures generated by fully-developed magnetohydrodynamic turbulence. A comprehensive set of statistical signatures is used to compare the line of sight -integrated emission signals predicted by the constructed numerical models with the loop profiles observed by the extreme ultraviolet telescope onboard the flight 2.1 of the High-Resolution Coronal Imager (Hi-C). The results obtained for the Hi-C loops cannot be attributed to randomly oriented quasi-two dimensional emitting structures such as those constituting "coronal veils" (Malanushenko et al., 2022), and they indicate that typical cross-sectional envelopes of loop emission cannot have high eccentricity. The possibility of apparent loop-like projections of very small (close to the resolution limit) or very large (comparable with the size of an active region) light-emitting sheets remains open, but the intermediate range of scales commonly associated with observed loop systems is most likely filled with true quasi-one dimensional (roughly axisymmetric) structures embedded into the three-dimensional coronal volume.

Plumelets: Dynamic Filamentary Structures in Solar Coronal Plumes

V.M. **Uritsky**, C.E. DeForest, J.T. Karpen, C.R. DeVore, P. Kumar, N.E. Raouafi, P.F. Wyper
2021 *ApJ* **907** 1
https://arxiv.org/pdf/2012.05728.pdf
Solar coronal plumes long seemed to possess a simple geometry supporting spatially coherent, stable outflow without significant fine structure. Recent high-resolution observations have challenged this picture by revealing numerous transient, small-scale, collimated outflows ("jetlets") at the base of plumes. The dynamic filamentary structure of solar plumes above these outflows, and its relationship with the overall plume structure, have remained largely unexplored. We analyzed the statistics of continuously observed fine structure inside a single representative bright plume within a mid-latitude coronal hole during **2016 July 2-3**. By applying advanced edge-enhancement and spatiotemporal analysis techniques to extended series of high-resolution images from the Solar Dynamics Observatory's Atmospheric Imaging Assembly, we determined that the plume was composed of numerous time-evolving filamentary substructures, referred to as "plumelets" in this paper, that accounted for most of the plume emission. The number of simultaneously identifiable plumelets was positively correlated with plume brightness, peaked in the fully formed plume, and remained saturated thereafter. The plumelets had transverse widths of 10 Mm and intermittently supported upwardly propagating periodic disturbances with phase speeds of 190-260 km/s and longitudinal wavelengths of 55-65 Mm. The characteristic frequency (3.5 mHz) is commensurate with that of solar p-modes. Oscillations in neighboring plumelets are uncorrelated, indicating that the waves could be driven by p-mode flows at spatial scales smaller than the plumelet separation. Multiple independent sources of outflow within a

single coronal plume should impart significant fine structure to the solar wind that may be detectable by Parker Solar Probe and Solar Orbiter.

Spatiotemporal organization of energy release events in the quiet solar corona

Vadim M. **Uritsky**, Joseph M. Davila
2014 ApJ 795 15
http://arxiv.org/pdf/1404.1086v1.pdf
Using data from STEREO and SOHO spacecraft, we show that temporal organization of energy release events in the quiet solar corona is close to random, in contrast to the clustered behavior of flaring times in solar active regions. The locations of the quiet-Sun events follow the meso- and supergranulation pattern of the underling photosphere. Together with earlier reports of the scale-free event size statistics, our findings suggest that quiet solar regions responsible for bulk coronal heating operate in a driven self-organized critical state, possibly involving long-range Alfv\'{e}nic interactions.

The Steady Global Corona and Solar Wind: A Three-dimensional MHD Simulation with Turbulence Transport and Heating

Arcadi V. **Usmanov**1,2, William H. Matthaeus1, Melvyn L. Goldstein3, and Rohit Chhiber1
2018 ApJ 865 25 https://doi.org/10.3847/1538-4357/aad687
We present a fully three-dimensional magnetohydrodynamic model of the solar corona and solar wind with turbulence transport and heating. The model is based on Reynolds-averaged solar wind equations coupled with transport equations for turbulence energy, cross helicity, and correlation scale. The model includes separate energy equations for protons and electrons and accounts for the effects of electron heat conduction, radiative cooling, Coulomb collisions, Reynolds stresses, eddy viscosity, and turbulent heating of protons and electrons. The computational domain extends from the coronal base to 5 au and is divided into two regions: the inner (coronal) region, 1–30 R ⊙, and the outer (solar wind) region, 30 R ⊙–5 au. Numerical steady-state solutions in both regions are constructed by time relaxation in the frame of reference corotating with the Sun. Inner boundary conditions are specified using either a tilted-dipole approximation or synoptic solar magnetograms. The strength of solar dipole is adjusted, and a scaling factor for magnetograms is estimated by comparison with Ulysses observations. Except for electron temperature, the model shows reasonable agreement with Ulysses data during its first and third fast latitude transits. We also derive a formula for the loss of angular momentum caused by the outflowing plasma. The formula takes into account the effects of turbulence. The simulation results show that turbulence can notably affect the Sun's loss of angular momentum.

Extreme Solar Events: Setting up a Paradigm **Review**

Usoskin, I., Miyake, F., Baroni, M. et al.
Space Sci Rev 219, 73 (**2023**).
https://doi.org/10.1007/s11214-023-01018-1
https://link.springer.com/content/pdf/10.1007/s11214-023-01018-1.pdf **File**
The Sun is magnetically active and often produces eruptive events on different energetic and temporal scales. Until recently, the upper limit of such events was unknown and believed to be roughly represented by direct instrumental observations. However, two types of extreme events were discovered recently: extreme solar energetic particle events on the multi-millennial time scale and super-flares on sun-like stars. Both discoveries imply that the Sun might rarely produce events, called extreme solar events (ESE), whose energy could be orders of magnitude greater than anything we have observed during recent decades. During the years following these discoveries, great progress has been achieved in collecting observational evidence, uncovering new events, making statistical analyses, and developing theoretical modelling. The ESE paradigm lives and is being developed. On the other hand, many outstanding questions still remain open and new ones emerge. Here we present an overview of the current state of the art and the forming paradigm of ESE from different points of view: solar physics, stellar–solar projections, cosmogenic-isotope data, modelling, historical data, as well as terrestrial, technological and societal effects of ESEs. Special focus is paid to open questions and further developments. This review is based on the joint work of the International Space Science Institute (ISSI) team #510 (2020–2022). 7176 BCE and 5259 BCE, **5410 BCE, 1279 CE, 1052 CE,** 774 CE, **1859, 4-6 Dec 2006, 13 Dec 2006**

A history of solar activity over millennia **Review**

Ilya G. **Usoskin**
Living Reviews in Solar Physics volume 20, Article number: 2 (**2023**)
https://link.springer.com/content/pdf/10.1007/s41116-023-00036-z.pdf
Here we review present knowledge of the long-term behaviour of solar activity on a multi-millennial timescale, as reconstructed using the indirect proxy method. The concept of solar activity is discussed along with an overview of

the dedicated indices used to quantify different aspects of variable solar activity, with special emphasis on sunspot numbers. Over long timescales, quantitative information about past solar activity is historically obtained using a method based on indirect proxies, such as cosmogenic isotopes 1414C and 1010Be in natural stratified archives (e.g., tree rings or ice cores). We give a historical overview of the development of the proxy-based method for past solar-activity reconstruction over millennia, as well as a description of the modern state of the art. Special attention is paid to the verification and cross-calibration of reconstructions. It is argued that the method of cosmogenic isotopes makes a solid basis for studies of solar variability in the past on a long timescale (centuries to millennia) during the Holocene (the past ∼∼12 millennia). A separate section is devoted to reconstructions of extremely rare solar eruptive events in the past, based on both cosmogenic-proxy data in terrestrial and lunar natural archives, as well as statistics of sun-like stars. Finally, the main features of the long-term evolution of solar magnetic activity, including the statistics of grand minima and maxima occurrence, are summarized and their possible implications, especially for solar/stellar dynamo theory, are discussed.
This article is a revised version of https://doi.org/10.1007/s41116-017-0006-9 (2017)

Solar cyclic activity over the last millennium reconstructed from annual 14C data

I.G. **Usoskin**, S.K. Solanki, N. Krivova, B. Hofer, G.A. Kovaltsov, L. Wacker, N. Brehm, B. Kromer
A&A 649, A141 **2021**
https://arxiv.org/pdf/2103.15112.pdf
https://www.aanda.org/articles/aa/pdf/2021/05/aa40711-21.pdf
https://doi.org/10.1051/0004-6361/202140711
The 11-year solar cycle is the dominant pattern of solar activity reflecting the oscillatory dynamo mechanism in the Sun. Solar cycles were directly observed since 1700, while indirect proxies suggest their existence over a much longer period of time but generally without resolving individual cycles and their continuity. Here we reconstruct individual cycles for the last millennium using recent 14C data and state-of-the-art models. Starting with the 14C production rate determined from the so far most precise measurements of radiocarbon content in tree rings, solar activity is reconstructed in three physics-based steps: (1) Correction of the 14C production rate for the changing geomagnetic field; (2) Computation of the open solar magnetic flux; and (3) Conversion into sunspot numbers outside of grand minima. Solar activity is reconstructed for the period 971-1900 (85 individual cycles). This more than doubles the number of solar cycles known from direct solar observations. We found that lengths and strengths of well-defined cycles outside grand minima are consistent with those obtained from the direct sunspot observations after 1750. The validity of the Waldmeier rule is confirmed at a highly significant level. Solar activity is found to be in a deep grand minimum when the activity is mostly below the sunspot formation threshold, during about 250 years. Therefore, although considerable cyclic variability in 14C is seen even during grand minima, individual solar cycles can hardly be reliably resolved therein. Three potential solar particle events, ca. 994, 1052 and 1279 AD, are shown. A new about 1000-year long solar activity reconstruction, in the form of annual (pseudo) sunspot numbers with full assessment of uncertainties, is presented based on new high-precision 14C measurements and state-of-the-art models, more than doubling the number of individually resolved solar cycles.

Robustness of Solar-Cycle Empirical Rules Across Different Series Including an Updated ADF Sunspot Group Series

Ilya **Usoskin**, Gennady Kovaltsov, Wilma Kiviaho
Solar Phys. **296**, Article number: 13 (**2021**)
https://arxiv.org/pdf/2012.08415.pdf
https://link.springer.com/content/pdf/10.1007/s11207-020-01750-9.pdf
Empirical rules of solar cycle evolution form important observational constraints for the solar dynamo theory. This includes the Waldmeier rule relating the magnitude of a solar cycle to the length of its ascending phase, and the Gnevyshev--Ohl rule clustering cycles to pairs of an even-numbered cycle followed by a stronger odd-numbered cycle. These rules were established as based on the "classical" Wolf sunspot number series, which has been essentially revisited recently, with several revised sets released by the research community. Here we test the robustness of these empirical rules for different sunspot (group) series for the period 1749--1996, using four classical and revised international sunspot numbers and group sunspot-number series. We also provide an update of the sunspot group series based on the active-day fraction (ADF) method, using the new database of solar observations. We show that the Waldmeier rule is robust and independent of the exact sunspot (group) series: its classical and n+1 (relating the length of n-th cycle to the magnitude of (n+1)-th cycle) formulations are significant or highly significant for all series, while its simplified formulation (relating the magnitude of a cycle to its full length) is insignificant for all series. The Gnevyshev--Ohl rule was found robust for all analyzed series for Cycles 8--21, but unstable across the Dalton minimum and before it.

Comment on the paper by Popova et al. On a role of quadruple component of magnetic field in defining solar activity in grand cycles,

Usoskin, I.
(**2017**). J. Atmosph. Solar-Terr. Phys., in press.
https://arxiv.org/pdf/1710.05203.pdf
The paper by Popova et al. presents an oversimplified mathematical model of solar activity with a claim of predicting/postdicting it for several millennia ahead/backwards. The work contains several flaws devaluating the results: (1) the method is unreliable from the point of view of signal processing (it is impossible to make harmonic predictions for thousands of years based on only 35 years of data) and lacks quality control, (2) the result of post-diction apparently contradicts the observational data. (3) theoretical speculations make little sense, To summarize, a multi-harmonic mathematical model, hardly related to full solar dynamo theory, is presented, which is not applicable to realistic solar conditions because of the significant chaotic/stochastic intrinsic component and strong non-stationarity of solar activity. The obtained result is apparently inconsistent with the data in the past and thus cannot be trusted for the future predictions.

Heliospheric modulation of cosmic rays during the neutron monitor era: Calibration using PAMELA data for 2006–201†

Ilya G. **Usoskin**, Agnieszka Gil, Gennady A. Kovaltsov, Alexander L. Mishev, Vladimir V. Mikhailov
JGR **Volume 122, Issue 4, pages 3875–3887, April 2017** **2017** DOI: 10.1002/2016JA023819
http://onlinelibrary.wiley.com.sci-hub.cc/doi/10.1002/2016JA023819/abstract;jsessionid=CDE52B06F06C8318AFBC1F81C9C09894.f03t03
A new reconstruction of the heliospheric modulation potential for galactic cosmic rays is presented for the neutron monitor era, since 1951. The new reconstruction is based on an updated methodology in comparison to previous reconstructions: (1) the use of the new-generation neutron monitor yield function; (2) the use of the new model of the local interstellar spectrum, employing in particular direct data from the distant missions; and (3) the calibration of the neutron monitor responses to direct measurements of the cosmic ray spectrum performed by the PAMELA space-borne spectrometer over 47 time intervals during 2006–2010. The reconstruction is based on data from six standard NM64-type neutron monitors (Apatity, Inuvik, Kergulen, Moscow, Newark and Oulu) since 1965, and two IGY-type ground-based detectors (Climax and Mt.Washington) for 1951–1964. The new reconstruction, along with the estimated uncertainties is tabulated in the paper. The presented series forms a benchmark record of the cosmic ray variability (in the energy range between 1–30 GeV) for the last 60 years, and can be used in long-term studies in the fields of solar, heliospheric and solar-terrestrial physics.

A history of solar activity over millennia **Review**

Ilya G. **Usoskin**
Living Reviews in Solar Physics December **2017**, 14:3
https://link.springer.com/content/pdf/10.1007%2Fs41116-017-0006-9.pdf
Presented here is a review of present knowledge of the long-term behavior of solar activity on a multi-millennial timescale, as reconstructed using the indirect proxy method. The concept of solar activity is discussed along with an overview of the special indices used to quantify different aspects of variable solar activity, with special emphasis upon sunspot number. Over long timescales, quantitative information about past solar activity can only be obtained using a method based upon indirect proxies, such as the cosmogenic isotopes 1414C and 1010Be in natural stratified archives (e.g., tree rings or ice cores). We give an historical overview of the development of the proxy-based method for past solar-activity reconstruction over millennia, as well as a description of the modern state. Special attention is paid to the verification and cross-calibration of reconstructions. It is argued that this method of cosmogenic isotopes makes a solid basis for studies of solar variability in the past on a long timescale (centuries to millennia) during the Holocene. A separate section is devoted to reconstructions of strong solar energetic-particle (SEP) events in the past, that suggest that the present-day average SEP flux is broadly consistent with estimates on longer timescales, and that the occurrence of extra-strong events is unlikely. Finally, the main features of the long-term evolution of solar magnetic activity, including the statistics of grand minima and maxima occurrence, are summarized and their possible implications, especially for solar/stellar dynamo theory, are discussed.

An Optical Atmospheric Phenomenon Observed in 1670 over the City of Astrakhan Was Not a Mid-Latitude Aurora

I. G. **Usoskin**, G. A. Kovaltsov, L. N. Mishina, D. D. Sokoloff, J. Vaquero
Solar Physics January **2017**, 292:15
http://link.springer.com/article/10.1007/s11207-016-1035-6

It has recently been claimed (Zolotova and Ponyavin Solar Phys., 291, 2869, 2016; ZP16 henceforth) that a mid-latitude optical phenomenon, which took place over the city of Astrakhan in July 1670, according to Russian chronicles, were a strong aurora borealis. If this were true, it would imply a very strong or even severe geomagnetic storm during the quietest part of the Maunder minimum. However, as we argue in this article, this conclusion is erroneous and caused by a misinterpretation of the chronicle record. As a result of a thorough analysis of the chronicle text, we show that the described phenomenon occurred during the daylight period of the day ("the last morning hour"), in the south ("towards noon"), and its description does not match that of an aurora. The date of the event was also interpreted incorrectly. We conclude that this phenomenon was not a mid-latitude aurora, but an atmospheric phenomenon, the so-called sundog (or parhelion), which is a particular type of solar halo. Accordingly, the claim of a strong mid-latitude aurora during the deep Maunder Minimum is not correct and should be dismissed.

Dependence of the Sunspot-group Size on the Level of Solar Activity and its Influence on the Calibration of Solar Observers

I.G. **Usoskin**, G.A. Kovaltsov, T. Chatzistergos
Solar Phys. Volume 291, Issue 12, pp 3793–3805 **2016**
http://arxiv.org/pdf/1609.00569.pdf

The distribution of the sunspot group size (area) and its dependence on the level of solar activity is studied. It is shown that the fraction of small groups is not constant but decreases with the level of solar activity so that high solar activity is largely defined by big groups. We study the possible influence of solar activity on the ability of a realistic observer to see and report the daily number of sunspot groups. It is shown that the relation between the number of sunspot groups as seen by different observers with different observational acuity thresholds is strongly non-linear and cannot be approximated by the traditionally used linear scaling (k−factors). The observational acuity threshold [Ath] is considered to quantify the quality of each observer, instead of the traditional relative k−factor. A nonlinear c−factor based on Ath is proposed, which can be used to correct each observer to the reference conditions. The method is tested on a pair of principal solar observers, Wolf and Wolfer, and it is shown that the traditional linear correction, with the constant k−factor of 1.66 to scale Wolf to Wolfer, leads to an overestimate of solar activity around solar maxima.

Solar activity during the Holocene: the Hallstatt cycle and its consequence for grand minima and maxima⋆

I. G. **Usoskin**1, Y. Gallet2, F. Lopes2, G. A. Kovaltsov3,4 and G. Hulot2
A&A 587, A150 (**2016**)

Aims. Cosmogenic isotopes provide the only quantitative proxy for analyzing the long-term solar variability over a centennial timescale. While essential progress has been achieved in both measurements and modeling of the cosmogenic proxy, uncertainties still remain in the determination of the geomagnetic dipole moment evolution. Here we aim at improving the reconstruction of solar activity over the past nine millennia using a multi-proxy approach.
Methods. We used records of the 14C and 10Be cosmogenic isotopes, current numerical models of the isotope production and transport in Earth's atmosphere, and available geomagnetic field reconstructions, including a new reconstruction relying on an updated archeo- and paleointensity database. The obtained series were analyzed using the singular spectrum analysis (SSA) method to study the millennial-scale trends.
Results. A new reconstruction of the geomagnetic dipole field moment, referred to as GMAG.9k, is built for the last nine millennia. New reconstructions of solar activity covering the last nine millennia, quantified in terms of sunspot numbers, are presented and analyzed. A conservative list of grand minima and maxima is also provided.
Conclusions. The primary components of the reconstructed solar activity, as determined using the SSA method, are different for the series that are based on 14C and 10Be. This shows that these primary components can only be ascribed to long-term changes in the terrestrial system and not to the Sun. These components have therefore been removed from the reconstructed series. In contrast, the secondary SSA components of the reconstructed solar activity are found to be dominated by a common ≈2400-year quasi-periodicity, the so-called Hallstatt cycle, in both the 14C and 10Be based series. This Hallstatt cycle thus appears to be related to solar activity. Finally, we show that the grand minima and maxima occurred intermittently over the studied period, with clustering near lows and highs of the Hallstatt cycle, respectively.

A New Calibrated Sunspot Group Series Since 1749: Statistics of Active Day Fractions

I. G. **Usoskin** , G. A. Kovaltsov, M. Lockwood, K. Mursula, M. Owens, S. K. Solanki
Solar Phys. Volume 291, Issue 9, pp 2685–2708 **2016**

Although sunspot-number series have existed since the mid-nineteenth century, they are still the subject of intense debate, with the largest uncertainty being related to the "calibration" of the visual acuity of individual observers in the past. A daisy-chain regression method is usually applied to inter-calibrate the observers, which may lead to significant bias and error accumulation. Here we present a novel method for calibrating the visual acuity of the key observers to the reference data set of Royal Greenwich Observatory sunspot groups for the period 1900 – 1976, using the statistics of the active-day fraction. For each observer we independently evaluate their observational thresholds [SS] defined such that the observer is assumed to miss all of the groups with an area smaller than SS and report all the groups larger than SS. Next, using a Monte-Carlo method, we construct a correction matrix for each observer from the reference data set. The correction matrices are significantly non-linear and cannot be approximated by a linear regression or proportionality. We emphasize that corrections based on a linear proportionality between annually averaged data lead to serious biases and distortions of the data. The correction matrices are applied to the original sunspot-group records reported by the observers for each day, and finally the composite corrected series is produced for the period since 1748. The corrected series is provided as supplementary material in electronic form and displays secular minima around 1800 (Dalton Minimum) and 1900 (Gleissberg Minimum), as well as the Modern Grand Maximum of activity in the second half of the twentieth century. The uniqueness of the grand maximum is confirmed for the last 250 years. We show that the adoption of a linear relationship between the data of Wolf and Wolfer results in grossly inflated group numbers in the eighteenth and nineteenth centuries in some reconstructions.

The Maunder minimum (1645--1715) was indeed a Grand minimum: A reassessment of multiple datasets

Ilya G. **Usoskin**, Rainer Arlt, Eleanna Asvestari, Ed Hawkins, Maarit Käpylä, Gennady A. Kovaltsov, Natalie Krivova, Michael Lockwood, Kalevi Mursula, Jezebel O'Reilly, Matthew Owens, Chris J. Scott, Dmitry D. Sokoloff, Sami K. Solanki, Willie Soon, José M. Vaquero
A&A 581, A95 **2015**
http://arxiv.org/pdf/1507.05191v1.pdf

Aims: Although the time of the Maunder minimum (1645--1715) is widely known as a period of extremely low solar activity, claims are still debated that solar activity during that period might still have been moderate, even higher than the current solar cycle #24. We have revisited all the existing pieces of evidence and datasets, both direct and indirect, to assess the level of solar activity during the Maunder minimum.
Methods: We discuss the East Asian naked-eye sunspot observations, the telescopic solar observations, the fraction of sunspot active days, the latitudinal extent of sunspot positions, auroral sightings at high latitudes, cosmogenic radionuclide data as well as solar eclipse observations for that period. We also consider peculiar features of the Sun (very strong hemispheric asymmetry of sunspot location, unusual differential rotation and the lack of the K-corona) that imply a special mode of solar activity during the Maunder minimum.
Results: The level of solar activity during the Maunder minimum is reassessed on the basis of all available data sets.
Conclusions: We conclude that solar activity was indeed at an exceptionally low level during the Maunder minimum. Although the exact level is still unclear, it was definitely below that during the Dalton minimum around 1800 and significantly below that of the current solar cycle #24. Claims of a moderate-to-high level of solar activity during the Maunder minimum are rejected at a high confidence level.

A two-wave dynamo model by Zharkova et al. (2015) disagrees with data on long-term solar variability

I. **Usoskin**, G. Kovaltsov
Sci. Rep **201**5
http://arxiv.org/pdf/1512.05516v1.pdf

A two-wave dynamo model was recently proposed by Zharkova et al. (2015, Zh15 henceforth), which aims at long-term predictions of solar activity for millennia ahead and backwards. Here we confront the backward model predictions for the last 800 years with known variability of solar activity, using both direct sunspot observations since 1610 and reconstructions based on cosmogenic radionuclide data. We show that the Zh15 model fails to reproduce the well-established features of the solar activity evolution during the last millennium. This means that the predictive part for the future is not reliable either.

Evidence for distinct modes of solar activity⋆

I. G. **Usoskin**1, G. Hulot2, Y. Gallet2, R. Roth3, A. Licht2, F. Joos3, G. A. Kovaltsov4, E. Thébault2 and A. Khokhlov
A&A 562, L10 (**2014**)
Aims. The Sun shows strong variability in its magnetic activity, from Grand minima to Grand maxima, but the nature of the variability is not fully understood, mostly because of the insufficient length of the directly observed solar activity records and of uncertainties related to long-term reconstructions. Here we present a new adjustment-free reconstruction of solar activity over three millennia and study its different modes.
Methods. We present a new adjustment-free, physical reconstruction of solar activity over the past three millennia, using the latest verified carbon cycle, 14C production, and archeomagnetic field models. This great improvement allowed us to study different modes of solar activity at an unprecedented level of details.
Results. The distribution of solar activity is clearly bi-modal, implying the existence of distinct modes of activity. The main regular activity mode corresponds to moderate activity that varies in a relatively narrow band between sunspot numbers 20 and 67. The existence of a separate Grand minimum mode with reduced solar activity, which cannot be explained by random fluctuations of the regular mode, is confirmed at a high confidence level. The possible existence of a separate Grand maximum mode is also suggested, but the statistics is too low to reach a confident conclusion.
Conclusions. The Sun is shown to operate in distinct modes – a main general mode, a Grand minimum mode corresponding to an inactive Sun, and a possible Grand maximum mode corresponding to an unusually active Sun. These results provide important constraints for both dynamo models of Sun-like stars and investigations of possible solar influence on Earth's climate.

A History of Solar Activity over Millennia

Ilya G. **Usoskin**
Living Reviews in Solar Physics, March **2013**
http://solarphysics.livingreviews.org/Articles/upcoming.html
Presented here is a review of present knowledge of the long-term behavior of solar activity on a multi-millennial timescale, as reconstructed using the indirect proxy method. The concept of solar activity is discussed along with an overview of the special indices used to quantify different aspects of variable solar activity, with special emphasis upon sunspot number.
Over long timescales, quantitative information about past solar activity can only be obtained using a method based upon indirect proxies, such as the cosmogenic isotopes 14C and 10Be in natural stratified archives (e.g., tree rings or ice cores). Special attention is paid to the verification and cross-calibration of reconstructions. It is argued that this method of cosmogenic isotopes makes a solid basis for studies of solar variability in the past on a long timescale (centuries to millennia) during the Holocene.
A separate section is devoted to reconstructions of strong solar energetic-particle (SEP) events in the past, that suggest that the present-day average SEP flux is broadly consistent with estimates on longer timescales, and that the occurrence of extra-strong events is unlikely.
Finally, the main features of the long-term evolution of solar magnetic activity, including the statistics of grand minima and maxima occurrence, are summarized and their possible implications, especially for solar/stellar dynamo theory, are discussed.

Temporal relations between magnetic bright points and the solar sunspot cycle

D. **Utz**, R. Muller, T. Van Doorsselaere
proceeding/paper of the 10-years anniversary Hinode conference **2017**
Publ. Astron. Soc. Japan Volume 69, Issue 6, 1 December **2017**, 98,
https://doi.org/10.1093/pasj/psx115
https://arxiv.org/pdf/1710.01678.pdf
The Sun shows a global magnetic field cycle traditionally best visible in the photosphere as a changing sunspot cycle featuring roughly an 11 year period. In addition we know that our host star also harbours small-scale magnetic fields often seen as strong concentrations of magnetic flux reaching kG field strengths. These features are situated in inter-granular lanes where they show up bright as so-called magnetic bright points (MBPs). In this short paper we wish to analyse a homogenous nearly 10 year long synoptic Hinode image data set recorded from November 2006 up to February 2016 in the G-band to inspect the relationship between the number of MBPs at the solar disc centre and the relative sunspot number.
Our findings suggest that indeed the number of MBPs at the solar disc centre is correlated to the relative sunspot number, but with the particular feature of showing two different temporal shifts between the decreasing phase of cycle 23 including the minimum and the increasing phase of cycle 24 including the maximum. While the former is shifted by about 22 months the later is only shifted by less than 12 months. Moreover, we introduce and discuss an

analytical model to predict the number of MBPs at the solar disc centre purely depending on the evolution of the relative sunspot number as well as the temporal change of the relative sunspot number and two background parameters describing a possibly acting surface dynamo as well as the strength of the magnetic field diffusion. Finally, we are able to confirm the plausibility of the temporal shifts by a simplistic random walk model.
The main conclusion to be drawn from this work is that the injection of magnetic flux, coming from active regions as represented by sunspots, happens on faster time scales than the removal of small-scale magnetic flux elements later on.

Long-term trends of magnetic bright points: I. Number of MBPs at disc centre

D. **Utz**, R. Muller, S. Thonhofer, A. Veronig, A. Hanslmeier, M. Bodnárová, M. Bárta, J. C. del Toro Iniesta

A&A A39 (**2016**)

http://arxiv.org/pdf/1511.07767v1.pdf

Context. The Sun shows an activity cycle that is caused by its varying global magnetic field. During a solar cycle, sunspots, i.e. extended regions of strong magnetic fields, occur in activity belts that are slowly migrating from middle to lower latitudes, finally arriving close to the equator during the cycle maximum phase. While this have been well known for centuries, much less is known about the solar cycle evolution of small-scale magnetic fields. Aims. To address this question, we study magnetic bright points (MBPs) as proxies for such small-scale, kG solar magnetic fields. This study is based on a homogeneous data set that covers a period of eight years. Methods. An automated MBP identification algorithm was applied to the synoptic Hinode/SOT G-band data over the period November 2006 to August 2014, i.e. covering the decreasing phase of Cycle 23 and the rise, maximum, and early decrease of Cycle 24. This data set includes, at the moment of investigation, a total of 4 162 images, with about 2.9 million single MBP detections.
Results. After a careful preselection and monthly median filtering of the data, the investigation revealed that the number of MBPs close to the equator is coupled to the global solar cycle but shifted in time by about 2.5 years. Furthermore, the instantaneous number of detected MBPs depends on the hemisphere, with one hemisphere being more prominent, i.e. showing a higher number of MBPs. After the end of Cycle 23 and at the starting point of Cycle 24, the more active hemisphere changed from south to north.
Conclusions. These findings suggest that there is indeed a coupling between the activity of MBPs close to the equator with the global magnetic field. The results also indicate that a significant fraction of the magnetic flux that is visible as MBPs close to the equator originates from the sunspot activity belts.

Observations of the Quiet Sun During the Deepest Solar Minimum of the Past Century with Chandrayaan-2 XSM -- Elemental Abundances in the Quiescent Corona

Santosh V. **Vadawale**, Biswajit Mondal, N. P. S. Mithun, Aveek Sarkar, P. Janardhan, Bhuwan Joshi, Anil Bhardwaj, M. Shanmugam, Arpit R. Patel, Hitesh Kumar L. Adalja, Shiv Kumar Goyal, Tinkal Ladiya, Neeraj Kumar Tiwari, Nishant Singh, Sushil Kumar

ApJL **912** L12 **2021**

https://arxiv.org/pdf/2103.16643.pdf

https://doi.org/10.3847/2041-8213/abf35d

Elements with low First Ionization Potential (FIP) are known to be three to four times more abundant in active region loops of the solar corona than in the photosphere. There have been observations suggesting that this observed "FIP bias" may be different in other parts of the solar corona and such observations are thus important in understanding the underlying mechanism. The Solar X-ray Monitor (XSM) on board the Chandrayaan-2 mission carried out spectroscopic observations of the Sun in soft X-rays during the 2019-20 solar minimum, considered to be the quietest solar minimum of the past century. These observations provided a unique opportunity to study soft X-ray spectra of the quiescent solar corona in the absence of any active regions. By modelling high resolution broadband X-ray spectra from XSM, we estimate the temperature and emission measure during periods of possibly the lowest solar X-ray intensity. We find that the derived parameters remain nearly constant over time with a temperature around 2 MK, suggesting the emission is dominated by X-ray Bright Points (XBPs). We also obtain the abundances of Mg, Al, and Si relative to H, and find that the FIP bias is ~2, lower than the values observed in active regions. **2019-Sep-17, 2019-09-21**

Solar Models in Light of New High Metallicity Measurements from Solar Wind Data

Sunny **Vagnozzi**1, Katherine Freese1,2, and Thomas H. Zurbuchen

2017 ApJ 839 55 DOI 10.3847/1538-4357/aa6931

We study the impact of new metallicity measurements, from solar wind data, on the solar model. The "solar modeling problem" refers to the persisting discrepancy between helioseismological observations and predictions of solar models computed implementing state-of-the-art photospheric abundances. We critically reassess the problem, in particular considering the new set of abundances of von Steiger & Zurbuchen, determined through the in situ

collection of solar wind samples from polar coronal holes. This new set of abundances indicates a solar metallicity , significantly higher than the currently established value. The new values hint at an abundance of volatile elements (i.e., C, N, O, Ne) close to previous results of Grevesse and Sauval, whereas the abundance of refractory elements (i.e., Mg, Si, S, Fe) is considerably increased. Using the Linear Solar Model formalism, we determine the variation of helioseismological observables in response to the changes in elemental abundances, in order to explore the consistency of these new measurements with constraints from helioseismology. We find that for observables that are particularly sensitive to the abundance of volatile elements, in particular the radius of the convective zone boundary (CZB) and the sound speed around the radius of CZB, improved agreement over previous models is obtained. Conversely, the high abundance of refractories correlates with a higher core temperature, resulting in an overproduction of neutrinos and a huge increase in the surface helium abundance. We conclude that the "solar modeling problem" remains unsolved.

New solar metallicity measurements

Sunny **Vagnozzi**

51st Rencontres de Moriond, Cosmology Session, ISBN: 979-10-968-7901-4 **2017**

https://arxiv.org/pdf/1703.10834.pdf

In the past years, a systematic downward revision of the metallicity of the Sun has led to the "solar modelling problem", namely the disagreement between predictions of standard solar models and inferences from helioseismology. Recent solar wind measurements of the metallicity of the Sun, however, provide once more indication for a high-metallicity Sun. Because of the effects of possible residual fractionation, the derived value of the metallicity $Z = 0.0196 \pm 0.0014$ actually represents a lower limit to the true metallicity of Sun.
However, when compared with helioseismological measurements, solar models computed using these new abundances fail to restore agreement, owing to the implausibly high abundance of refractory (Mg, Si, S, Fe) elements, which correlates with a higher core temperature and hence an over-production of solar neutrinos. Moreover, the robustness of these measurements is challenged by possible first ionization potential fractionation processes. In this talk I will discuss these solar wind measurements, which leave the "solar modelling problem" unsolved.

A successful solar model using new solar composition data

Sunny **Vagnozzi**, Katherine Freese, Thomas H. Zurbuchen

2016

http://arxiv.org/pdf/1603.05960v1.pdf

A resolution is proposed to the "solar abundance problem", that is, the discrepancy between helioseismological observations and the predictions of solar models, computed implementing state-of-the-art photospheric abundances. We reassess the problem considering a newly determined set of abundances, which indicate a lower limit to the metallicity of $Z_\odot = 0.0196 \pm 0.0014$, significantly higher than findings during the past decade. Such value for the metallicity is determined in situ, measuring the least fractionated solar winds over the poles of the Sun, rather than spectroscopically. We determine the response of helioseismological observables to the corresponding changes in elemental abundances. Our findings indicate that, taking inversion errors into account, good agreement between models and observations is achieved. The definitive test for these abundances will be measurements of the CNO neutrino fluxes by SNO+ (which we expect to be $\sim$ 30-50\% higher than predictions using abundances based on photospheric spectroscopy). We briefly comment on the implausibility of previously proposed solutions based on dark matter. The results also imply that 3D spectroscopic inversion processes systematically underestimate elemental abundances in the photosphere. Our conclusion is that the solar abundance problem has found a definitive compelling solution.

Why is solar cycle 24 an inefficient producer of high-energy particle events?

Rami **Vainio**, Osku Raukunen, Allan J. Tylka, William F. Dietrich, Alexandr Afanasiev

A&A **2017**

https://arxiv.org/pdf/1707.00485.pdf

The aim of the study is to investigate the reason for the low productivity of high-energy SEPs in the present solar cycle. We employ scaling laws derived from diffusive shock acceleration theory and simulation studies including proton-generated upstream Alfv\'en waves to find out how the changes observed in the long-term average properties of the erupting and ambient coronal and/or solar wind plasma would affect the ability of shocks to accelerate particles to the highest energies. Provided that self-generated turbulence dominates particle transport around coronal shocks, it is found that the most crucial factors controlling the diffusive shock acceleration process are the number density of seed particles and the plasma density of the ambient medium. Assuming that suprathermal populations

provide a fraction of the particles injected to shock acceleration in the corona, we show that the lack of most energetic particle events as well as the lack of low charge-to-mass ratio ion species in the present cycle can be understood as a result of the reduction of average coronal plasma and suprathermal densities in the present cycle over the previous one.

Interaction of Large- and Small-scale Dynamos in Isotropic Turbulent Flows from GPU-accelerated Simulations

Miikka S. **Väisälä**1, Johannes Pekkilä2, Maarit J. Käpylä2,3,4, Matthias Rheinhardt2, Hsien Shang (尚賢)1, and Ruben Krasnopolsky1
2021 ApJ 907 83
https://doi.org/10.3847/1538-4357/abceca
Magnetohydrodynamical (MHD) dynamos emerge in many different astrophysical situations where turbulence is present, but the interaction between large-scale dynamos (LSDs) and small-scale dynamos (SSDs) is not fully understood. We performed a systematic study of turbulent dynamos driven by isotropic forcing in isothermal MHD with magnetic Prandtl number of unity, focusing on the exponential growth stage. Both helical and nonhelical forcing was employed to separate the effects of LSD and SSD in a periodic domain. Reynolds numbers ($\mathrm{Re_M}$) up to ≈250 were examined and multiple resolutions used for convergence checks. We ran our simulations with the Astaroth code, designed to accelerate 3D stencil computations on graphics processing units (GPUs) and to employ multiple GPUs with peer-to-peer communication. We observed a speedup of ≈35 in single-node performance compared to the widely used multi-CPU MHD solver Pencil Code. We estimated the growth rates from both the averaged magnetic fields and their power spectra. At low $\mathrm{Re_M}$ LSD growth dominates, but at high $\mathrm{Re_M}$ SSD appears to dominate in both helically and nonhelically forced cases. Pure SSD growth rates follow a logarithmic scaling as a function of $\mathrm{Re_M}$. Probability density functions of the magnetic field from the growth stage exhibit SSD behavior in helically forced cases even at intermediate $\mathrm{Re_M}$. We estimated mean field turbulence transport coefficients using closures like the second-order correlation approximation (SOCA). They yield growth rates similar to the directly measured ones and provide evidence of α quenching. Our results are consistent with the SSD inhibiting the growth of the LSD at moderate $\mathrm{Re_M}$, while the dynamo growth is enhanced at higher $\mathrm{Re_M}$.

Long-Term and Solar Cycle Variation of Galactic Cosmic Rays: Evidence for Variable Heliospheric Turbulence

Pauli **Väisänen**, Ilya Usoskin, Kalevi Mursula
JGR Volume124, Issue2 February **2019** Pages 804-811
sci-hub.tw/10.1029/2018JA026135
The Sun modulates the flux of galactic cosmic rays (GCR) reaching the Earth's orbit. GCR flux has been measured by ground-based neutron monitors (NMs) for several decades, which provides an interesting long-term monitor of solar activity and the heliospheric magnetic field. Here we study the long-term evolution of the power spectrum of GCR over the last six solar cycles, using the power law slope in the frequency range 5.56·10−6 to 2.14·10−6 Hz (between 50 and 130 hr). We use data from 31 neutron monitors during 1953–2016. We show that the power law slopes vary within the solar cycle, with a Kolmogorov-type slope observed at solar minimum and a random-walk-type slope observed at solar maximum. This implies that the different conditions in the different phases of the solar cycle affect the scaling properties of heliospheric turbulence and, thereby, cosmic ray variability.

Correlations of Sunspot Physical Characteristics during Solar Cycle 23

Adriana **Valio**, Eduardo Spagiari, Mauricio Marengoni & Caius L. Selhorst
Solar Physics volume 295, Article number: 120 (**2020**)
https://link.springer.com/content/pdf/10.1007/s11207-020-01691-3.pdf
The behavior of sunspots is governed by the magnetic dynamo acting deep within the convection zone of the Sun. Therefore, knowledge of sunspot physical characteristics and how they evolve in time during a solar cycle can help to improve our understanding of the solar magnetic behavior. This work analyzes the physical characteristics of sunspots during the Solar Activity Cycle 23, detected using computer vision techniques. The main goal is to derive the relationships between sunspot properties. Images in visible light and magnetograms of the Michelson Doppler Imager (MDI) on board the Solar and Heliospheric Observatory (SOHO) were used to detect sunspots and to extract their characteristics such as area, intensity (or temperature), and magnetic field magnitude. A total of 32,223 sunspots were analyzed, with longitudes between −40∘−40∘ and 40∘40∘, throughout the entire Solar Cycle 23, from May 1996 through April 2008. These spots fell mainly into three categories. Most sunspots (85%) did not exhibit a well defined umbra, with average intensities larger than 0.657 relative to disk center, which corresponds to temperatures greater than 5200 K. A second group comprising less than 12% of the spots, was cooler (temperature less than 5200 K) and with more intense magnetic fields (2000 – 4000 G) and mostly presented a well defined umbra. Lastly, only 3% of the spots had large areas and strong magnetic fields with complex umbrae, but intermediate temperatures. The temporal behavior of sunspot physical characteristics throughout the 11 year cycle

and the relationships between them were verified. Sunspot physical properties presented variations over time during Solar Cycle 23, such that larger, cooler sunspots with stronger magnetic fields occurred more frequently during periods of maximum activity. Linear correlations were found regarding the logarithm of the area and the intensity with extreme magnetic field, and of the temperature (or intensity) with the area; whereas a quadratic relation was found between magnetic field and temperature of spots.

Additivity of relative magnetic helicity in finite volumes

Gherardo **Valori**, Pascal Démoulin, Etienne Pariat, Anthony Yeates, Kostas Moraitis, Luis Linan
A&A **2020**
https://arxiv.org/pdf/2008.00968.pdf
Relative magnetic helicity is conserved by magneto-hydrodynamic evolution even in the presence of moderate resistivity. For that reason, it is often invoked as the most relevant constraint to the dynamical evolution of plasmas in complex systems, such as solar and stellar dynamos, photospheric flux emergence, solar eruptions, and relaxation processes in laboratory plasmas. However, such studies often indirectly imply that relative magnetic helicity in a given spatial domain can be algebraically split into the helicity contributions of the composing subvolumes, i.e., that it is an additive quantity. A limited number of very specific applications have shown that this is not the case. Progress in understanding the non-additivity of relative magnetic helicity requires removal of restrictive assumptions in favour of a general formalism that can be used both in theoretical investigations as well as in numerical applications. We derive the analytical gauge-invariant expression for the partition of relative magnetic helicity between contiguous finite-volumes, without any assumptions on either the shape of the volumes and interface, or the employed gauge. The non-additivity of relative magnetic helicity in finite volumes is proven in the most general, gauge-invariant formalism, and verified numerically. More restrictive assumptions are adopted to derive known specific approximations, yielding a unified view of the additivity issue. As an example, the case of a flux rope embedded in a potential field shows that the non-additivity term in the partition equation is, in general, non-negligible. The relative helicity partition formula can be applied to numerical simulations to precisely quantify the effect of non-additivity on global helicity budgets of complex physical processes.

Magnetic helicity estimations in models and observations of the solar magnetic field. Part I: Finite volume methods **Review**

Gherardo **Valori**, Etienne Pariat, Sergey Anfinogentov, Feng Chen, Manolis K. Georgoulis, Yang Guo, Yang Liu, Kostas Moraitis, Julia K. Thalmann, Shangbin Yang
Space Science Reviews **2016**
https://arxiv.org/pdf/1610.02193v1.pdf
Magnetic helicity is a conserved quantity of ideal magneto-hydrodynamics characterized by an inverse turbulent cascade. Accordingly, it is often invoked as one of the basic physical quantities driving the generation and structuring of magnetic fields in a variety of astrophysical and laboratory plasmas. We provide here the first systematic comparison of six existing methods for the estimation of the helicity of magnetic fields known in a finite volume. All such methods are reviewed, benchmarked, and compared with each other, and specifically tested for accuracy and sensitivity to errors. To that purpose, we consider four groups of numerical tests, ranging from solutions of the three-dimensional, force-free equilibrium, to magneto-hydrodynamical numerical simulations. Almost all methods are found to produce the same value of magnetic helicity within few percent in all tests. In the more solar-relevant and realistic of the tests employed here, the simulation of an eruptive flux rope, the spread in the computed values obtained by all but one method is only 3%, indicating the reliability and mutual consistency of such methods in appropriate parameter ranges. However, methods show differences in the sensitivity to numerical resolution and to errors in the solenoidal property of the input fields. In addition to finite volume methods, we also briefly discuss a method that estimates helicity from the field lines' twist, and one that exploits the field's value at one boundary and a coronal minimal connectivity instead of a pre-defined three-dimensional magnetic-field solution.

Chromospheric evaporation and phase mixing of Alfvén waves in coronal loops

A&A 635, A174 **2020**
https://arxiv.org/pdf/2002.11695.pdf
https://www.aanda.org/articles/aa/pdf/2020/03/aa37266-19.pdf
Phase mixing of Alfvén waves has been studied extensively as a possible coronal heating mechanism but without the full thermodynamic consequences considered self-consistently. It has been argued that in some cases, the thermodynamic feedback of the heating could substantially affect the transverse density gradient and even inhibit the phase mixing process. In this paper, we use MHD simulations with the appropriate thermodynamical terms included to quantify the evaporation following heating by phase mixing of Alfvén waves in a coronal loop and the effect of this evaporation on the transverse density profile. The numerical simulations were performed using the Lare2D code. We set up a 2D loop model consisting of a field-aligned thermodynamic equilibrium and a cross-field

(background) heating profile. A continuous, sinusoidal, high-frequency Alfvén wave driver was implemented. As the Alfvén waves propagate along the field, they undergo phase mixing due to the cross-field density gradient in the coronal part of the loop. We investigated the presence of field-aligned flows, heating from the dissipation of the phase-mixed Alfvén waves, and the subsequent evaporation from the lower atmosphere. We find that phase mixing of Alfvén waves leads to modest heating in the shell regions of the loop and evaporation of chromospheric material into the corona with upflows of the order of only 5-20 m/s. Although the evaporation leads to a mass increase in the shell regions of the loop, the effect on the density gradient and, hence, on the phase mixing process, is insignificant. This paper self-consistently investigates the effect of chromospheric evaporation on the cross-field density gradient and the phase mixing process in a coronal loop. We found that the effects in our particular setup (small amplitude, high frequency waves) are too small to significantly change the density gradient.

Predictions for the First Parker Solar Probe Encounter

B. **van der Holst**1, W. B. Manchester IV1, K. G. Klein2, and J. C. Kasper
2019 ApJL 872 L18
https://doi.org/10.3847/2041-8213/ab04a5
https://arxiv.org/pdf/1902.03921.pdf
We examine Alfvén Wave Solar atmosphere Model (AWSoM) predictions of the first Parker Solar Probe (PSP) encounter. We focus on the 12 day closest approach centered on the first perihelion. AWSoM allows us to interpret the PSP data in the context of coronal heating via Alfvén wave turbulence. The coronal heating and acceleration is addressed via outward-propagating low-frequency Alfvén waves that are partially reflected by Alfvén speed gradients. The nonlinear interaction of these counter-propagating waves results in a turbulent energy cascade. To apportion the wave dissipation to the electron and anisotropic proton temperatures, we employ the results of the theories of linear wave damping and nonlinear stochastic heating as described by Chandran et al. We find that during the first encounter, PSP was in close proximity to the heliospheric current sheet (HCS) and in the slow wind. PSP crossed the HCS two times, at **2018 November 3** UT 01:02 and **2018 November 8** UT 19:09, with perihelion occurring on the south of side of the HCS. We predict the plasma state along the PSP trajectory, which shows a dominant proton parallel temperature causing the plasma to be firehose unstable.

Intermittent reconnection and plasmoids in UV bursts in the low solar atmosphere

L. Rouppe **van der Voort**, B. De Pontieu, G.B. Scharmer, J. de la Cruz Rodriguez, J. Martinez-Sykora, D. Nobrega-Siverio, L.J. Guo, S. Jafarzadeh, T.M.D. Pereira, V.H. Hansteen, M. Carlsson, G. Vissers
ApJL **2017**
https://arxiv.org/pdf/1711.04581.pdf
Magnetic reconnection is thought to drive a wide variety of dynamic phenomena in the solar atmosphere. Yet the detailed physical mechanisms driving reconnection are difficult to discern in the remote sensing observations that are used to study the solar atmosphere. In this paper we exploit the high-resolution instruments Interface Region Imaging Spectrograph (IRIS) and the new CHROMIS Fabry-Perot instrument at the Swedish 1-m Solar Telescope (SST) to identify the intermittency of magnetic reconnection and its association with the formation of plasmoids in so-called UV bursts in the low solar atmosphere. The Si IV 1403A UV burst spectra from the transition region show evidence of highly broadened line profiles with often non-Gaussian and triangular shapes, in addition to signatures of bidirectional flows. Such profiles had previously been linked, in idealized numerical simulations, to magnetic reconnection driven by the plasmoid instability. Simultaneous CHROMIS images in the chromospheric Ca II K 3934A line now provide compelling evidence for the presence of plasmoids, by revealing highly dynamic and rapidly moving brightenings that are smaller than 0.2 arcsec and that evolve on timescales of order seconds. Our interpretation of the observations is supported by detailed comparisons with synthetic observables from advanced numerical simulations of magnetic reconnection and associated plasmoids in the chromosphere. Our results highlight how subarcsecond imaging spectroscopy sensitive to a wide range of temperatures combined with advanced numerical simulations that are realistic enough to compare with observations can directly reveal the small-scale physical processes that drive the wide range of phenomena in the solar atmosphere. **2016 September 3-5**

Heating signatures in the disk counterparts of solar spicules in IRIS observations

L. Rouppe **van der Voort**, B. De Pontieu, T.M.D. Pereira, M. Carlsson, V. Hansteen
ApJL, **799** L3 **2015**
http://arxiv.org/pdf/1412.4531v1.pdf
We use coordinated observations with the Interface Region Imaging Spectrograph (IRIS) and the Swedish 1-m Solar Telescope (SST) to identify the disk counterpart of type II spicules in upper-chromospheric and transition region (TR) diagnostics. These disk counterparts were earlier identified through short-lived asymmetries in chromospheric spectral lines: rapid blue- or red-shifted excursions (RBEs or RREs). We find clear signatures of RBEs and RREs in Mg II h & k, often with excursions of the central h3 and k3 absorption features in concert with asymmetries in co-

temporal and co-spatial H-alpha spectral profiles. We find spectral signatures for RBEs and RREs in C II 1335 and 1336 A and Si IV 1394 and 1403 A spectral lines and interpret this as a sign that type II spicules are heated to at least TR temperatures, supporting other recent work. These C II and Si IV spectral signals are weaker for a smaller network region than for more extended network regions in our data. A number of bright features around extended network regions observed in IRIS slit-jaw imagery SJI 1330 and 1400, recently identified as network jets, can be clearly connected to H-alpha RBEs and/or RREs in our coordinated data. We speculate that at least part of the diffuse halo around network regions in the IRIS SJI 1330 and 1400 images can be attributed to type II spicules with insufficient opacity in the C II and Si IV lines to stand out as single features in these passbands. Movies are available at this http URL **13-23 Sep 2013**

Coronal heating by MHD waves **Review**

https://arxiv.org/pdf/2012.01371.pdf

The heating of the solar chromosphere and corona to the observed high temperatures, imply the presence of ongoing heating that balances the strong radiative and thermal conduction losses expected in the solar atmosphere. It has been theorized for decades that the required heating mechanisms of the chromospheric and coronal parts of the active regions, quiet-Sun, and coronal holes are associated with the solar magnetic fields. However, the exact physical process that transport and dissipate the magnetic energy which ultimately leads to the solar plasma heating are not yet fully understood. The current understanding of coronal heating relies on two main mechanism: reconnection and MHD waves that may have various degrees of importance in different coronal regions. In this review we focus on recent advances in our understanding of MHD wave heating mechanisms. First, we focus on giving an overview of observational results, where we show that different wave modes have been discovered in the corona in the last decade, many of which are associated with a significant energy flux, either generated in situ or pumped from the lower solar atmosphere. Afterwards, we summarise the recent findings of numerical modelling of waves, motivated by the observational results. Despite the advances, only 3D MHD models with Alfvén wave heating in an unstructured corona can explain the observed coronal temperatures compatible with the quiet Sun, while 3D MHD wave heating models including cross-field density structuring are not yet able to account for the heating of coronal loops in active regions to their observed temperature.

Editorial: Magnetohydrodynamic Waves in the Solar Atmosphere: Heating and Seismology **Review**

Energy Propagation by Transverse Waves in Multiple Flux Tube Systems Using Filling Factors

T. **Van Doorsselaere**1, S. E. Gijsen1, J. Andries2, and G. Verth

2014 ApJ 795 18.

https://perswww.kuleuven.be/~u0041608/docs/vd2014fillingfactors.pdf

In the last few years, it has been found that transverse waves are present at all times in coronal loops or spicules. Their energy has been estimated with an expression derived for bulk Alfvén waves in homogeneous media, with correspondingly uniform wave energy density and flux. The kink mode, however, is localized in space with the energy density and flux dependent on the position in the cross-sectional plane. The more relevant quantities for the kink mode are the integrals of the energy density and flux over the cross-sectional plane. The present paper provides an approximation to the energy propagated by kink modes in an ensemble of flux tubes by means of combining the analysis of single flux tube kink oscillations with a filling factor for the tube cross-sectional area. This finally allows one to compare the expressions for energy flux of Alfvén waves with an ensemble of kink waves. We find that the correction factor for the energy in kink waves, compared to the bulk Alfvén waves, is between f and 2f, where f is the density filling factor of the ensemble of flux tubes.

Plasma outflows from active regions: are they sources of the slow solar wind?

Lidia **van Driel-Gesztelyi**, Deb Baker, and Lucie Green

Hinode EIS science nugget for September **2012**

http://msslxr.mssl.ucl.ac.uk:8080/SolarB/nuggets/nugget_2012sep.jsp
Since the discovery of hot plasma upflows from the edges of solar active regions (ARs) by Hinode/XRT (Sakao et al., 2008) and EIS (Harra et al. 2008) it has been suspected that these upflows are in fact outflows, i.e. sources of the slow solar wind (SW). In an article to be published in Solar Physics (van Driel-Gesztelyi et al., 2012) we make an attempt to step beyond anecdotic evidence and show that this is indeed the case - at least for some of the flows.

Using Bright-Point Shapes to Constrain Wave-Heating of the Solar Corona: Predictions for DKIST

Samuel J. **Van Kooten**, Steven R. Cranmer
ApJ **2024**
https://arxiv.org/pdf/2402.10915.pdf
Magnetic bright points on the solar photosphere mark the footpoints of kilogauss magnetic flux tubes extending toward the corona. Convective buffeting of these tubes is believed to excite magnetohydrodynamic waves, which can propagate to the corona and there deposit heat. Measuring wave excitation via bright-point motion can thus constrain coronal and heliospheric models, and this has been done extensively with centroid tracking, which can estimate kink-mode wave excitation. DKIST is the first telescope to provide well-resolved observations of bright points, allowing shape and size measurements to probe the excitation of other wave modes that have been difficult, if not impossible, to study to date. In this work, we demonstrate a method of automatic bright-point tracking that robustly identifies the shapes of bright points, and we develop a technique for interpreting measured bright-point shape changes as the driving of a range of thin-tube wave modes. We demonstrate these techniques on a MURaM simulation of DKIST-like resolution. These initial results suggest that modes other than the long-studied kink mode could increase the total available energy budget for wave-heating by 50%. Pending observational verification as well as modeling of the propagation and dissipation of these additional wave modes, this could represent a significant increase in the potency of wave-turbulence heating models.

Image restoration of solar spectra

Michiel **van Noort**
A&A **2017**
https://arxiv.org/pdf/1711.09629.pdf
When recording spectra from the ground, atmospheric turbulence causes degradation of the spatial resolution. We present a data reduction method that restores the spatial resolution of the spectra to their undegraded state. By assuming that the point spread function (PSF) estimated from a strictly synchronized, broadband slit-jaw camera is the same as the PSF that spatially degraded the spectra, we can quantify what linear combination of undegraded spectra is present in each degraded data point. The set of equations obtained in this way is found to be generally well-conditioned and sufficiently diagonal to be solved using an iterative linear solver. The resulting solution has regained a spatial resolution comparable to that of the restored slit-jaw images.

Active region upflows I. Multi-instrument observations⋆

K. **Vanninathan**1, M. S. Madjarska2, K. Galsgaard3, Z. Huang4 and J. G. Doyle
A&A 584, A38 (**2015**)
Context. We study upflows at the edges of active regions, called AR outflows, using multi-instrument observations.
Aims. This study intends to provide the first direct observational evidence of whether chromospheric jets play an important role in furnishing mass that could sustain coronal upflows. The evolution of the photospheric magnetic field, associated with the footpoints of the upflow region and the plasma properties of active region upflows is investigated with the aim of providing information for benchmarking data-driven modelling of this solar feature.
Methods. We spatially and temporally combine multi-instrument observations obtained with the Extreme-ultraviolet Imaging Spectrometer on board the Hinode, the Atmospheric Imaging Assembly and the Helioseismic Magnetic Imager instruments on board the Solar Dynamics Observatory and the Interferometric BI-dimensional Spectro-polarimeter installed at the National Solar Observatory, Sac Peak, to study the plasma parameters of the upflows and the impact of the chromosphere on active region upflows.
Results. Our analysis shows that the studied active region upflow presents similarly to those studied previously, i.e. it displays blueshifted emission of 5–20 kms-1 in Fe xii and Fe xiii and its average electron density is 1.8 × 109 cm-3 at 1 MK. The time variation of the density is obtained showing no significant change (in a 3σ error). The plasma density along a single loop is calculated revealing a drop of 50% over a distance of ~20 000 km along the loop. We find a second velocity component in the blue wing of the Fe xii and Fe xiii lines at 105 kms-1 reported only once before. For the first time we study the time evolution of this component at high cadence and find that it is persistent during the whole observing period of 3.5 h with variations of only±15 kms-1. We also, for the first time, study the evolution of the photospheric magnetic field at high cadence and find that magnetic flux diffusion is responsible for the formation of the upflow region. High cadence Hα observations are used to study the chromosphere at the footpoints of the upflow region. We find no significant jet-like (spicule/rapid blue excursion) activity to account for

several hours/days of plasma upflow. The jet-like activity in this region is not continuous and blueward asymmetries are a bare minimum. Using an image enhancement technique for imaging and spectral data, we show that the coronal structures seen in the AIA 193 Å channel are comparable to the EIS Fe xii images, while images in the AIA 171 Å channel reveal additional loops that are a result of contribution from cooler emission to this channel. Conclusions. Our results suggest that at chromospheric heights there are no signatures that support the possible contribution of spicules to active region upflows. We suggest that magnetic flux diffusion is responsible for the formation of the coronal upflows. The existence of two velocity components possibly indicates the presence of two different flows, which are produced by two different physical mechanisms, e.g. magnetic reconnection and pressure-driven jets.

Erratum to: Off-limb (Spicule) DEM Distribution from SoHO/SUMER Observations

K. **Vanninathan**, M. S. Madjarska, E. Scullion, J. G. Doyle
Solar Phys. **2014**
Erratum to: Solar Phys. (**2012**) 280:425–434 DOI10.1007/s11207-012-9986-8

Off-limb (Spicule) DEM Distribution from SoHO/SUMER Observations

K. **Vanninathan**, M. S. Madjarska, E. Scullion, J. G. Doyle
Solar Phys. Volume 280, Issue 2, pp.425-434 **2012**
In the present work we derive a Differential Emission Measure (DEM) distribution from a region dominated by spicules. We use spectral data from the Solar Ultraviolet Measurements of Emitted Radiation (SUMER) spectrometer on-board the Solar Heliospheric Observatory (SoHO) covering the entire SUMER wavelength range taken off-limb in the Northern polar coronal hole to construct this DEM distribution using the CHIANTI atomic database. This distribution is then used to study the thermal properties of the emission contributing to the 171 Å channel in the Atmospheric Imaging Assembly (AIA) on-board the Solar Dynamics Observatory (SDO). From our off-limb DEM we found that the radiance in the AIA 171 Å channel is dominated by emission from the Fe ix 171.07 Å line and has sparingly little contribution from other lines. The product of the Fe ix 171.07 Å line contribution function with the off-limb DEM was found to have a maximum at log T max (K)=5.8 indicating that during spicule observations the emission in this line comes from plasma at transition region temperatures rather than coronal. For comparison, the same product with a quiet Sun and prominence DEM were found to have a maximum at log T max (K)=5.9 and log T max (K)=5.7, respectively. We point out that the interpretation of data obtained from the AIA 171 Å filter should be done with foreknowledge of the thermal nature of the observed phenomenon. For example, with an off-limb DEM we find that only 3.6 % of the plasma is above a million degrees, whereas using a quiet Sun DEM, this contribution rises to 15 %.

A Revised Collection of Sunspot Group Numbers

J. M. **Vaquero**, L. Svalgaard, V. M. S. Carrasco, F. Clette, L. Lefèvre, M. C. Gallego, R. Arlt, A. J. P. Aparicio, J.-G. Richard, R. Howe
Solar Phys. **2016**
http://arxiv.org/pdf/1609.04882v1.pdf
We describe a revised collection of the number of sunspot groups from 1610 to the present. This new collection is based on the work of Hoyt and Schatten (Solar Phys. 179, 189, 1998). The main changes are the elimination of a considerable number of observations during the Maunder Minimum (hereafter, MM) and the inclusion of several long series of observations. Numerous minor changes are also described. Moreover, we have calculated the active-day percentage during the MM from this new collection as a reliable index of the solar activity. Thus, the level of solar activity obtained in this work is greater than the level obtained using the original Hoyt and Schatten data, although it remains compatible with a grand minimum of solar activity. The new collection is available in digital format.

Monitoring the Solar Radius from the Royal Observatory of the Spanish Navy during the Last Quarter-Millennium

J.M. **Vaquero**, M.C. Gallego, J.J. Ruiz-Lorenzo, T. López-Moratalla, V.M.S. Carrasco, A.J.P. Aparicio, F.J. González-González, E. Hernández-García
Solar Phys. Volume 291, Issue 6, pp 1599–1612 **2016**

http://arxiv.org/pdf/1606.03932v1.pdf

The solar diameter has been monitored at the Royal Observatory of the Spanish Navy (today the Real Instituto y Observatorio de la Armada: ROA) almost continuously since its creation in 1753 (i.e. during the last quarter of a millennium). After a painstaking effort to collect data in the historical archive of this institution, we present here the data of the solar semidiameter from 1773 to 2006, making up an extensive new database for solar-radius measurements can be considered. We have calculated the solar semidiameter from the transit times registered by the observers (except values of the solar radius from the modern Danjon astrolabe, which were published by ROA). These data were analysed to reveal any significant long-term trends, but no such trends were found. Therefore, the data sample confirms the constancy of the solar diameter during the last quarter of a millennium (approximately) within instrumental and methodological limits. Moreover, no relationship between solar radius and the new sunspot-number index has been found from measurements of the ROA. Finally, the mean value for solar semidiameter (with one standard deviation) calculated from the observations made in the ROA (1773-2006), after applying corrections by refraction and diffraction, is equal to 958.87" \pm 1.77"

Level and length of cyclic solar activity during the Maunder minimum as deduced from the active day statistics

J.M. **Vaquero**, G. A. Kovaltsov, I.G. Usoskin, V.M.S. Carrasco, M.C. Gallego
A&A 577, A71 **2015**
http://arxiv.org/pdf/1503.07664v1.pdf

The Maunder minimum (MM) of greatly reduced solar activity took place in 1645-1715, but the exact level of sunspot activity is uncertain as based, to a large extent, on historical generic statements of the absence of spots on the Sun. Here we aim, using a conservative approach, to assess the level and length of solar cycle during the Maunder minimum, on the basis of direct historical records by astronomers of that time. A database of the active and inactive days (days with and without recorded sunspots on the solar disc respectively) is constructed for three models of different levels of conservatism (loose ML, optimum MO and strict MS models) regarding generic no-spot records. We have used the active day fraction to estimate the group sunspot number during the MM. A clear cyclic variability is found throughout the MM with peaks at around 1655--1657, 1675, 1684 and 1705, and possibly 1666, with the active day fraction not exceeding 0.2, 0.3 or 0.4 during the core MM, for the three models. Estimated sunspot numbers are found very low in accordance with a grand minimum of solar activity.
We have found, for the core MM (1650-1700), that: (1) A large fraction of no-spot records, corresponding to the solar meridian observations, may be unreliable in the conventional database. (2) The active day fraction remained low (below 0.3-0.4) throughout the MM, indicating the low level of sunspot activity. (3) The solar cycle appears clearly during the core MM. (4) The length of the solar cycle during the core MM appears 9±1 years, but there is an uncertainty in that. (5) The magnitude of the sunspot cycle during MM is assessed to be below 5-10 in sunspot numbers;
A hypothesis of the high solar cycles during the MM is not confirmed.

Sunspot latitudes during the Maunder Minimum: a machine-readable catalogue from previous studies

J. M. **Vaquero**, J. M. Nogales, F. Sánchez-Bajo
Advances in Space Volume 55, Issue 6, Pages 1546–1552 **2015**
http://arxiv.org/ftp/arxiv/papers/1501/1501.05989.pdf
http://www.sciencedirect.com/science/article/pii/S0273117715000204

The Maunder Minimum (1645-1715 approximately) was a period of very low solar activity and a strong hemispheric asymmetry, with most of sunspots in the southern hemisphere. In this paper, two data sets of sunspot latitudes during the Maunder minimum have been recovered for the international scientific community. The first data set is constituted by latitudes of sunspots appearing in the catalogue published by Gustav Sp\"orer nearly 130 years ago. The second data set is based on the sunspot latitudes displayed in the butterfly diagram for the Maunder Minimum which was published by Ribes and Nesme-Ribes almost 20 years ago. We have calculated the asymmetry index using these data sets confirming a strong hemispherical asymmetry in this period. A machine-readable version of this catalogue with both data sets is available in the Historical Archive of Sunspot Observations (this http URL) and in the appendix of this article.

Redefining the limit dates for the Maunder Minimum

J. M. **Vaquero**, R. M. Trigo
2014
http://arxiv.org/pdf/1406.1630v1.pdf

The Maunder Minimum corresponds to a prolonged minimum of solar activity a phenomenon that is of particular interest to many branches of natural and social sciences commonly considered to extend from 1645 until 1715. However, our knowledge of past solar activity has improved significantly in recent years and, thus, more precise dates for the onset and termination of this particularly episode of our Sun can be established. Based on the simultaneous analysis of distinct proxies we propose a redefinition of the Maunder Minimum period with the core "Deep Maunder Minimum" spanning from 1645 to 1700 (that corresponds to the Grand Minimum state) and a wider "Extended Maunder Minimum" for the longer period 1618-1723 that includes the transition periods.

COMPOSITION MOSAICS FROM MARCH 2022

T. **Varesano**1,2,3, D. M. Hassler2, N. Zambrana Prado4, J. Plowman2, G. Del Zanna5, et al.
Solar Orbiter Nugget #34 Aug **2024**
https://www.cosmos.esa.int/web/solar-orbiter/-/science-nugget-composition-mosaics-from-march-2022
We found higher FIP bias values at the footpoints of the loops, indicating that fractionation occurs – even at lower heights below the corona and in the transition region – using sulfur and nitrogen diagnostics. The behavior of the element sulfur is especially interesting because it lies in the “intermediate-FIP” category, meaning that it does not always behave as a high-FIP nor as a low-FIP element. Rather, its behavior depends on the geometry of the magnetic field [9] . From our observations, sulfur behaves as a high-FIP element in closed magnetic loops, but as a low-FIP in the solar wind (open field). **2 Mar 2022**

The role of meridional flow in the generation of solar/stellar magnetic fields and cycles

Vindya **Vashishth**, Bidya Binay Karak
ApJ **974** 6 **2024**
https://arxiv.org/pdf/2407.16620
https://iopscience.iop.org/article/10.3847/1538-4357/ad7027/pdf
Meridional flow is crucial in generating the solar poloidal magnetic field by facilitating the poleward transport of the field from the decayed Bipolar Magnetic Regions (BMRs). As the meridional circulation changes with the stellar rotation rate, the properties of stellar magnetic cycles are expected to be influenced by this flow. In this study, we explore the role of meridional flow in generating magnetic fields in Sun and sun-like stars using STABLE, Surface flux Transport And Babcock-Leighton, dynamo model. We find that a moderate meridional flow increases the polar field by efficiently driving the trailing polarity flux toward the pole, while a strong flow tends to transport both polarities of BMRs poleward, potentially reducing the polar field. Our findings are in perfect agreement with what one can expect from the surface flux transport model. Similarly, the toroidal field initially increases with moderate flow speeds and then decreases after a certain value. This trend is due to the competitive effects of shearing and diffusion. Furthermore, our study highlights the impact of meridional flow on the cycle strength and duration in stellar cycles. By including the meridional flow from a mean-field hydrodynamics model in STABLE, we show that the magnetic field strength initially increases with the stellar rotation rate and then declines in rapidly rotating stars, offering an explanation of the observed variation of stellar magnetic field with rotation rate.

Hysteresis near the transition of the large-scale dynamo in the presence of the small-scale dynamo

Vindya **Vashishth**
Solar Phys. **299**, 115 **2024**
https://arxiv.org/pdf/2407.09042
https://doi.org/10.1007/s11207-024-02360-5
In Sun and solar-type stars, there is a critical dynamo number for the operation of a large-scale dynamo, below which the dynamo ceases to operate. This region is known as the subcritical region. Previous studies showed the possibility of operating the solar-like large-scale (global) dynamo in the subcritical region without a small-scale dynamo. As in the solar convection zone, both large- and small-scale dynamos are expected to operate at the same time and location, we check the robustness of the previously identified subcritical dynamo branch in a numerical model in which both large- and small-scale dynamos are excited. For this, we use the {\sc Pencil Code} and set up an $\alpha\Omega$ dynamo model with uniform shear and helically forced turbulence. We have performed a few sets of simulations at different relative helicity to explore the generation of large-scale oscillatory fields in the presence of small-scale dynamo. We find that in some parameter regimes, the dynamo shows hysteresis behavior, i.e., two dynamo solutions are possible depending on the initial parameters used. A decaying solution when the dynamo was started with a weak field and a strong oscillatory solution if the dynamo was initialized with a strong field. Thus, the existence of the sub-critical branch of the large-scale dynamo in the presence of small-scale dynamo is established. However, the regime of hysteresis is quite narrow with respect to the case without the small-scale dynamo. Our work supports the possible existence of large-scale dynamo in the sub-critical regime of slowly rotating stars.

Bistability in the sunspot cycle

Sumit **Vashishtha**, Katepalli R Sreenivasan

2024
https://arxiv.org/pdf/2406.05289
A direct dynamical test of the sunspot-cycle is carried out which indicates that a stochastically forced non-linear oscillator characterizes its dynamics. The sunspot series is then decomposed into its eigen time-delay coordinates. The analysis of these coordinates reveals that the sunspot series exhibits bistability, and suggests the possibility of modeling the solar cycle as a stochastically and periodically forced bistable oscillator, accounting for the Poloidal and Toroidal modes of the solar magnetic field. Such a representation of the sunspot series in terms of stochastic bistable dynamical system enables us to conjecture stochastic resonance as the key mechanism in amplifying the planetary influence of Jupiter on the sun, and that extreme events, due to turbulent convection noise inside the sun, dictate crucial phases of the sunspot cycle, such as the Maunder minimum.

Subcritical dynamo and hysteresis in a Babcock-Leighton type kinematic dynamo model

Vindya **Vashishth**, Bidya Binay Karak, Leonid Kitchatinov
Research in Astronomy and Astrophysics **2021**
https://arxiv.org/pdf/2107.01546.pdf
In Sun and sun-like stars, it is believed that the cycles of the large-scale magnetic field are produced due to the existence of differential rotation and helicity in the plasma flows in their convection zones (CZs). Hence, it is expected that for each star, there is a critical dynamo number for the operation of a large-scale dynamo. As a star slows down, it is expected that the large-scale dynamo ceases to operate above a critical rotation period. In our study, we explore the possibility of the operation of the dynamo in the subcritical region using the Babcock--Leighton type kinematic dynamo model. In some parameter regimes, we find that the dynamo shows hysteresis behavior, i.e., two dynamo solutions are possible depending on the initial parameters -- decaying solution if started with weak field and strong oscillatory solution (subcritical dynamo) when started with a strong field. However, under large fluctuations in the dynamo parameter, the subcritical dynamo mode is unstable in some parameter regimes. Therefore, our study supports the possible existence of subcritical dynamo in some stars which was previously shown in a mean-field dynamo model with distributed α and MHD turbulent dynamo simulations.

The solar dynamo begins near the surface

Geoffrey M **Vasil**, Daniel Lecoanet, Kyle Augustson, Keaton J Burns, Jeffrey S Oishi, Benjamin P Brown, Nicholas Brummell, Keith Julien
Nature **2024**
https://arxiv.org/pdf/2404.07740
The Sun's magnetic dynamo cycle features a distinct pattern: a propagating region of sunspot emergence appears around 30 degrees latitude and vanishes near the equator every 11 years. Moreover, longitudinal flows called ``torsional oscillations'' closely shadow sunspot migration, undoubtedly sharing a common. Contrary to theories suggesting deep origins for these phenomena, helioseismology pinpoints low-latitude torsional oscillations to the Sun's outer 5-10 percent, the ``Near-Surface Shear Layer''. Within this zone, inwardly increasing differential rotation coupled with a poloidal magnetic field strongly implicates the Magneto-Rotational Instability renowned in accretion-disk theory and observed in laboratory experiments. Together, these two facts prompt the general question: Is it possible that the solar dynamo is a near-surface instability? Here, we report strong affirmative evidence in stark contrast to traditional paradigms focusing on the deeper tachocline. Simple analytic estimates show that the near-surface magneto-rotational instability better explains the spatiotemporal scales of the torsional oscillations and inferred subsurface magnetic field amplitudes. State-of-the-art numerical simulations corroborate these estimates and, strikingly, reproduce hemispherical magnetic current helicity laws. The dynamo resulting from a well-understood near-surface phenomenon improves prospects for accurate predictions of full magnetic cycles and space weather, impacting Earth's electromagnetic infrastructure.

The rotational influence on solar convection

Geoffrey M. **Vasil**, Keith Julien, Nicholas A. Featherstone
2020
https://arxiv.org/pdf/2010.15383.pdf
This paper considers the dominant dynamical, thermal and rotational balances within the solar convection zone. The reasoning is such that: Coriolis forces balance pressure gradients. Background vortex stretching, baroclinic torques and nonlinear advection balance jointly. Turbulent fluxes convey what part of the solar luminosity that radiative diffusion cannot. These four relations determine estimates for the dominant length scales and dynamical amplitudes strictly in terms of known physical quantities. We predict that the dynamical Rossby number for convection is less than unity below the near-surface shear layer, indicating strong rotational constraint. We also predict a characteristic convection length scale of roughly 30 Mm throughout much of the convection zone. These inferences help explain recent observations that reveal weak flow amplitudes at 100-200 Mm scales.

Detecting stellar activity cycles in p-mode travel times: Proof of concept using SOHO/VIRGO solar observations

Valeriy **Vasilyev**, Laurent Gizon

A&A **2023**

https://arxiv.org/pdf/2312.01528.pdf

The eleven year solar cycle is known to affect the global modes of solar acoustic oscillations. In particular, p mode frequencies increase with solar activity. We propose a new method to detect the solar cycle from the p-mode autocorrelation function, and we validate this method using VIRGO/SPM photometric time series from solar cycles 23 and 24. The p-mode autocorrelation function shows multiple wavepackets separated by time lags of ∼123 min. Using a one-parameter fitting method (from local helioseismology), we measure the seismic travel times from each wavepacket up to skip number 40. We find that the travel-time variations due to the solar cycle depend sensitively on the skip number, with the strongest signature in odd skips from 17 to 31. Taking the noise covariance into account, the travel-time perturbations can be averaged over all skip numbers to enhance the signal-to-noise ratio. This method is robust to noise, simpler to implement than peak bagging in the frequency domain, and is promising for asteroseismology. We estimate that the activity cycle of a Sun-like star should be detectable with this new method in Kepler-like observations down to a visual magnitude of mK∼11. However, for fainter stars, activity cycles are easier to detect in the photometric variability on rotational timescales.

Tomography of the Solar Corona with the Wide-Field Imager for the Parker Solar Probe

Alberto M. **Vásquez**, Richard A. Frazin, Angelos Vourlidas, Ward B. ManchesterIV, Bart van der Holst, Russell A. Howard, Philippe Lamy

Solar Physics June **2019**, 294:81

sci-hub.se/10.1007/s11207-019-1471-1

The Wide-field Imager for the Parker Solar Probe (PSP/WISPR) comprises two telescopes that record white-light total brightness [B][B] images of the solar corona. Their fields of view cover a widely changing range of heliocentric heights over the 24 highly eccentric orbits planned for the mission. In this work, the capability of PSP/WISPR data to carry out tomographic reconstructions of the three-dimensional (3D) distribution of the coronal electron density is investigated. Based on the precise orbital information of the mission, BB-images for Orbits 1, 12, and 24 are synthesized from a 3D magnetohydrodynamic model of the corona. For each orbit, the time series of synthetic images is used to carry out a tomographic reconstruction of the coronal electron density and results are compared with the model. As the PSP perihelion decreases, the range of heights that can be tomographically reconstructed progressively shifts to lower values, and the period required to gather the data decreases. For Orbit 1 tomographic reconstruction is not possible. For Orbit 12, tomographic reconstruction is possible in the heliocentric height range ≈5--15 R⊙, over a region spanning up to ≈160∘≈160∘in Carrington longitude, with data gathered over a ≈3.4≈3.4 day-long period. For Orbit 24, tomographic reconstruction is possible in the heliocentric height range ≈3--10 R⊙, over a region spanning up to ≈170∘≈170∘ in Carrington longitude, with data gathered over a ≈2.8≈2.8 day-long period.

Long-Term Trends and Gleissberg Cycles in Aurora Borealis Records (1600 – 2015)

M. **Vázquez**, J. M. Vaquero , M. C. Gallego, T. Roca Cortés, P. L. Pallé

Solar Phys. Vol. 291, Issue 2 **2016**

The long-term spatial and temporal variation of aurora borealis events from 1600 to the present were studied using catalogues and other records of these phenomena. Geographic and geomagnetic coordinates were assigned to approximately 45 000 auroral events with more than 160 000 observations. They were analysed separately for three large-scale areas: i) Europe and North Africa, ii) North America, and iii) Asia. Variations in the cumulative numbers of auroral events with latitude (in both geographic and geomagnetic coordinates) were used to distinguish between the two main solar sources: coronal mass ejections and high-speed streams from coronal holes. We find significant long-term variations in the space-time distribution of auroras. We mainly identify these with four Gleissberg solar activity cycles whose overall characteristics we examine. The Asian observations are crucial in this context, and therefore merit further studies and verifications.

Connection between solar activity cycles and grand minima generation

A. **Vecchio**1, F. Lepreti2, M. Laurenza3, T. Alberti2 and V. Carbone

A&A 599, A58 (**2017**)

Aims. The revised dataset of sunspot and group numbers (released by WDC-SILSO) and the sunspot number reconstruction based on dendrochronologically dated radiocarbon concentrations have been analyzed to provide a deeper characterization of the solar activity main periodicities and to investigate the role of the Gleissberg and Suess cycles in the grand minima occurrence.

Methods. Empirical mode decomposition (EMD) has been used to isolate the time behavior of the different solar activity periodicities. A general consistency among the results from all the analyzed datasets verifies the reliability of the EMD approach.
Results. The analysis on the revised sunspot data indicates that the highest energy content is associated with the Schwabe cycle. In correspondence with the grand minima (Maunder and Dalton), the frequency of this cycle changes to longer timescales of ~14 yr. The Gleissberg and Suess cycles, with timescales of 60−120 yr and ~ 200−300 yr, respectively, represent the most energetic contribution to sunspot number reconstruction records and are both found to be characterized by multiple scales of oscillation. The grand minima generation and the origin of the two expected distinct types of grand minima, Maunder and longer Spörer-like, are naturally explained through the EMD approach. We found that the grand minima sequence is produced by the coupling between Gleissberg and Suess cycles, the latter being responsible for the most intense and longest Spörer-like minima (with typical duration longer than 80 yr). Finally, we identified a non-solar component, characterized by a very long scale oscillation of ~ 7000 yr, and the Hallstatt cycle (~ 2000 yr), likely due to the solar activity.
Conclusions. These results provide new observational constraints on the properties of the solar cycle periodicities, the grand minima generation, and thus the long-term behavior of the solar dynamo.

Understanding the origins of the heliosphere: integrating observations and measurements from Parker Solar Probe, Solar Orbiter, and other space- and ground-based observatories

Review

M. **Velli**1,7, L. K. Harra2,3, A. Vourlidas4, N. Schwadron5, O. Panasenco6 ….
A&A 642, A4 (**2020**)
https://www.aanda.org/articles/aa/pdf/2020/10/aa38245-20.pdf
https://doi.org/10.1051/0004-6361/202038245
Context. The launch of Parker Solar Probe (PSP) in 2018, followed by Solar Orbiter (SO) in February 2020, has opened a new window in the exploration of solar magnetic activity and the origin of the heliosphere. These missions, together with other space observatories dedicated to solar observations, such as the Solar Dynamics Observatory, Hinode, IRIS, STEREO, and SOHO, with complementary in situ observations from WIND and ACE, and ground based multi-wavelength observations including the DKIST observatory that has just seen first light, promise to revolutionize our understanding of the solar atmosphere and of solar activity, from the generation and emergence of the Sun's magnetic field to the creation of the solar wind and the acceleration of solar energetic particles.
Aims. Here we describe the scientific objectives of the PSP and SO missions, and highlight the potential for discovery arising from synergistic observations. Here we put particular emphasis on how the combined remote sensing and in situ observations of SO, that bracket the outer coronal and inner heliospheric observations by PSP, may provide a reconstruction of the solar wind and magnetic field expansion from the Sun out to beyond the orbit of Mercury in the first phases of the mission. In the later, out-of-ecliptic portions of the SO mission, the solar surface magnetic field measurements from SO and the multi-point white-light observations from both PSP and SO will shed light on the dynamic, intermittent solar wind escaping from helmet streamers, pseudo-streamers, and the confined coronal plasma, and on solar energetic particle transport.
Methods. Joint measurements during PSP–SO alignments, and magnetic connections along the same flux tube complemented by alignments with Earth, dual PSP–Earth, and SO-Earth, as well as with STEREO-A, SOHO, and BepiColumbo will allow a better understanding of the in situ evolution of solar-wind plasma flows and the full three-dimensional distribution of the solar wind from a purely observational point of view. Spectroscopic observations of the corona, and optical and radio observations, combined with direct in situ observations of the accelerating solar wind will provide a new foundation for understanding the fundamental physical processes leading to the energy transformations from solar photospheric flows and magnetic fields into the hot coronal plasma and magnetic fields and finally into the bulk kinetic energy of the solar wind and solar energetic particles.
Results. We discuss the initial PSP observations, which already provide a compelling rationale for new measurement campaigns by SO, along with ground- and space-based assets within the synergistic context described above.

Multicomponent Activity Cycles Using Hilbert–Huang Analysis

E. N. **Velloso**1, F. Anthony1, J.-D. do Nascimento Jr.1,2, L. F. Q. Silveira1, J. Hall3, and S. H. Saar2
2023 ApJL 945 L12
https://iopscience.iop.org/article/10.3847/2041-8213/acb8b4/pdf
The temporal analysis of stellar activity evolution is usually dominated by a complex trade-off between model complexity and interpretability, often by neglecting the nonstationary nature of the process. Recent studies appear to indicate that the presence of multiple coexisting cycles in a single star is more common than previously thought. The correct identification of physically meaningful cyclic components in spectroscopic time series is therefore a crucial task, which cannot overlook local behaviors. Here we propose a decomposition technique that adaptively recovers amplitude- and frequency-varying components. We present our results for the solar activity as measured both by the

sunspot number and the K-line emission index, and we consistently recover the Schwabe and Gleissberg cycles as well as the Gnevyshev–Ohl pattern probably related to the Hale cycle. We also recover the known 8 yr cycle for 61 Cygni A, in addition to evidence of a three-cycles-long pattern reminiscent of the Gnevyshev–Ohl rule. This is particularly interesting as we cannot discard the possibility of a relationship between the measured field polarity reversals and this Hale-like periodicity.

Successive injection of opposite magnetic helicity in solar active region NOAA 11928

P. **Vemareddy**1 and P. Démoulin2
A&A 597, A104 (**2017**)
http://www.aanda.org/articles/aa/pdf/2017/01/aa29282-16.pdf
https://arxiv.org/pdf/1611.00699v1.pdf
Aims. Understanding the nature and evolution of the photospheric helicity flux transfer is crucial to revealing the role of magnetic helicity in coronal dynamics of solar active regions.
Methods. We computed the boundary-driven helicity flux with a 12-min cadence during the emergence of the AR 11928 using SDO/HMI photospheric vector magnetograms and the derived flow velocity field. Accounting for the footpoint connectivity defined by nonlinear, force-free magnetic extrapolations, we derived and analyzed the corrected distribution of helicity flux maps.
Results. The photospheric helicity flux injection is found to change sign during the steady emergence of the AR. This reversal is confirmed with the evolution of the photospheric electric currents and with the coronal connectivity as observed in EUV wavelengths with SDO/AIA. During approximately the three first days of emergence, the AR coronal helicity is positive while later on the field configuration is close to a potential field. As theoretically expected, the magnetic helicity cancellation is associated with enhanced coronal activity.
Conclusions. The study suggests a boundary driven transformation of the chirality in the global AR magnetic structure. This may be the result of the emergence of a flux rope with positive twist around its apex while it has negative twist in its legs. The origin of such mixed helicity flux rope in the convective zone is challenging for models. **16-20 Dec 2013**

Recurrent solar density transients in the slow wind observed with the Metis coronagraph⋆

R. **Ventura**1, E. Antonucci2, C. Downs3, P. Romano1, R. Susino2, +++
A&A 675, A170 (**2023**)
https://www.aanda.org/articles/aa/pdf/2023/07/aa46623-23.pdf
Aims We aim to investigate and characterize the morphology and dynamics of small-scale coronal plasma density inhomogeneities detected as brighter, denser features propagating outward through the solar corona in the visible-light images of the Metis coronagraph on board Solar Orbiter on **February 22, 2021**. Our main focus is on investigating their possible origin and contribution to the slow wind variability and dynamics and their dependence on coronal magnetic field configurations and structure.
Methods. The method adopted is based on the computations of autocorrelation and cross-correlation functions applied to temporal and spatial series of total brightness as a function of the heliocentric distance and solar latitudes.
Results. We find that the plasma density inhomogeneities studied here are small-scale structures with typical radial and transverse sizes, as projected on the plane of sky, on the order of 500 Mm and 40 Mm, respectively, and that they are up to 24 times brighter than the ambient solar wind. The brighter density structures exhibit longer lifetime and more stable shape and dimensions as they travel toward the outer edge of the field of view. The enhanced density structures are ejected with a most probable cadence of about 80 min at or below the inner edge of the Metis field of view (within 3.1 R⊙–5.7 R⊙ at the time of observations) in a wide latitudinal region corresponding to the site of a complex web of separatrix and quasi-separatrix layers, as resulting from the simulated magnetohydrodynamic configuration of the west limb of the solar corona. Some of the moving density enhancements clearly show morphological characteristics compatible with the switchback phenomenon, supporting the results indicating that the switchbacks occur at the coronal level. The enhanced density structures were ejected into the ambient slow wind with a mean velocity of about 240 ± 40 km s−1, which is significantly higher than that deduced for the ambient solar wind on the basis of previous Metis observations during the solar minimum of cycle 24. The absence of acceleration observed across the coronagraph field of view suggests that the ejected plasmoids are progressively reaching the expansion rate of the ambient wind.
Conclusions. The results suggest that the quasi-periodic enhanced-density plasmoids might be the consequence of reconnection phenomena occurring in the complex web of the separatrix and quasi-separatrix layers present in the solar corona. Moreover, the structural characteristics of some of the detected plasmoids are in favor of the presence of switchbacks that originate during interchange reconnection processes occurring at or below 3 R⊙ in the S-web. The speed of the plasma ejected in the reconnection process is higher than that of the ambient slow solar wind and is likely to be related to the energy involved in the process generating the propagating structures.

Solar-wind predictions for the Parker Solar Probe orbit

M. S. **Venzmer**, V. Bothmer

A&A **2017**
https://arxiv.org/pdf/1711.07534.pdf
The scope of this study is to model the solar-wind environment for the Parker Solar Probe's unprecedented distances down to 9.86 Rs in its mission phase during 2018-2025. The study is performed within the CGAUSS project which is the German contribution to the PSP mission as part of the WISPR imager on PSP. We present an empirical solar-wind model for the inner heliosphere which is derived from OMNI and Helios data. The sunspot number (SSN) and its predictions are used to derive dependencies of solar-wind parameters on solar activity and to forecast them for the PSP mission. The frequency distributions for the solar-wind key parameters magnetic field strength, proton velocity, density, and temperature, are represented by lognormal functions, considering the velocity distribution's bi-componental shape. Functional relations to the SSN are compiled using OMNI data and based on data from both Helios probes, the parameters' frequency distributions are fitted with respect to solar distance. Thus, an empirical solar-wind model for the inner heliosphere is derived, accounting for solar activity and solar distance. The inclusion of SSN predictions and the extrapolation down to PSP's perihelion region enables us to estimate the solar-wind environment for PSP's planned trajectory during its mission duration. This empirical model yields estimated solar-wind values for PSP's 1st perihelion in 2018 at 0.16 au: 87 nT, 340 km s-1, 214 cm-3 and 503000 K. The estimates for PSP's first closest perihelion, occurring in 2024 at 0.046 au, are 943 nT, 290 km s-1, 2951 cm-3, and 1930000 K. Since the modeled velocity and temperature values below approximately 20 Rs appear overestimated in comparison with existing observations, this suggests that PSP will directly measure solar-wind acceleration and heating processes below 20 Rs as planned.

Classification of High-resolution Solar Hα Spectra using t-distributed Stochastic Neighbor Embedding

Meetu **Verma**, Gal Matijevič, Carsten Denker, Andrea Diercke, Ekaterina Dineva, Horst Balthasar, Robert Kamlah, Ioannis Kontogiannis, Christoph Kuckein, Partha S. Pal
ApJ **907** 54 **2020**
https://arxiv.org/pdf/2011.13214.pdf
https://doi.org/10.3847/1538-4357/abcd95
The H{\alpha} spectral line is a well-studied absorption line revealing properties of the highly structured and dynamic solar chromosphere. This study is based on high-spectral resolution H{\alpha} spectra obtained with the echelle spectrograph of the Vacuum Tower Telescope (VTT) located at Observatorio del Teide (ODT), Tenerife, Spain. The t-distributed Stochastic Neighbor Embedding (t-SNE) is a machine learning algorithm, which is used for nonlinear dimensionality reduction. In this application, it projects H{\alpha} spectra onto a two-dimensional map, where it becomes possible to classify the spectra according to results of Cloud Model (CM) inversions. The CM parameters optical depth, Doppler width, line-of-sight velocity, and source function describe properties of the cloud material. Initial results of t-SNE indicate its strong discriminatory power to separate quiet-Sun and plage profiles from those that are suitable for CM inversions. In addition, a detailed study of various t-SNE parameters is conducted, the impact of seeing conditions on the classification is assessed, results for various types of input data are compared, and the identified clusters are linked to chromospheric features. Although t-SNE proves to be efficient in clustering high-dimensional data, human inference is required at each step to interpret the results. This exploratory study provides a framework and ideas on how to tailor a classification scheme towards specific spectral data and science questions. **11 September 2018**

Long-term variations of the Sun's photospheric magnetic field

E.S. **Vernova**, M.I. Tyasto, D.G. Baranov
Geomagnetism and Aeronomy **63**, 966–974 **2023**
https://arxiv.org/pdf/2307.08009
https://doi.org/10.1134/S0016793223070277
Variations of the weak magnetic fields of the photosphere with periods of the order of the solar magnetic cycle were investigated. Synoptic maps of the photospheric magnetic field produced by NSO Kitt Peak for the period from 1978 to 2016 were used as initial data. In order to study weak magnetic fields, the saturation threshold for synoptic maps was set at 5 G. On the base of transformed synoptic maps the time-latitude chart was built. 18 profiles of the magnetic field evenly distributed along the sine of latitude from the north to the south pole were selected in the diagram for the further analysis. Time dependencies were averaged by sliding smoothing over 21 Carrington rotations. The approximation of averaged time dependencies by the sinusoidal function made it possible to distinguish in weak magnetic fields a cyclic component with a period of about 22 years (the period of the Hale magnetic cycle). The dependence of 22-year variation on latitude was studied. In addition to the well-known 22-year change in the near-polar field, similar variations were found for the fields at all latitudes. The exception was latitudes 26◦ and 33◦ in the northern and 26◦ in the southern hemisphere. These mid-latitude intervals were characterized by a predominance of short-period variations. The amplitude of the long-term variation decreased from the poles to the equator, with the period of variation remaining almost constant (T = 22.3 years).

Ripples and Rush-to-the-Poles in the photospheric magnetic field

Elena S. **Vernova**, Marta I. Tyasto, Dmitrii G. Baranov

Solar Phys. **298**, Article number: 69 **2023**

https://arxiv.org/pdf/2211.01140.pdf

https://doi.org/10.1007/s11207-023-02164-z

The distribution of magnetic fields of positive and negative polarities over the surface of the Sun was studied on the basis of synoptic maps NSO Kitt Peak (1978-2016). To emphasize the contribution of weak fields the following transformation of synoptic maps was made: for each synoptic map only magnetic fields with modulus less than 5 G (|B| < 5 G) were left unchanged on each synoptic map while larger or smaller fields were replaced by the corresponding limiting values +5 G or -5 G. Cyclic variations of the magnetic field polarity have been observed associated with two types of magnetic field flows in the photosphere. Rush-to-the-Poles (RTTP) form near the maximum of solar activity and have the same sign as the following sunspots. The lifetime of RTTP is 3 yrs, during which time they drift from latitudes 30 - 40 deg. to the pole, causing the polarity change of the Sun's polar field. We studied another type of variations which has the form of series of flows with individual flows of 0.5-1 yr and with alternating polarity (ripples). Ripples are located in time between two RTTP and drift from the equator to the latitudes of 50 deg. Magnetic field variations were considered in 6 time intervals along the latitudes +33 deg. in the northern and -33 deg. in the southern hemispheres. The time change of the field strength was approximated by the sinusoidal function. The period of variation of ripples was 1.1 yr for the N-hemisphere and 1.3 yr for the S-hemisphere. The amplitude of variation was higher for the time intervals where the polar field had a positive sign. Within the same flow, fields of positive and negative signs developed in anti-phase.

Nonaxisymmetric Component of Solar Activity: the Vector of the Longitudinal Asymmetry

E. S. **Vernova**, M. I. Tyasto, D. G. Baranov & O. A. Danilova

Solar Physics volume 295, Article number: 86 (**2020**)

https://link.springer.com/content/pdf/10.1007/s11207-020-01651-x.pdf

The vector representation of sunspots is used to study the nonaxisymmetric features of the solar activity distribution (sunspot data from Greenwich–USAF/NOAA, 1874–2016). Each sunspot is represented by a polar vector with modulus equal to the sunspot area and the phase equal to the sunspot heliolongitude. The vector sum of these individual vectors defines both the magnitude of the longitudinal asymmetry and the dominating longitude of the sunspot distribution. These characteristics are to a large extent free from the influence of a stochastic component and emphasize the nonaxisymmetric component of the solar activity. The longitudinal asymmetry follows the 11-year solar cycle with the amplitude three times lower than the sunspot area maximum. Longitudinal asymmetry is mostly determined by large sunspots: 82% of the longitudinal asymmetry is given by sunspots with area from 100 to 2000 MSH. Longitudinal asymmetries of the northern and southern hemispheres are connected only weakly (correlation coefficient R=0.29R=0.29). The longitudinal distribution displays a maximum at the longitude ∼180∘∼180∘ during ascent-maximum and at ∼0∘/360∘∼0∘/360∘ during descent-minimum. The active longitude changes with the reversals of polarity of the local (minimum of solar activity) and global magnetic fields (reversal of polar magnetic field).

Nonaxisymmetric Component of Solar Activity and the Gnevyshev-Ohl Rule

Elena **Vernova**, Marta Tyasto, Dmitrii Baranov, Olga Danilova

Solar Phys. **2019**

https://arxiv.org/pdf/1912.00388.pdf

The vector representation of sunspots is used to study the nonaxisymmetric features of the solar activity distribution (sunspot data from Greenwich - USAF/NOAA, 1874 - 2016).The vector of the longitudinal asymmetry is defined for each Carrington rotation; its modulus characterizes the magnitude of the asymmetry, while its phase points to the active longitude. These characteristics are to a large extent free from the influence of a stochastic component and emphasize the deviations from the axisymmetry. For the sunspot area, the modulus of the vector of the longitudinal asymmetry changes with the 11-year period; however, in contrast to the solar activity, the amplitudes of the asymmetry cycles obey a special scheme. Each pair of cycles from 12 to 23 follows in turn the Gnevyshev - Ohl rule (an even solar cycle is lower than the following odd cycle) or the anti-Gnevyshev - Ohl rule (an odd solar cycle is lower than the preceding even cycle). This effect is observed in the longitudinal asymmetry of the whole disk and the southern hemisphere. Possibly, this effect is a manifestation of the 44-year structure in the activity of the Sun. Northern hemisphere follows the Gnevyshev - Ohl rule in Solar Cycles 12 - 17, while in Cycles 18 - 23 the anti-rule is observed.

Non-axisymmetric component of the photospheric magnetic field

E. S. **Vernova**, **M. I. Tyasto**, **D. G. Baranov**, **O. A. Danilova**

Solar Phys. **2019**

https://arxiv.org/pdf/1904.03034.pdf

The longitudinal asymmetry of the photospheric magnetic field distribution is studied on the basis of the data of the Kitt Peak National Solar Observatory (synoptic maps for the period 1976 - 2016). The method of vector summing of magnetic fields is used, which allows to decrease the influence of the stochastic components uniformly distributed over the whole longitude interval, and to stress a steady non-axisymmetric component of the field. The distributions of magnetic fields of different intensity are considered separately for the strong (B > 50 G), weak (B < 5 G) and medium (50 > B > 5 G) fields. It is shown that the longitudinal asymmetry for all groups of fields changes in phase with the 11-year cycle of solar activity. The asymmetry of strong and medium fields changes in phase with magnetic fluxes of these fields, while the asymmetry of weak fields is in antiphase with the flux of weak fields. The distributions of strong and medium magnetic fields over the longitude are similar in the shape: The maximum of distribution is located at the longitude ~180° during the period of ascent - maximum of solar cycle and at the longitude ~360° during the period of descent - minimum. The weak fields exhibit the opposite picture: the maximum of their distribution is always observed at the longitude, where the strong and medium fields show minimum.

Positive and Negative Photospheric Fields in Solar Cycles 21 - 24

E.S. **Vernova**, M.I. Tyasto, D.G. Baranov, O.A. Danilova
Geomagnetism and Aeronomy **2018**
https://arxiv.org/pdf/1812.03552.pdf
Distribution of the positive and negative photospheric fields is studied on the base of synoptic maps of the photospheric magnetic field produced by the National Solar Observatory Kitt Peak (NSO Kitt Peak) for 1976-2016. In the analysis only the sign of the field irrespective of its strength is taken into account, emphasizing the role of the fields with average and weak strengths.
Time changes in the positive and negative magnetic fields for two hemispheres, for the high latitudes and for the sunspot zone as well as their imbalances are considered. Distributions of fields of opposite polarities, which are defined mostly by the fields of the high latitudes, change with a 22-year cycle. The polarity imbalance in each hemisphere is closely connected with the dipole moment g10.
The imbalance of high latitudes for two hemispheres changes with the 22-year period and coincides with the sign of both the polar field in the southern hemisphere, and the quadrupole moment g20. For the magnetic fields of the sunspot zone during ~75% of time a connection of the magnetic field imbalance with the quadrupole moment taken with the reversed sign −g20 and with the sign of the polar field in the northern hemisphere is observed. The received results testify to cyclic changes in the polarity imbalance.

Polarity imbalance of the photospheric magnetic field

E. S. **Vernova** (1), M. I. Tyasto (1), D. G. Baranov (2), O. A. Danilova (1)
Solar Phys. 293:158 **2018**
https://arxiv.org/pdf/1801.09249.pdf
https://link.springer.com/content/pdf/10.1007%2Fs11207-018-1382-6.pdf
Polarity imbalance of the photospheric magnetic field was studied using synoptic maps of NSO Kitt Peak (1976-2016). Imbalance of positive and negative fluxes was considered for the fields with strength B>50 G in the sunspot zone (5 deg - 40 deg) and for the fields with strength B<50 G at higher latitudes (40 deg - 90 deg). The 22-year periodicity in the imbalance of positive and negative fields was found which maintained itself during four solar cycles. While for the sunspot zone the sign of the imbalance always coincides with the northern hemisphere polarity, for the high latitudes the sign of the imbalance always coincides with the southern hemisphere polarity. Good correspondence of the flux imbalance with the quadrupole moment (g20) of the potential-field source-surface (PFSS) model was observed. The polarity imbalance of the sunspot zone correlates, on one hand, with the asymmetry of the magnetic field of the Sun-as-a-star and, on the other hand, with the sector structure of the interplanetary magnetic field. The obtained results show the close connection of the magnetic fields in active regions with the Sun's polar magnetic field. The weakest fields B<5 G represent quite a special group with the magnetic flux developing in antiphase to the fluxes of the stronger fields.

Photospheric Magnetic Field: Relationship Between North–South Asymmetry and Flux Imbalance

E. S. **Vernova**, M. I. Tyasto, D. G. Baranov
Solar Phys., **2014**
Photospheric magnetic fields were studied using the Kitt Peak synoptic maps for 1976 – 2003. Only strong magnetic fields (B>100 G) of the equatorial region were taken into account. The north–south asymmetry of the magnetic fluxes was considered as well as the imbalance between positive and negative fluxes. The north–south asymmetry displays a regular alternation of the dominant hemisphere during the solar cycle: the northern hemisphere dominated in the ascending phase, the southern one in the descending phase during Solar Cycles 21 – 23. The sign of the imbalance did not change during the 11 years from one polar-field reversal to the next and always coincided with the sign of the Sun’s polar magnetic field in the northern hemisphere. The dominant sign of leading sunspots in one

of the hemispheres determines the sign of the magnetic-flux imbalance. The sign of the north–south asymmetry of the magnetic fluxes and the sign of the imbalance of the positive and the negative fluxes are related to the quarter of the 22-year magnetic cycle where the magnetic configuration of the Sun remains constant (from the minimum where the sunspot sign changes according to Hale's law to the magnetic-field reversal and from the reversal to the minimum). The sign of the north–south asymmetry for the time interval considered was determined by the phase of the 11-year cycle (before or after the reversal); the sign of the imbalance of the positive and the negative fluxes depends on both the phase of the 11-year cycle and on the parity of the solar cycle. The results obtained demonstrate the connection of the magnetic fields in active regions with the Sun's polar magnetic field in the northern hemisphere.

Hemispheric sunspot numbers 1874--2020

Astrid M. **Veronig**, Shantanu Jain, Tatiana Podladchikova, Werner Poetzi, Frederic Clette
A&A 652, A56 **2021**
https://arxiv.org/pdf/2107.00553.pdf
https://www.aanda.org/articles/aa/pdf/2021/08/aa41195-21.pdf
https://doi.org/10.1051/0004-6361/202141195
We create a continuous series of daily and monthly hemispheric sunspot numbers (HSNs) from 1874 to 2020, which will be continuously expanded in the future with the HSNs provided by SILSO. Based on the available daily measurements of hemispheric sunspot areas from 1874 to 2016 from Greenwich Royal Observatory and NOAA, we derive the relative fractions of the northern and southern activity. These fractions are applied to the international sunspot number (ISN) to derive the HSNs. This method and obtained data are validated against published HSNs for the period 1945--2020. We provide a continuous data series and catalogue of daily, monthly mean, and 13-month smoothed monthly mean HSNs for the time range 1874--2020 that are consistent with the newly calibrated ISN. Validation of the reconstructed HSNs against the direct data available since 1945 reveals a high level of consistency, with a correlation of r=0.94 (0.97) for the daily (monthly) data. The cumulative hemispheric asymmetries for cycles 12-24 give a mean value of 16%, with no obvious pattern in north-south predominance over the cycle evolution. The strongest asymmetry occurs for cycle no. 19, in which the northern hemisphere shows a cumulated predominance of 42%. The phase shift between the peaks of solar activity in the two hemispheres may be up to 28 months, with a mean absolute value of 16.4 months. The phase shifts reveal an overall asymmetry of the northern hemisphere reaching its cycle maximum earlier (in 10 out of 13 cases). Relating the ISN and HSN peak growth rates during the cycle rise phase with the cycle amplitude reveals higher correlations when considering the two hemispheres individually, with r = 0.9. Our findings demonstrate that empirical solar cycle prediction methods can be improved by investigating the solar cycle dynamics in terms of the hemispheric sunspot numbers.

MHD wave modes resolved in fine-scale chromospheric magnetic structures **Review**

G. **Verth**, D. B. Jess
AGU/Wiley book "Low-frequency Waves in Space Plasmas", Reviews of Geophysics **2015**
http://arxiv.org/pdf/1505.01155v1.pdf
Within the last decade, due to significant improvements in the spatial and temporal resolution of chromospheric data, magnetohydrodynamic (MHD) wave studies in this fascinating region of the Sun's atmosphere have risen to the forefront of solar physics research. In this review we begin by reviewing the challenges and debates that have manifested in relation to MHD wave mode identification in fine-scale chromospheric magnetic structures, including spicules, fibrils and mottles. Next we go on to discuss how the process of accurately identifying MHD wave modes also has a crucial role to play in estimating their wave energy flux. This is of cardinal importance for estimating what the possible contribution of MHD waves is to solar atmospheric heating. Finally, we detail how such advances in chromospheric MHD wave studies have also allowed us, for the first time, to implement cutting-edge magnetoseismological techniques that provide new insight into the sub-resolution plasma structuring of the lower solar atmosphere.

Excitation and evolution of vertically polarised transverse loop oscillations by coronal rain

E. **Verwichte** and P. Kohutova
A&A 601, L2 (**2017**)
Context. Coronal rain is composed of cool dense blobs that form in solar coronal loops and are a manifestation of catastrophic cooling linked to thermal instability. The nature and excitation of oscillations associated with coronal rain is not well understood.
Aims. We consider observations of coronal rain in a bid to elucidate the excitation mechanism and evolution of wave characteristics.
Methods. We analyse IRIS and Hinode/SOT observations of an oscillating coronal rain event on the 17th Aug. 2014 and determine the wave characteristics as a function of time using tried and tested time-space analysis techniques.

Results. We exploit the seismological capability of the oscillation to deduce the relative rain mass from the oscillation amplitude. This is consistent with the evolution of the oscillation period showing the loop losing a third of its mass due to falling coronal rain in a 10−15 min time period.
Conclusions. We present the first evidence of the excitation of vertically polarised transverse loop oscillations triggered by catastrophic cooling at the loop top and consistent with two thirds of the loop mass being comprised of cool rain mass.

Kinematics of coronal rain in a transversely oscillating loop: Ponderomotive force and rain-excited oscillations

E. **Verwichte**1, P. Antolin2, G. Rowlands1, P. Kohutova1 and T. Neukirch
A&A 598, A57 (**2017**)
http://www.aanda.org/articles/aa/pdf/2017/02/aa29634-16.pdf
Context. Coronal rain is composed of cool dense blobs that form in solar coronal loops and are a manifestation of catastrophic cooling linked to thermal instability. Once formed, rain falls towards the solar surface at sub-ballistic speeds, which is not well understood. Pressure forces seem to be the prime candidate to explain this. In many observations rain is accompanied by transverse oscillations and the interaction between rain and these oscillations needs to be explored.
Aims. Therefore, an alternative kinematic model for coronal rain kinematics in transversely oscillating loops is developed to understand the physical nature of the observed sub-ballistic falling motion of rain. This model explicitly explores the role of the ponderomotive force arising from the transverse oscillation on the rain motion and the capacity of rain to excite wave motion.
Methods. An analytical model is presented that describes a rain blob guided by the coronal magnetic field supporting a one-dimensional shear Alfvén wave as a point mass on an oscillating string. The model includes gravity and the ponderomotive force from the oscillation acting on the mass and the inertia of the mass acting on the oscillation.
Results. The kinematics of rain in the limit of negligible rain mass are explored and falling and trapped regimes are found, depending on wave amplitude. In the trapped regime for the fundamental mode, the rain blob bounces back and forth around the loop top at a long period that is inversely proportional to the oscillation amplitude. The model is compared with several observational rain studies, including one in-depth comparison with an observation that shows rain with up-and-down bobbing motion. The role of rain inertia in exciting transverse oscillations is explored in inclined loops.
Conclusions. It is found that the model requires displacement amplitudes of the transverse oscillation that are typically an order of magnitude larger than observed to explain the measured sub-ballistic motion of the rain. Therefore, it is concluded that the ponderomotive force is not the primary reason for understanding sub-ballistic motion, but it plays a role in cases of large loop oscillations. The appearance of rain causes the excitation of small-amplitude transverse oscillations that may explain observed events and provide a seismological tool to measure rain mass.

Multiheight Observations of Atmospheric Gravity Waves at Solar Disk Center

Oana **Vesa**1, Jason Jackiewicz1, and Kevin Reardon2
2023 ApJ 952 58
https://iopscience.iop.org/article/10.3847/1538-4357/acd930/pdf
Atmospheric gravity waves (AGWs) are low-frequency, buoyancy-driven waves that are generated by turbulent convection and propagate obliquely throughout the solar atmosphere. Their proposed energy contribution to the lower solar atmosphere and sensitivity to atmospheric parameters (e.g., magnetic fields and radiative damping) highlight their diagnostic potential. We investigate AGWs near a quiet-Sun disk center region using multiwavelength data from the Interferometric Bidimensional Spectrometer and the Solar Dynamics Observatory. These observations showcase the complex wave behavior present in the entire acoustic-gravity wave spectrum. Using Fourier spectral analysis and local helioseismology techniques on simultaneously observed line core Doppler velocity and intensity fluctuations, we study both the vertical and horizontal properties of AGWs. Propagating AGWs with perpendicular group and phase velocities are detected at the expected temporal and spatial scales throughout the lower solar atmosphere. We also find previously unobserved, varied phase difference distributions among our velocity and intensity diagnostic combinations. Time–distance analysis indicates that AGWs travel with an average group speed of 4.5 km s−1, which is only partially described by a simple simulation, suggesting that high-frequency AGWs dominate the signal. Analysis of the median magnetic field (4.2 G) suggests that propagating AGWs are not significantly affected by quiet-Sun photospheric magnetic fields. Our results illustrate the importance of multiheight observations and the necessity of future work to properly characterize this observed behavior. **2019 April 25**

The luminosity constraint in the era of precision solar physics

Diego **Vescovi**, Carlo Mascaretti, Francesco Vissani, Luciano Piersanti, Oscar Straniero
JPhG **2020**
https://arxiv.org/pdf/2009.05676.pdf
The luminosity constraint is a very precise relationship linking the power released by the Sun as photons and the solar neutrino fluxes. Such a relation, which is a direct consequence of the physical processes controlling the production and the transport of energy in the solar interior, is of great importance for the studies of solar neutrinos and has a special role for the search of neutrinos from the CNO cycle, whose first detection with a 5σ significance has been recently announced by the Borexino collaboration. Here we revise the luminosity constraint, discussing and validating its underlying hypotheses, in the light of latest solar neutrino and luminosity measurements. We generalize the current formulation of the luminosity constraint relation so that it can be easily used in future analysis of solar neutrino data, and we provide a specific application showing the link between CNO and pp neutrino fluxes.

Solar and Heliospheric Phenomena in October–November 2003: Causes and Effects

I. S. **Veselovsky**, M. I. Panasyuk, S. I. Avdyushin, et al.
*Cosmic Research, Vol. 42, No. 5, **2004**, pp. 435–488. Translated from Kosmicheskie Issledovaniya, Vol. 42, No. 5, 2004, pp. 453–508.*
We present new observational data on the phenomena of extremely high activity on the Sun and in the heliosphere that took place in October–November 2003. A large variety of solar and heliospheric parameters give evidence that the interval under consideration is unique over the entire observation time. Based on these data, comparing them with similar situations in the past and using available theoretical concepts, we discuss possible cause-and-effect connections between the processes observed. The paper includes the first results and conclusions derived by the collaboration “Solar Extreme Events-2003” organized in Russia for detailed investigations of these events. As a result of our consideration, it is beyond question that the physical causes of solar and heliospheric phenomena in October–November 2003 are not exclusively local and do not belong only to the active regions and solar atmosphere above them. The energy reservoirs and driving forces of these processes have a more global nature. In general, they are hidden from an observer, since ultimately their sources lie in the subphotospheric layers of the Sun, where changes that are fast and difficult to predict can sometimes take place (and indeed they do). Solar flares can serve as sufficiently good tracers of these sudden changes and reconstructions on the Sun, although one can still find other diagnostic indicators among the parameters of magnetic fields, motions of matter, and emission characteristics.

The effects of a revised 7Be e−-capture rate on solar neutrino fluxes

D. **Vescovi**, L. Piersanti, S. Cristallo, M. Busso, F. Vissani, S. Palmerini, S. Simonucci, S. Taioli
A&A **2019**
https://arxiv.org/pdf/1902.01826.pdf
The electron-capture rate on 7Be is the main production channel for 7Li in several astrophysical environments. Theoretical evaluations have to account for not only the nuclear interaction, but also the processes in the plasma where 7Be ions and electrons interact. In the past decades several estimates were presented, pointing out that the theoretical uncertainty in the rate is in general of few percents. In the framework of fundamental solar physics, we consider here a recent evaluation for the 7Be+e− rate, not used up to now in the estimate of neutrino fluxes. We analysed the effects of the new assumptions on Standard Solar Models (SSMs) and compared the results obtained by adopting the revised 7Be+e− rate to those obtained by the one reported in a widely used compilation of reaction rates (ADE11). We found that new SSMs yield a maximum difference in the efficiency of the 7Be channel of about -4\% with respect to what is obtained with the previously adopted rate. This fact affects the production of neutrinos from 8B, increasing the relative flux up to a maximum of 2.7\%. Negligible variations are found for the physical and chemical properties of the computed solar models. The agreement with the SNO measurements of the neutral current component of the 8B neutrino flux is improved.

Neutral Hydrogen and its Emission Lines in the Solar Corona

Jean-Claude **Vial**, Martine Chane-Yook
Solar Physics **2016**
http://arxiv.org/pdf/1609.05092v1.pdf
Since the Lalpha rocket observations of (Gabriel, Solar Phys. 21, 392, 1971), it has been realized that the hydrogen (H) lines could be observed in the corona and offer an interesting diagnostic for the temperature, density, and radial velocity of the coronal plasma. Moreover, various space missions have been proposed to measure the coronal magnetic and velocity fields through polarimetry in H lines. A necessary condition for such measurements is to benefit from a sufficient signal-to-noise ratio. The aim of this article is to evaluate the emission in three representative lines of H for three different coronal structures. The computations have been performed with a full non-local thermodynamic equilibrium (non-LTE) code and its simplified version without radiative transfer. Since all collisionnal and radiative quantities (including incident ionizing and exciting radiation) are taken into account, the

ionization is treated exactly. Profiles are presented at two heights (1.05 and 1.9 solar radii, from Sun center) in the corona, and the integrated intensities are computed at heights up to five solar radii.We compare our results with previous computations and observations (e.g. Lalpha from UVCS) and find a rough (model-dependent) agreement. Since the Halpha line is a possible candidate for ground-based polarimetry, we show that in order to detect its emission in various coronal structures, it is necessary to use a very narrow (less than 2 A wide) bandpass filter.

Signatures of Steady Heating in Time Lag Analysis of Coronal Emission

Nicholeen M. **Viall**, James A. Klimchuk

ApJ 828 76 **2016**

http://arxiv.org/pdf/1607.02008v1.pdf

Among the many ways of investigating coronal heating, the time lag method of Viall & Klimchuk (2012) is becoming increasingly prevalent as an analysis technique complementary to those traditionally used. The time lag method cross correlates light curves at a given spatial location obtained in spectral bands that sample different temperature plasmas. It has been used most extensively with data from the Atmospheric Imaging Assembly on the Solar Dynamics Observatory. We have previously applied the time lag method to entire active regions and surrounding quiet Sun and create maps of the results (Viall & Klimchuk 2012; Viall & Klimchuk 2015). We find that the majority of time lags are consistent with the cooling of coronal plasma that has been impulsively heated. Additionally, a significant fraction of the map area has a time lag of zero. This does not indicate a lack of variability. Rather, strong variability must be present, and it must occur in phase in the different channels. We have shown previously that these zero time lags are consistent with the transition region response to coronal nanoflares (Viall & Klimchuk 2015; Bradshaw & Viall 2016), but other explanations are possible. A common misconception is that the zero time lag indicates steady emission resulting from steady heating. Using simulated and observed light curves, we demonstrate here that highly correlated light curves at zero time lag are not compatible with equilibrium solutions. Such light curves can only be created by evolution.

Periodic Density Structures and the Origin of the Slow Solar Wind

Nicholeen M. **Viall**1 and Angelos Vourlidas

2015 ApJ 807 176

The source of the slow solar wind has challenged scientists for years. Periodic density structures (PDSs), observed regularly in the solar wind at 1 AU, can be used to address this challenge. These structures have length scales of hundreds to several thousands of megameters and frequencies of tens to hundreds of minutes. Two lines of evidence indicate that PDSs are formed in the solar corona as part of the slow solar wind release and/or acceleration processes. The first is corresponding changes in compositional data in situ, and the second is PDSs observed in the inner Heliospheric Imaging data on board the Solar Terrestrial Relations Observatory (STEREO)/Sun Earth Connection Coronal and Heliospheric Investigation (SECCHI) suite. The periodic nature of these density structures is both a useful identifier as well as an important physical constraint on their origin. In this paper, we present the results of tracking periodic structures identified in the inner Heliospheric Imager in SECCHI back in time through the corresponding outer coronagraph (COR2) images. We demonstrate that the PDSs are formed around or below 2.5 solar radii—the inner edge of the COR2 field of view. We compute the occurrence rates of PDSs in 10 days of COR2 images both as a function of their periodicity and location in the solar corona, and we find that this set of PDSs occurs preferentially with a periodicity of ~90 minutes and occurs near streamers. Lastly, we show that their acceleration and expansion through COR2 is self-similar, thus their frequency is constant at distances beyond 2.5 solar radii.

SMESE (SMall Explorer for Solar Eruptions): A microsatellite mission with combined solar payload

J.-C. **Vial**, F. Auchère[a], J. Chang[b], C. Fang[c], W.Q. Gan[b], K.-L. Klein[d], J.-Y. Prado[e], F. Rouesnel[a], A. Sémery[d], G. Trottet[d] and C. Wang[f]

Advances in Space Research Volume 41, Issue 1, **2008**, Pages 183-189

The SMESE (SMall Explorer for Solar Eruptions) mission is a microsatellite proposed by France and China. The payload of SMESE consists of three packages: LYOT (a Lyman α imager and a Lyman α coronagraph), DESIR (an Infra-red Telescope working at 35–80 and 100–250 μm), and HEBS (a High Energy Burst Spectrometer working in X- and gamma-rays).

The scientific objectives of the mission are shortly presented. We describe the three instrumental packages and the profile of the mission which accommodates them. With a launch around 2012–2013, the SMESE microsatellite mission will provide a unique tool for detecting and understanding eruptions (flares and coronal mass ejections). Observations should start around solar maximum, and continue in the declining phase of activity, at a time when the Solar Dynamics Observatory (SDO) should still be operating.

Analysis of Pseudo-Lyapunov Exponents of Solar Convection Using State-of-the-Art Observations

Giorgio **Viavattene**, Mariarita Murabito, Salvatore L. Guglielmino, Ilaria Ermolli, Giuseppe Consolini, Fabrizio Giorgi, Shahin Jafarzadeh

Entropy **2021**

DOI: 10.3390/e23040413

https://arxiv.org/pdf/2103.16980.pdf

The solar photosphere and the outer layer of the Sun's interior are characterized by convective motions, which display a chaotic and turbulent character. In this work, we evaluated the pseudo-Lyapunov exponents of the overshooting convective motions observed on the Sun's surface by using a method employed in the literature to estimate those exponents, as well as another technique deduced from their definition. We analyzed observations taken with state-of-the-art instruments at ground- and space-based telescopes, and we particularly benefited from the spectro-polarimetric data acquired with the Interferometric Bidimensional Spectrometer, the Crisp Imaging SpectroPolarimeter, and the Helioseismic and Magnetic Imager. Following previous studies in the literature, we computed maps of four quantities which were representative of the physical properties of solar plasma in each observation, and estimated the pseudo-Lyapunov exponents from the residuals between the values of the quantities computed at any point in the map and the mean of values over the whole map. In contrast to previous results reported in the literature, we found that the computed exponents hold negative values, which are typical of a dissipative regime, for all the quantities derived from our observations. The values of the estimated exponents increase with the spatial resolution of the data and are almost unaffected by small concentrations of magnetic field. Finally, we showed that similar results were also achieved by estimating the exponents from residuals between the values at each point in maps derived from observations taken at different times. The latter estimation technique better accounts for the definition of these exponents than the method employed in previous studies.

Propagation of Leaky MHD Waves at Discontinuities with Tilted Magnetic Field

E.**Vickers**, I. Ballai, R. Erdélyi

Solar Phys. 293:139 **2018**

https://arxiv.org/pdf/1809.03907.pdf

We investigate the characteristics of magneto-acoustic surface waves propagating at a single density interface, in the presence of an inclined magnetic field. For linear wave propagation, dispersion relation is obtained and analytical solutions are derived for small inclination angle. The inclination of the field renders the frequency of waves to be complex, where the imaginary part describes wave attenuation, due to lateral energy leakage.

The magnetic field vector of the Sun-as-a-star.
II. Evolution of the large-scale vector field through activity cycle 24

A. A. **Vidotto** (Trinity College Dublin), L. Lehmann (St Andrews), M. Jardine (St Andrews), A. Pevtsov(NSO)

MNRAS **2018**

https://arxiv.org/pdf/1807.06334.pdf

In the present work, we investigate how the large-scale magnetic field of the Sun, in its three vector components, has evolved during most of cycle 24, from 2010 Jan to 2018 Apr. To filter out the small-scale field of the Sun, present in high-resolution synoptic maps, we use a spherical harmonic decomposition method, which decomposes the solar field in multipoles with different l degrees. By summing together the low-l multipoles, we reconstruct the large-scale field at a resolution similar to observed stellar magnetic fields, which allows the direct comparison between solar and stellar magnetic maps. During cycle 24, the `Sun-as-a-star' magnetic field shows a polarity reversal in the radial and meridional components, but not in the azimuthal component. The large-scale solar field remains mainly poloidal with > 70% of its energy contained in the poloidal component. During its evolution, the large-scale field is more axisymmetric and more poloidal when near minima in sunspot numbers, and with a larger intensity near maximum. There is a correlation between toroidal energy and sunspot number, which indicates that spot fields are major contributors to the toroidal large-scale energy of the Sun. The solar large-scale magnetic properties fit smoothly with observational trends of stellar magnetism reported in See et al. The toroidal (Etor) and poloidal (Epol) energies are related as Etor ~Epol^{1.38 \pm 0.04}. Similar to the stellar sample, the large-scale field of the Sun shows a lack of toroidal non-axisymmetric field.

On the influence of magnetic topology on the propagation of internal gravity waves in the solar atmosphere

G. **Vigeesh**, M. Roth, O. Steiner, B. Fleck

Phil. Trans. R. Soc. A, **2020**

https://arxiv.org/pdf/2010.06926.pdf
The solar surface is a continuous source of internal gravity waves (IGWs). IGWs are believed to supply the bulk of the wave energy for the lower solar atmosphere, but their existence and role for the energy balance of the upper layers is still unclear, largely due to the lack of knowledge about the influence of the Sun's magnetic fields on their propagation. In this work, we look at naturally excited IGWs in realistic models of the solar atmosphere and study the effect of different magnetic field topographies on their propagation. We carry out radiation-magnetohydrodynamic (R-MHD) simulations of a magnetic field free and two magnetic models -- one with an initial, homogeneous, vertical field of 100 G magnetic flux density and one with an initial horizontal field of 100 G flux density. The propagation properties of IGWs are studied by examining the phase-difference and coherence spectra in the kh-ω diagnostic diagram. We find that IGWs in the upper solar atmosphere show upward propagation in the model with predominantly horizontal field similar to the model without magnetic field. In contrast to that the model with predominantly vertical fields show downward propagation. This crucial difference in the propagation direction is also revealed in the difference in energy transported by waves for heights below 0.8 Mm. Higher up, the propagation properties show a peculiar behaviour, which require further study. Our analysis suggests that IGWs may play a significant role in the heating of the chromospheric layers of the internetwork region where horizontal fields are thought to be prevalent.

Synthetic observations of internal gravity waves in the solar atmosphere

https://doi.org/10.1051/0004-6361/201936846
We study the properties of internal gravity waves (IGWs) detected in synthetic observations that are obtained from realistic numerical simulation of the solar atmosphere. We used four different simulations of the solar magneto-convection performed using the CO5BOLD code. A magnetic-field-free model and three magnetic models were simulated. The latter three models start with an initial vertical, homogeneous field of 10, 50, and 100 G magnetic flux density, representing different regions of the quiet solar surface. We used the NICOLE code to compute synthetic spectral maps from all the simulated models for the two magnetically insensitive neutral iron lines Fe I 5434 Å and 5576 Å. We find the signatures of the internal gravity waves in the synthetic spectra to be consistent with observations of the real Sun. The phase differences obtained using the spectral lines are significantly different from the phase differences in the simulation. The phase coherency between two atmospheric layers in the gravity wave regime is height dependent and is seen to decrease with the travel distance between the observed layers. We conclude that the energy flux of IGWs determined from the phase difference analysis may be overestimated by an order of magnitude. Spectral lines that are weak and less temperature sensitive may be better suited to detecting internal waves and accurately determining their energy flux in the solar atmosphere.

Internal Gravity Waves in the Magnetized Solar Atmosphere. II. Energy Transport

G. **Vigeesh**, M. Roth, O. Steiner, J. Jackiewicz
ApJ **2019**
https://arxiv.org/pdf/1901.08871.pdf
In this second paper of the series on internal gravity waves (IGWs), we present a study of the generation and propagation of IGWs in a model solar atmosphere with diverse magnetic conditions. A magnetic field free, and three magnetic models that start with an initial, vertical, homogeneous field of 10 G, 50 G, and 100 G magnetic flux density, are simulated using the CO5BOLD code. We find that the IGWs are generated in similar manner in all four models in spite of the differences in the magnetic environment. The mechanical energy carried by IGWs is significantly larger than that of the acoustic waves in the lower part of the atmosphere, making them an important component of the total wave energy budget. The mechanical energy flux (106 - 103 W m−2) is few orders of magnitude larger than the Poynting flux (103 - 101 W m−2). The Poynting fluxes show a downward component in the frequency range corresponding to the IGWs, which confirm that these waves do not propagate upwards in the atmosphere when the fields are predominantly vertical and strong. We conclude that, in the upper photosphere, the propagation properties of IGWs depend on the average magnetic field strength and therefore these waves can be potential candidate for magnetic field diagnostics of these layers. However, their subsequent coupling to Alfvénic waves are unlikely in a magnetic environment permeated with predominantly vertical fields and therefore they may not directly or indirectly contribute to the heating of layers above plasma-β less than 1.

Internal Gravity Waves in the Magnetized Solar Atmosphere. I. Magnetic Field Effects

G. **Vigeesh**1,2, J. Jackiewicz2, and O. Steiner
2017 ApJ 835 148
Observations of the solar atmosphere show that internal gravity waves are generated by overshooting convection, but are suppressed at locations of magnetic flux, which is thought to be the result of mode conversion into magnetoacoustic waves. Here, we present a study of the acoustic-gravity wave spectrum emerging from a realistic,

self-consistent simulation of solar (magneto)convection. A magnetic field free, hydrodynamic simulation and a magnetohydrodynamic (MHD) simulation with an initial, vertical, homogeneous field of 50 G flux density were carried out and compared with each other to highlight the effect of magnetic fields on the internal gravity wave propagation in the Sun's atmosphere. We find that the internal gravity waves are absent or partially reflected back into the lower layers in the presence of magnetic fields and argue that the suppression is due to the coupling of internal gravity waves to slow magnetoacoustic waves still within the high-β region of the upper photosphere. The conversion to Alfvén waves is highly unlikely in our model because there is no strongly inclined magnetic field present. We argue that the suppression of internal waves observed within magnetic flux concentrations may also be due to nonlinear breaking of internal waves due to vortex flows that are ubiquitously present in the upper photosphere and the chromosphere.

Internal Gravity Waves in the Magnetized Solar Atmosphere. I. Magnetic Field Effects

ApJ **2016**
https://arxiv.org/pdf/1612.04729v1.pdf
Observations of the solar atmosphere show that internal gravity waves are generated by overshooting convection, but are suppressed at locations of magnetic flux, which is thought to be the result of mode conversion into magneto-acoustic waves. Here, we present a study of the acoustic-gravity wave spectrum emerging from a realistic, self-consistent simulation of solar (magneto-)convection. A magnetic field free, hydrodynamic simulation and a magneto-hydrodynamic (MHD) simulation with an initial, vertical, homogeneous field of 50 G flux density were carried out and compared with each other to highlight the effect of magnetic fields on the internal gravity wave propagation in the Sun's atmosphere. We find that the internal gravity waves are absent or partially reflected back into the lower layers in the presence of magnetic fields and argue that the suppression is due to the coupling of internal gravity waves to slow magneto acoustic waves still within the high-beta region of the upper photosphere. The conversion to Alfven waves is highly unlikely in our model because there is no strongly inclined magnetic field present. We argue that the suppression of internal waves observed within magnetic flux-concentrations may also be due to non-linear breaking of internal waves due to vortex flows that are ubiquitously present in the upper photosphere and the chromosphere.

The relevance of nuclear reactions for Standard Solar Models construction **Review**

Francesco L. **Villante**, Aldo Serenelli
Front. Astron. Space Sci. **2021**
https://arxiv.org/pdf/2101.03077.pdf
The fundamental processes by which nuclear energy is generated in the Sun have been known for many years. However, continuous progress in areas such as neutrino experiments, stellar spectroscopy and helioseismic data and techniques requires ever more accurate and precise determination of nuclear reaction cross sections, a fundamental physical input for solar models. In this work, we review the current status of (standard) solar models and present a detailed discussion on the relevance of nuclear reactions for detailed predictions of solar properties. In addition, we also provide an analytical model that helps understanding the relation between nuclear cross sections, neutrino fluxes and the possibility they offer for determining physical characteristics of the solar interior. The latter is of particular relevance in the context of the conundrum posed by the solar composition, the solar abundance problem, and in the light of the first ever direct detection of solar CN neutrinos recently obtained by the Borexino collaboration. Finally, we present a short list of wishes about the precision with which nuclear reaction rates should be determined to allow for further progress in our understanding of the Sun.

An updated discussion of the solar abundance problem **Review**

F.L. **Villante**, A. Serenelli
Proceedings of 5th International Solar Neutrino Conference **2020**
https://arxiv.org/pdf/2004.06365.pdf
We discuss the level of agreement of a new generation of standard solar models (SSMs), Barcelona 2016 or B16 for short, with helioseismic and solar neutrino data, confirming that models implementing the AGSS09met surface abundances, based on refined three-dimensional hydrodynamical simulations of the solar atmosphere, do not not reproduce helioseismic constraints. We clarify that this solar abundance problem can be equally solved by a change of the composition and/or of the opacity of the solar plasma, since effects produced by variations of metal abundances are equivalent to those produced by suitable modifications of the solar opacity profile. We discuss the importance of neutrinos produced in the CNO cycle for removing the composition-opacity degeneracy and the perspectives for their future detection.

The Chemical Composition of the Sun from Helioseismic and Solar Neutrino Data

Francesco L. **Villante**1,2, Aldo M. Serenelli3, Franck Delahaye4, and Marc H. Pinsonneault
2014 ApJ 787 13
We perform a quantitative analysis of the solar composition problem by using a statistical approach that allows us to combine the information provided by helioseismic and solar neutrino data in an effective way. We include in our analysis the helioseismic determinations of the surface helium abundance and of the depth of the convective envelope, the measurements of the 7Be and 8B neutrino fluxes, and the sound speed profile inferred from helioseismic frequencies. We provide all the ingredients to describe how these quantities depend on the solar surface composition, different from the initial and internal composition due to the effects of diffusion and nuclear reactions, and to evaluate the (correlated) uncertainties in solar model predictions. We include error sources that are not traditionally considered such as those from inversion of helioseismic data. We, then, apply the proposed approach to infer the chemical composition of the Sun. Our result is that the opacity profile of the Sun is well constrained by the solar observational properties. In the context of a two-parameter analysis in which elements are grouped as volatiles (i.e., C, N, O, and Ne) and refractories (i.e., Mg, Si, S, and Fe), the optimal surface composition is found by increasing the abundance of volatiles by (45 ± 4)% and that of refractories by (19 ± 3)% with respect to the values provided by Asplund et al. (2009, ARA&A, 47, 481). This corresponds to the abundances $\varepsilon O = 8.85 \pm 0.01$ and $\varepsilon Fe = 7.52 \pm 0.01$, which are consistent at the ~1σ level with those provided by Grevesse & Sauval (1998, SSRv, 85, 161). As an additional result of our analysis, we show that the best fit to the observational data is obtained with values of input parameters of the standard solar models (radiative opacities, gravitational settling rate, and the astrophysical factors S 34 and S 17) that differ at the ~1σ level from those presently adopted.

A new Generation of Standard Solar Models

Núria **Vinyoles**, Aldo M. Serenelli, Francesco L. Villante, Sarbani Basu, Johannes Bergström, M.C. Gonzalez-Garcia, Michele Maltoni, Carlos Peña-Garay, Ningqiang Song
2017 ApJ 835 202
https://arxiv.org/pdf/1611.09867v1.pdf
We compute a new generation of standard solar models (SSMs) that includes recent updates on some important nuclear reaction rates and a more consistent treatment of the equation of state. Models also include a novel and flexible treatment of opacity uncertainties based on opacity kernels, required in the light of recent theoretical and experimental works on radiative opacity. Two large sets of SSMs, each based on a different canonical set of solar abundances with high and low metallicity (Z), are computed to determine model uncertainties and correlations among different observables. We present detailed comparisons of high- and low-Z models against different ensembles of solar observables including solar neutrinos, surface helium abundance, depth of convective envelope and sound speed profile. A global comparison, including all observables, yields a p-value of 2.7σ for the high-Z model and 4.7σ for the low-Z one. When the sound-speed differences in the narrow region of $0.65<r/R_{sun}<0.70$ are excluded from the analysis, results are 0.9σ and 3.0σ for high- and low-Z models respectively. These results show that: high-Z models agree well with solar data but have a systematic problem right below the bottom of the convective envelope linked to steepness of molecular weight and temperature gradients, and that low-Z models lead to a much more general disagreement with solar data. We also show that, while simple parametrizations of opacity uncertainties can strongly alleviate the solar abundance problem, they are insufficient to substantially improve the agreement of SSMs with helioseismic data beyond that obtained for high-Z models due to the intrinsic correlations of theoretical predictions.

New axion and hidden photon constraints from a solar data global fit

Núria **Vinyoles**, Aldo Serenelli, Francesco L. Villante, Sarbani Basu, Javier Redondo, Jordi Isern
2015
http://arxiv.org/pdf/1501.01639v1.pdf
We present a new statistical analysis that combines helioseismology (sound speed, surface helium and convective radius) and solar neutrino observations (boron and beryllium fluxes) to place upper limits to the properties of non standard weakly interacting particles. Our analysis includes theoretical and observational errors, accounts for tensions between input parameters of solar models and can be easily extended to include other observational constraints. We present two applications to test the method: the well studied case of axions and axion-like particles and the more novel case of low mass hidden photons. For axions we obtain an upper limit at 3 sigma for the axion-photon coupling constant of g_a-gamma < 4 x 10^-10 GeV^-1. For hidden photons we obtain the most restrictive upper limit for the product of the kinetic mixing and mass of chi < 1.82 x 10^-12 eV/m at 3 sigma. Both cases improve the previous solar constraints based on the Standard Solar Models showing the power of our global statistical approach.

Periodicity analysis of galactic cosmic rays using Fourier, Hilbert, and higher-order spectral methods

V. **Vipindas**, Sumesh Gopinath, T. E. Girish
Astrophysics and Space Science April **2016**, 361:135
Galactic cosmic rays (GCRs) that traverse the heliosphere, in the energy range from several 100 MeV to a few GeV, are subjected to heliospheric modulation. GCRs interact with varying fields of the heliosphere to produce fluctuations in cosmic-ray intensity with variations in solar activity. The effects of modulation are continuously measured by the well-established world-wide neutron monitor network. Solar activity indices and cosmic-ray neutron monitor rates (at different cut-off rigidities) have been used to compare Fourier, Hilbert, and higher-order spectral (bispectral) features of GCR intensity variations at six stations for a period of nearly 50 years. The present study reveals that GCRs exhibit a number of short- and long-term periodicities that vary between 9 days and 22 years. The bispectral analysis shows the characteristic features of nonlinear coupling and complex phase relationships between various harmonics present in GCRs and solar activity proxies. We also offer possible explanations for the observed periodicities with the help of the previous findings.

Abrupt Shrinking of Solar Corona in the Late 1990s

Ilpo I. **Virtanen**, Jennimari S. Koskela, and Kalevi Mursula
2020 ApJL 889 L28
https://doi.org/10.3847/2041-8213/ab644b
We derive the longest uniform record of rotational intensities solar coronal magnetic field since 1968 and compare it with the heliospheric magnetic field (HMF) observed at the Earth. We scale the Mount Wilson Observatory and Wilcox Solar Observatory observations of the photospheric magnetic field to the level of the Synoptic Optical Long-term Investigations of the Sun/Vector Spectro Magnetograph and apply the potential field source surface model to calculate the coronal magnetic field. We find that the evolution of the coronal magnetic field during the last 50 yr agrees with the HMF observed at the Earth only if the effective coronal size, the distance of the coronal source surface of the HMF, is allowed to change in time. We calculate the optimum source surface distance for each rotation and find that it experienced an abrupt decrease in the late 1990s. The effective volume of the solar corona shrunk to less than one half during a short period of only a few years. We note that this abrupt shrinking coincides with other changes in solar magnetic fields that are likely related to the decrease of the overall solar activity, i.e., the demise of the Grand Modern Maximum.

Reconstructing solar magnetic fields from historical observations - VI. Axial dipole moments of solar active regions in cycles 21−24

I. O. I. **Virtanen**, I. I. Virtanen, A. A. Pevtsov and K. Mursula
A&A 632, A39 (**2019**)
https://sci-hub.se/10.0000/www.aanda.org/articles/aa/abs/2019/12/aa36134-19/aa36134-19.html
Context. The axial dipole moments of emerging active regions control the evolution of the axial dipole moment of the whole photospheric magnetic field and the strength of polar fields. Hale's and Joy's laws of polarity and tilt orientation affect the sign of the axial dipole moment of an active region. If both laws are valid (or both violated), the sign of the axial moment is normal. However, for some active regions, only one of the two laws is violated, and the signs of these axial dipole moments are the opposite of normal. Those opposite-sign active regions can have a significant effect, for example, on the development of polar fields.
Aims. Our aim is to determine the axial dipole moments of active regions identified from magnetographic observations and study how the axial dipole moments of normal and opposite signs are distributed in time and latitude in solar cycles 21−24.
Methods. We identified active regions in the synoptic maps of the photospheric magnetic field measured at the National Solar Observatory (NSO) Kitt Peak (KP) observatory, the Synoptic Optical Long term Investigations of the Sun (SOLIS) vector spectromagnetograph (VSM), and the Helioseismic and Magnetic Imager (HMI) aboard the Solar Dynamics Observatory (SDO), and determined their axial dipole moments.
Results. We find that, typically, some 30% of active regions have opposite-sign axial moments in every cycle, often making more than 20% of the total axial dipole moment. Most opposite-signed moments are small, but occasional large moments, which can affect the evolution of polar fields on their own, are observed. Active regions with such a large opposite-sign moment may include only a moderate amount of total magnetic flux. We find that in cycles 21−23 the northern hemisphere activates first and shows emergence of magnetic flux over a wider latitude range, while the southern hemisphere activates later, and emergence is concentrated to lower latitudes. Cycle 24 differs from cycles 21−23 in many ways. Cycle 24 is the only cycle where the northern butterfly wing includes more active regions than the southern wing, and where axial dipole moment of normal sign emerges on average later than opposite-signed axial dipole moment. The total axial dipole moment and even the average axial moment of active regions is smaller in cycle 24 than in previous cycles.

Reconstructing solar magnetic fields from historical observations - IV. Testing the reconstruction method

I. O. I. **Virtanen**, I. I. Virtanen, A. A. Pevtsov, L. Bertello, A. Yeates and K. Mursula
A&A 627, A11 (**2019**)
DOI: https://doi.org/10.1051/0004-6361/201935606
Aims. The evolution of the photospheric magnetic field has only been regularly observed since the 1970s. The absence of earlier observations severely limits our ability to understand the long-term evolution of solar magnetic fields, especially the polar fields that are important drivers of space weather. Here, we test the possibility to reconstruct the large-scale solar magnetic fields from Ca II K line observations and sunspot magnetic field observations, and to create synoptic maps of the photospheric magnetic field for times before modern-time magnetographic observations.
Methods. We reconstructed active regions from Ca II K line synoptic maps and assigned them magnetic polarities using sunspot magnetic field observations. We used the reconstructed active regions as input in a surface flux transport simulation to produce synoptic maps of the photospheric magnetic field. We compared the simulated field with the observed field in 1975−1985 in order to test and validate our method.
Results. The reconstruction very accurately reproduces the long-term evolution of the large-scale field, including the poleward flux surges and the strength of polar fields. The reconstruction has slightly less emerging flux because a few weak active regions are missing, but it includes the large active regions that are the most important for the large-scale evolution of the field. Although our reconstruction method is very robust, individual reconstructed active regions may be slightly inaccurate in terms of area, total flux, or polarity, which leads to some uncertainty in the simulation. However, due to the randomness of these inaccuracies and the lack of long-term memory in the simulation, these problems do not significantly affect the long-term evolution of the large-scale field.

Reconstructing solar magnetic fields from historical observations
III. Activity in one hemisphere is sufficient to cause polar field reversals in both hemispheres

I. O. I. **Virtanen**1, I. I. Virtanen1, A. A. Pevtsov2,1 and K. Mursula1
A&A 616, A134 (**2018**)
Aims. Sunspot activity is often hemispherically asymmetric, and during the Maunder minimum, activity was almost completely limited to one hemisphere. In this work, we use surface flux simulation to study how magnetic activity limited only to the southern hemisphere affects the long-term evolution of the photospheric magnetic field in both hemispheres. The key question is whether sunspot activity in one hemisphere is enough to reverse the polarity of polar fields in both hemispheres.
Methods. We simulated the evolution of the photospheric magnetic field from 1978 to 2016 using the observed active regions of the southern hemisphere as input. We studied the flow of magnetic flux across the equator and its subsequent motion towards the northern pole. We also tested how the simulated magnetic field is changed when the activity of the southern hemisphere is reduced.
Results. We find that activity in the southern hemisphere is enough to reverse the polarity of polar fields in both hemispheres by the cross-equatorial transport of magnetic flux. About 1% of the flux emerging in the southern hemisphere is transported across the equator, but only 0.1%–0.2% reaches high latitudes to reverse and regenerate a weak polar field in the northern hemisphere. The polarity reversals in the northern hemisphere are delayed compared to the southern hemisphere, leading to a quadrupole Sun lasting for several years.

Photospheric and coronal magnetic fields in six magnetographs
I. Consistent evolution of the bashful ballerina

Ilpo **Virtanen** and Kalevi Mursula
A&A 591, A78 **(2016)**
Aims. We study the long-term evolution of photospheric and coronal magnetic fields and the heliospheric current sheet (HCS), especially its north-south asymmetry. Special attention is paid to the reliability of the six data sets used in this study and to the consistency of the results based on these data sets.
Methods. We use synoptic maps constructed from Wilcox Solar Observatory (WSO), Mount Wilson Observatory (MWO), Kitt Peak (KP), SOLIS, SOHO/MDI, and SDO/HMI measurements of the photospheric field and the potential field source surface (PFSS) model.
Results. The six data sets depict a fairly similar long-term evolution of magnetic fields and the heliospheric current sheet, including polarity reversals and hemispheric asymmetry. However, there are time intervals of several years long, when first KP measurements in the 1970s and 1980s, and later WSO measurements in the 1990s and early 2000s, significantly deviate from the other simultaneous data sets, reflecting likely errors at these times. All of the six magnetographs agree on the southward shift of the heliospheric current sheet (the so-called bashful ballerina phenomenon) in the declining to minimum phase of the solar cycle during a few years of the five included cycles.

We show that during solar cycles 20–22, the southward shift of the HCS is mainly due to the axial quadrupole term, reflecting the stronger magnetic field intensity at the southern pole during these times. During cycle 23 the asymmetry is less persistent and mainly due to higher harmonics than the quadrupole term. Currently, in the early declining phase of cycle 24, the HCS is also shifted southward and is mainly due to the axial quadrupole as for most earlier cycles. This further emphasizes the special character of the global solar field during cycle 23.

North-South Asymmetric Solar Cycle Evolution: Signatures in the Photosphere and Consequences in the Corona

I. I. **Virtanen** and K. Mursula
2014 ApJ 781 99
The heliospheric current sheet is the continuum of the coronal magnetic equator that divides the heliospheric magnetic field into two sectors (polarities). Several recent studies have shown that the heliospheric current sheet is southward shifted during approximately 3 years in the solar declining phase (the so-called bashful ballerina phenomenon). In this article we study the hemispherical asymmetry in the photospheric and coronal magnetic fields using Wilcox Solar Observatory measurements of the photospheric magnetic field since 1976 as well as the potential field source surface model. Multipole analysis of the photospheric magnetic field shows that during the late declining phase of solar cycles since the 1970s, the "bashful ballerina phenomenon" is a consequence of the quadrupole term, signed oppositely to the dipole moment. Surges of new flux transport magnetic field from low latitudes to the poles, thus leading to a systematically varying contribution to the -term from different latitudes. In the case of a north-south asymmetric flux production, this is seen as a quadrupole contribution traveling toward higher latitudes. When the quadrupole term is largest, the main contribution comes from the polar latitudes. At least during the four recent solar cycles, the -term arises because the magnitude of the southern polar field is larger than the magnitude found in the north in the declining phase of the cycle. In the heliosphere this hemispheric asymmetry of the coronal fields is seen as a southward shift of the heliospheric current sheet by about 2°.

Solar Mean Magnetic Field of the Chromosphere

M. **Vishnu**, K. Nagaraju, Harsh Mathur
J. Astrophys. Astr. **2023**
https://arxiv.org/pdf/2302.06924.pdf
The Solar Mean Magnetic Field (SMMF) is the mean value of the line of sight (LOS) component of the solar vector magnetic field averaged over the visible hemisphere of the Sun. So far, the studies on SMMF have mostly been confined to the magnetic field measurements at the photosphere. In this study, we calculate and analyse the SMMF using magnetic field measurements at the chromosphere, in conjunction with that of photospheric measurements. For this purpose, we have used full disk LOS magnetograms derived from spectropolarimetric observations carried out in Fe I 630.15 nm and Ca II 854.2 nm by the Synoptic Optical Long term Investigations of the Sun (SOLIS)/Vector Spectromagnetograph (VSM) instrument during 2010 to 2017. It is found from this study that the SMMF at the chromosphere is weaker by a factor of 0.60 compared to the SMMF at the upper photosphere. The correlation analysis between them gives a Pearson correlation coefficient of 0.80. The similarity and reduced intensity of the chromospheric SMMF with respect to the photospheric SMMF corroborate the idea that it is the source of the Interplanetary Magnetic Field (IMF).

Luminosity constraint and entangled solar neutrino signals

Francesco **Vissani**
Presented at the 5th International Solar Neutrino Conference, Dresden, Germany, June **2018**
https://arxiv.org/pdf/1808.01495.pdf
Now that neutrino propagation phenomena are understood, solar neutrino physics is entering an era when observational progresses indicate new challenges. The luminosity constraint plays a key role for current needs. We present it in a new form, improving the coefficients originally obtained by J. Bahcall, Phys. Rev. C 65 (2002) 025801. It turns out that the PP- and CNO-neutrino signals are entangled: In fact, pp-neutrinos can be extracted from the luminosity constraint only when CNO-neutrinos are quantified; the interpretation of the results of the gallium experiments depends upon both fluxes; a precise knowledge of pep-neutrinos is a precondition to extract the CNO-neutrino signal with Borexino.

Dissecting bombs and bursts: non-LTE inversions of low-atmosphere reconnection in SST and IRIS observations

G. J. M. **Vissers**, J. de la Cruz Rodriguez, T. Libbrecht, L. H. M. Rouppe van der Voort, G. B. Scharmer, M. Carlsson
A&A 627, A101 **2019**
https://arxiv.org/pdf/1905.02035.pdf

Ellerman bombs and UV bursts are transient brightenings that are ubiquitously observed in the lower atmospheres of active and emerging flux regions. Here we present inversion results of SST/CRISP and CHROMIS, as well as IRIS data of such transient events. Combining information from the Mg II h & k, Si IV and Ca II 8542A and Ca II H & K lines, we aim to characterise their temperature and velocity stratification, as well as their magnetic field configuration. We find average temperature enhancements of a few thousand kelvin close to the classical temperature minimum, but localised peak temperatures of up to 10,000-15,000 K from Ca II inversions. Including Mg II generally dampens these temperature enhancements to below 8000 K, while Si IV requires temperatures in excess of 10,000 K at low heights, but may also be reproduced with secondary temperature enhancements of 35,000-60,000 K higher up. However, reproducing Si IV comes at the expense of overestimating the Mg II emission. The line-of-sight velocity maps show clear bi-directional jet signatures and strong correlation with substructure in the intensity images, with slightly larger velocities towards the observer than away. The magnetic field parameters show an enhancement of the horizontal field co-located with the brightenings at similar heights as the temperature increase. We are thus able to largely reproduce the observational properties of Ellerman bombs with UV burst signature with temperature stratifications peaking close to the classical temperature minimum. Correctly modelling the Si IV emission in agreement with all other diagnostics is, however, an outstanding issue. Accounting for resolution differences, fitting localised temperature enhancements and/or performing spatially-coupled inversions is likely necessary to obtain better agreement between all considered diagnostics. **September 3 and 5, 2016**,

Automating Ellerman bomb detection in ultraviolet continua

Gregal J. M. **Vissers**, Luc H. M. Rouppe van der Voort, Robert J. Rutten
A&A 626, A4 **2019**
https://arxiv.org/pdf/1901.07975.pdf
Ellerman bombs are transient brightenings in the wings of H-alpha 6563 {\AA} that pinpoint photospheric sites of magnetic reconnection in solar active regions. Their partial visibility in the 1600 {\AA} and 1700 {\AA} continua registered routinely by the Atmospheric Imaging Assembly (AIA) onboard the Solar Dynamics Observatory (SDO) offers a unique opportunity to inventory such magnetic-field disruptions throughout the AIA database if a reliable recipe for their detection can be formulated. This is done here. We improve and apply an H-alpha Ellerman bomb detection code to ten data sets spanning viewing angles from solar disc centre to the limb. They combine high-quality H-alpha imaging spectroscopy from the Swedish 1-m Solar Telescope with simultaneous AIA imaging around 1600 {\AA} and 1700 {\AA}. A trial grid of brightness, lifetime and area constraints is imposed on the AIA images to define optimal recovery of the 1735 Ellerman bombs detected in H-alpha. The best results when optimising simultaneously for recovery fraction and reliability are obtained from 1700 {\AA} images by requiring 5-sigma brightening above the average 1700 {\AA} nearby quiet-Sun intensity, lifetime above one minute, area of 1-18 AIA pixels. With this recipe 27% of the AIA detections are H-alpha-detected Ellerman bombs while it recovers 19% of these (of which many are smaller than the AIA resolution). Better yet, among the top 10% AIA 1700 {\AA} detections selected with combined brightness, lifetime and area thresholds as many as 80% are H-alpha Ellerman bombs. Automated selection of the best 1700 {\AA} candidates therefore opens the entire AIA database for detecting most of the more significant photospheric reconnection events. This proxy is applicable as flux-dynamics tell-tale in studying any Earth-side solar active region since early 2010 up to the present.

Sunspot periodicity

Claudio **Vita-Finzi**
2022
https://arxiv.org/ftp/arxiv/papers/2212/2212.03249.pdf
The Schwabe (~11 yr) value for the annual sunspot number is sometimes uncritically applied to other measures of solar activity, direct and indirect, including the 10.7 cm radio flux, the inflow of galactic cosmic rays, solar flare frequency, terrestrial weather, and components of space climate, with the risk of a resulting loss of information. The ruling (Babcock) hypothesis and its derivatives link the sunspot cycle to dynamo processes mediated by differential solar rotation, but despite 60 years of observation and analysis the ~11 yr periodicity remains difficult to model; the possible contribution of planetary dynamics is undergoing a revival. The various solar sequences that genuinely display an ~11 yr cycle stand to benefit from an understanding of its periodicity that goes beyond statistical kinship. The outcome could ironically prompt the demotion of sunspots from their dominant historical role in favour of other possible indicators of solar cyclicity, such as the solar wind flux and its isotopic signatures, even if they are less accessible.

Core to solar wind: a stepwise model for heating the solar corona

Claudio **Vita-Finzi**
2021
https://arxiv.org/ftp/arxiv/papers/2101/2101.08251.pdf
Operating experience from fusion research shows how Spitzer resistivity may render ohmic heating in the chromosphere self limiting and thus serve to define the lower margin of the transition region. Its upper margin is at

about 6000 K, where radiative cooling of He:H plasma decelerates sharply. The third and last stage in the proposed scheme is expansion into the tenuous plasma of space, which leads to the acceleration of ions to high energies, long recorded by spacecraft instruments. There is thus dynamic continuity all the way from the solar interior, the energy source for spinning columns in the Rayleigh Benard setting of the convection zone, to the coronal exhalation of the solar wind, a finding which should benefit the analysis of space weather, witness the association between helium in the solar wind and the incidence of coronal mass ejections.

The contribution of the Joule-Thomson effect to solar coronal heating

Claudio **Vita-Finzi**

2016

https://arxiv.org/pdf/1612.07943v1.pdf

Two of the three gases that display isenthalpic Joule-Thomson (J-T) warming under laboratory conditions are hydrogen and helium, the main constituents of the solar plasma, but the temperatures that are attained by this route are at most a few hundred K. Increases in ion temperature by several orders of magnitude are claimed for hydrogen plasmas subject to expansion into a vacuum; modest increases are reported for the shortlived tests of this effect that have been carried out in space in the wakes of artificial satellites and of the Moon. Attempts to calculate the J-T coefficient at very high temperatures using equations of state and thermodynamics remain very preliminary. The potential contribution of plasma expansion to heating of the solar corona must therefore be assessed empirically, but this is consistent with how the J-T effect was first identified. The sunspot record, EUV measurements by the EVE instrument on the SDO satellite, and solar wind fluctuations documented by the ACE satellite indicate broadly coherent periodicity from the photosphere to the outer corona consistent with a non-pulsatory heating process. It comprises three successive stages characterised by induction, the J-T mechanism, and plasma expansion. Astronomical data may therefore be used to derive rather than to test an extension of the J-T effect which could help to explain heating in other solar system bodies and other stellar coronae.

The solar chromosphere as induction disk and the inverse Joule-Thomson effect

Claudio **Vita-Finzi**

2016

https://arxiv.org/ftp/arxiv/papers/1609/1609.00508.pdf

The connection between nuclear fusion in the Sun's core and solar irradiance is obscured among other things by uncertainty over the mechanism of coronal heating. Data for solar wind density and velocity, sunspot number, and EUV flux suggest that electromagnetic energy from the Sun's convection zone is converted by induction through the chromosphere into thermal energy. The helium and hydrogen mixture exhaled by the Sun is then heated by the inverse Joule-Thomson effect when it expands via the corona into space. The almost complete shutdown of the solar wind on **10-11 May 1999** demonstrated that its velocity is a more faithful indicator of solar activity than are sunspots as it reflects short-term variations in coronal heating rather than quasicyclical fluctuations in the Sun's magnetism. Its reconstruction from the cosmic ray flux using isotopes spanning over 800,000 yr should therefore benefit the analysis and long-term forecasting of Earth and space weather.

Hunting down the cause of solar magnetism

https://arxiv.org/ftp/arxiv/papers/2102/2102.03168.pdf

To understand solar and stellar dynamos combining local and global numerical modelling with long-term observations is a challenging task: even with state of the art computational methods and resources, the stellar parameter regime remains unattainable. Our goal is to relax some approximations, in order to simulate more realistic systems, and try to connect the results with theoretical predictions and state-of-the-art observations. We present here the first test-field measurements from our higher-resolution runs with improved heat conduction description. They indicate significant changes in the profiles of the most crucial inductive effect related to solar and stellar dynamo mechanisms. Higher resolution runs, currently undertaken, will bring us into an even more turbulent regime, in which we will be able to study, for the first time, the interaction of small- and large-scale dynamos in a quantitative way.

Physically motivated heat-conduction treatment in simulations of solar-like stars: effects on dynamo transitions

M. **Viviani1**,2 and M. J. Käpylä3,2,4

A&A 645, A141 (**2021**)

https://doi.org/10.1051/0004-6361/202038603

https://www.aanda.org/articles/aa/pdf/2021/01/aa38603-20.pdf
Results from global magnetoconvection simulations of solar-like stars are at odds with observations in many respects: simulations show a surplus of energy in the kinetic power spectrum at large scales; anti-solar differential rotation profiles with accelerated poles, and a slow equator for the solar rotation rate; and a transition from axi- to nonaxisymmetric dynamos at a much lower rotation rate than what is observed. Even though the simulations reproduce the observed active longitudes in fast rotators, their motion in the rotational frame (the so-called azimuthal dynamo wave, ADW) is retrograde, in contrast to the prevalent prograde motion in observations.
Aims. We study the effect of a more realistic treatment of heat conductivity in alleviating the discrepancies between observations and simulations.
Methods. We use physically motivated heat conduction by applying Kramers opacity law to a semi-global spherical setup that describes the convective envelopes of solar-like stars, instead of a prescribed heat conduction profile from mixing-length arguments.
Results. We find that some aspects of the results now better correspond to observations: the axi- to nonaxisymmetric transition point is shifted towards higher rotation rates. We also find a change in the propagation direction of ADWs that means that prograde waves are also now found. However, the transition from an anti-solar to solar-like rotation profile is also shifted towards higher rotation rates, leaving the models in an even more unrealistic regime.
Conclusions. Although Kramers-based heat conduction does not help in reproducing the solar rotation profile, it does help in the faster rotation regime, where the dynamo solutions now better match the observations.

Stellar Dynamos in the Transition Regime: Multiple Dynamo Modes and Antisolar Differential Rotation

What drives a cyclic dynamo in a solar-like star with anti-solar differential rotation?

M. **Viviani** (1), M. J. Käpylä (1,2), J. Warnecke (1), P. J. Käpylä (3,2), M. Rheinhardt (2
ApJ **886** 21 **2019**
https://arxiv.org/pdf/1902.04019.pdf
https://doi.org/10.3847/1538-4357/ab3e07
Global and semi-global convective dynamo simulations of solar-like stars are known to show a transition from an anti-solar (fast poles, slow equator) to solar-like (fast equator, slow poles) differential rotation for increasing rotation rate. The dynamo solutions in the latter regime can exhibit regular cyclic modes, whereas in the former regime such cyclic solutions have not been obtained so far. In this paper we present a semi-global dynamo simulation, which for the first time produces clear cyclic magnetic activity in the anti-solar differential rotation regime. We analyze the large-scale flow properties (differential rotation and meridional circulation) together with the turbulent transport coefficients obtained with the test-field method. We find that turbulent dynamo effects play an important role in the dynamics of the system as effective large-scale flows are significantly altered by turbulent pumping. Neither an αΩdynamo wave nor advection-dominated dynamo are able to explain the cycle period and the propagation direction of the mean magnetic field. Furthermore, we find that the α effect is comparable or even larger than the Ω effect in generating the toroidal magnetic field and therefore the dynamo seems to be α2Ω or α2 type.

Transition from axi- to nonaxisymmetric dynamo modes in spherical convection models of solar-like stars

Viviani, M., Warnecke, J., Käpylä, M. J., Käpylä, P. J., Olspert, N., Cole-Kodikara, E. M., Lehtinen, J. J., & Brandenburg, A.
A&A 616, A160 (**2018**)
https://arxiv.org/pdf/1710.10222.pdf
We seek to understand the transition from nearly axisymmetric configurations at solar rotation rates to nonaxisymmetric configurations for rapid rotation using 3D numerical simulations of turbulent convection and considering rotation rates between 1 and 30 times the solar value. We find a transition from axi- to nonaxisymmetric solutions at around 1.8 times the solar rotation rate. This transition coincides with a change in the rotation profile from antisolar- to solar-like differential rotation with a faster equator and slow poles. In the solar-like rotation regime, the field configuration consists of an axisymmetric oscillatory field accompanied by an m=1 azimuthal mode (two active longitudes), which also shows temporal variability. At slow (rapid) rotation, the axisymmetric (nonaxisymmetric) mode dominates. The axisymmetric mode produces latitudinal dynamo waves with polarity reversals, while the nonaxisymmetric mode often exhibits a drift in the rotating reference frame and the strength of the active longitudes changes cyclically over time between the different hemispheres. Most of the obtained dynamo solutions exhibit cyclic variability either caused by latitudinal or azimuthal dynamo waves. In an activity-period diagram, the cycle lengths normalized by the rotation period form two different populations as a function of rotation rate or magnetic activity level. The slowly rotating axisymmetric population lies close to what is called the inactive branch in observations, while the rapidly rotating models are close to the superactive branch with a declining cycle to rotation frequency ratio with increasing rotation rate. We can successfully reproduce the transition from axi- to

nonaxisymmetric dynamo solutions for high rotation rates, but high-resolution simulations are required to limit the effect of rotational quenching of convection at rotation rates above 20 times the solar value.

Are Nanoflares Responsible for Coronal Heating?

Loukas **Vlahos**, Heinz Isliker, Nikos Sioulas
2021
https://arxiv.org/pdf/2108.01722.pdf
Parker (1983) suggested a mechanism for the formation of current sheets (CSs) in the solar atmosphere. His main idea was that the tangling of coronal magnetic field lines by photospheric random flows facilitates the continuous formation of CSs in the solar atmosphere. This part of his idea represents one of the many ways by which the turbulent convection zone drives the formation of coherent structures and CSs in the solar atmosphere. Other mechanisms include emerging magnetic flux, interaction of current filaments, and explosive magnetic structures. However, there are two unproven assumptions in the initial idea of Parker for the coronal heating through nanoflares that must be re-examined. They are related to his suggestion that {ALL CSs formed are led to magnetic reconnection and that magnetic reconnection heats the plasma in the solar atmosphere. Let us discuss these two assumptions briefly in this short comment: (1) Are ALL coherent structures and CSs formed by the turbulent convection zone reconnecting? Does turbulence associated with non-reconnecting CSs play a role in the heating of the corona? (2) Does magnetic reconnection heat the plasma?

Particle Acceleration and Heating in a Turbulent Solar Corona **Review**

Loukas **Vlahos**, Heinz Isliker
Plasma Physics and Controled Fusion (PPCF) **61**, Issue 1, article id. 014020 (**2019**).
https://arxiv.org/pdf/1808.07136.pdf
sci-hub.se/10.1088/1361-6587/aadbe7
Turbulence, magnetic reconnection, and shocks can be present in explosively unstable plasmas, forming a new electromagnetic environment, which we call here turbulent reconnection, and where spontaneous formation of current sheets takes place. We will show that the heating and the acceleration of particles is the result of the synergy of stochastic (second order Fermi) and systematic (first order Fermi) acceleration inside fully developed turbulence. The solar atmosphere is magnetically coupled to a turbulent driver (the convection zone), therefore the appearance of turbulent reconnection in the solar atmosphere is externally driven. Turbulent reconnection, once it is established in the solar corona, drives the coronal heating and particle acceleration.

Suprathermal electron distributions in the solar transition region

C. **Vocks**1, E. Dzifčáková2 and G. Mann1
A&A 596, A41 (**2016**)
https://arxiv.org/pdf/1610.03789v1.pdf
Context. Suprathermal tails are a common feature of solar wind electron velocity distributions, and are expected in the solar corona. From the corona, suprathermal electrons can propagate through the steep temperature gradient of the transition region towards the chromosphere, and lead to non-Maxwellian electron velocity distribution functions (VDFs) with pronounced suprathermal tails.
Aims. We calculate the evolution of a coronal electron distribution through the transition region in order to quantify the suprathermal electron population there.
Methods. A kinetic model for electrons is used, which is based on solving the Boltzmann-Vlasov equation for electrons including Coulomb collisions with both ions and electrons. Initial and chromospheric boundary conditions are Maxwellian VDFs with densities and temperatures based on a background fluid model. The coronal boundary condition has been adopted from earlier studies of suprathermal electron formation in coronal loops.
Results. The model results show the presence of strong suprathermal tails in transition region electron VDFs, starting at energies of a few 10 eV. Above electron energies of 600 eV, electrons can traverse the transition region essentially collision-free.
Conclusions. The presence of strong suprathermal tails in transition region electron VDFs shows that the assumption of local thermodynamic equilibrium is not justified there. This has a significant impact on ionization dynamics, as is shown in a companion paper.

On the possibilities of classical nova identifications among historical Far Eastern guest star observations

Nikolaus **Vogt**, Susanne M. Hoffmann, Claus Tappert
Astronomische Nachrichten **2019**
https://arxiv.org/pdf/1910.13464.pdf
More than 100 guest star observations have been obtained by Chinese, Korean, Japanese and Vietnamese astronomers between ~600 BCE and ~1690 CE. Comparing the coordinates from the information given in old texts

for eight supernova recoveries with modern supernova remnant positions, we estimate a typical positional accuracy of the order of 0.3 to 7 deg for these supernovae. These values turn out to be also a start for the expected deviation angle between a classical nova observed as a guest star and its modern counterpart among known cataclysmic variables (CVs). However, there are considerable disagreements among modern authors in the interpretation of ancient Far Eastern texts, emphasizing the need to consult again the original historic sources, in order to improve the positioning reliability. We also discuss the typical amplitudes of well observed classical novae and find that modern counterparts of nova guest stars should be V = 18 mag and thus easily observable. In this context we also consider the "hibernation scenario" and conclude that it is impossible to decide from currently-available observations whether hibernation is common. In addition to the limiting magnitude around 2 mag for ancient guest star detections mentioned in the literature, we consider the possibility that also fainter guest stars (4-5 mag) could have been detected by ancient observers and give arguments in favor of this possibility. For these limits we compare the expected nova detection rate of ancient naked-eye observers with that during modern times, and conclude that they coincide in order of magnitude, which implies that, indeed, a considerable number of classical nova remnants should be hidden among the Far Eastern guest star reports. Finally, we present a statistical analysis of the probability of casual misidentifications based on frequency and galactic distribution of CVs in the AAVSO-VSX catalogue.

Sunspot Positions and Areas from Observations by Cigoli, Galilei, Cologna, Scheiner, and Colonna in 1612 – 1614

Mikhail **Vokhmyanin**, Rainer Arlt & Nadezhda Zolotova
Solar Physics volume 296, Article number: 4 (**2021**)
https://link.springer.com/content/pdf/10.1007/s11207-020-01752-7.pdf
Digital images of manuscripts stored in the Galilean collection of the Central National Library of Florence are analyzed to obtain sunspot groups, their areas and heliographic positions. Overall, 142 drawings were processed. The way of drawing is usually schematic resulting in area uncertainty which may exceed a factor of two for small sunspots. We suggest that there is an upper limit of a factor of two between sunspot group numbers from the drawings and the actual ones. The computed penumbra-to-umbra ratio is consistent with modern observations. A distribution of sunspot latitudes versus time is reconstructed by means of two methods: exploiting the observation time noted by an observer and minimizing the day-to-day variability of sunspot latitudes.

Sunspot Positions and Areas from Observations by Thomas Harriot

Mikhail **Vokhmyanin**, Rainer Arlt & Nadezhda Zolotova
Solar Physics volume 295, Article number: 39 (**2020**)
https://link.springer.com/content/pdf/10.1007/s11207-020-01604-4.pdf
The reconstruction of sunspot parameters in the early era of telescopic observations extends our knowledge on visual sunspot activity up to 400 years into the past. 200 digital solar images from 18 December 1610 to 28 January 1613 by the English astronomer Thomas Harriot were analyzed to yield sunspot counts, areas and positions. Harriot generally observed in the early morning when the Sun was near the horizon, and he specified the local time of observation, date, place, number of spots, zenith and ecliptic lines, and other information. We assigned 753 sunspots into 293 groups and defined their areas. We developed two approaches to reconstructing the heliographic coordinates of the sunspots. Method I makes use of the time of observation noted by Harriot, and Method II minimizes the day-to-day variability of sunspot latitudes independently of Harriot's notes. The results of the two methods are discussed.

Sunspot Positions and Areas from Observations by Pierre Gassendi

M. V. **Vokhmyanin**, N. V. Zolotova
Solar Physics November **2018**, 293:150
Solar activity behaviour on the eve of the Maunder minimum may provide important information on the period of further suppression of sunspot population. We analyse sunspot positions and areas in the 1630s extracted from rare drawings published by Pierre Gassendi in Opera Omnia. This work was published in two different editions, the first in Lyon and the second almost 70 years later in Florence. The drawings published in Lyon are found to be slightly different from those published in Florence, which produces a discrepancy in the position of spots of a few degrees, while sunspot group areas may differ by a factor of two. We reveal that the orientation of the drawings in the book is not always the same as might be seen in the telescope. We conjecture that the time of Gassendi's observations covers the beginning of a new Schwabe cycle in the southern hemisphere. The differential rotation rate in the 1630s is also assessed and discussed.

Sunspot Positions and Areas from Observations by Galileo Galilei

M. V. **Vokhmyanin**, N. V. Zolotova
Solar Physics February **2018**, 293:31
https://link.springer.com/article/10.1007%2Fs11207-018-1245-1

Sunspot records in the seventeenth century provide important information on the solar activity before the Maunder minimum, yielding reliable sunspot indices and the solar butterfly diagram. Galilei's letters to Cardinal Francesco Barberini and Marcus Welser contain daily solar observations on **3 – 11 May, 2 June – 8 July, and 19 – 21 August 1612**. These historical archives do not provide the time of observation, which results in uncertainty in the sunspot coordinates. To obtain them, we present a method that minimizes the discrepancy between the sunspot latitudes. We provide areas and heliographic coordinates of 82 sunspot groups. In contrast to Sheiner's butterfly diagram, we found only one sunspot group near the Equator. This provides a higher reliability of Galilei's drawings. Large sunspot groups are found to emerge at the same longitude in the northern hemisphere from 3 May to 21 August, which indicates an active longitude.

Long-term Pulses of Dynamic Coupling between Solar Hemispheres

D.M. **Volobuev**, N.G. Makarenko
Solar Phys. 292:68 **2017**
https://arxiv.org/pdf/1704.01330.pdf
North-south (N-S) asymmetry of solar activity is a known statistical phenomenon but its significance is difficult to prove or theoretically explain. Here we consider each solar hemisphere as a separate dynamical system connected with the other hemisphere via an unknown coupling parameter. We use a non-linear dynamics approach to calculate the scale-dependent conditional dispersion (CD) of sunspots between hemispheres. Using daily Greenwich sunspot areas, we calculated the Neumann and Pearson chi-squared distances between CDs as indices showing the direction of coupling. We introduce an additional index of synchronization which shows the strength of coupling and allows us to discriminate between complete synchronization and independency of hemispheres. All indices are evaluated in a four-year moving window showing the evolution of coupling between hemispheres. We find that the driver-response interrelation changes between hemispheres have a few pulses during 130 years of Greenwich data with an at least 40 years-long period of unidirectional coupling. These sharp nearly simultaneous pulses of all causality indices are found at the decay of some 11-year cycles. The pulse rate of this new phenomenon of dynamic coupling is irregular: although the first two pulses repeate after 22-year Hale cycles, the last two pulses repeat after three and four 11-year cycles respectively. The last pulse occurs at the decay phase of Cycle 23 so the next pulse will likely appear during the decay of future Cycle 25 or later. This new phenomenon of dynamic coupling reveals additional constraints for understanding and modeling of the long-term solar activity cycles.

Recent advances in neutrino astrophysics **Review**

Cristina **Volpe**
http://arxiv.org/pdf/1411.6533v1.pdf
Proceedings for the Symposium "Frontiers of Fundamental Physics **2014**", July 15-18, Marseille
Neutrinos are produced by a variety of sources that comprise our Sun, explosive environments such as core-collapse supernovae, the Earth and the Early Universe. The precise origin of the recently discovered ultra-high energy neutrinos is to be determined yet. These weakly interacting particles give us information on their sources, although the neutrino fluxes can be modified when neutrinos traverse an astrophysical environment. Here we highlight recent advances in neutrino astrophysics and emphasise the important progress in our understanding of neutrino flavour conversion in media.

Observations of magnetic reconnection in the deep solar atmosphere in the Hε line⋆

Luc H. M. Rouppe van der **Voort**1,2, Jayant Joshi3 and Kilian Krikova1,2
A&A, 683, A190 (**2024**)
https://www.aanda.org/articles/aa/pdf/2024/03/aa48976-23.pdf
Context. Magnetic reconnection in the deep solar atmosphere can give rise to enhanced emission in the Balmer hydrogen lines, a phenomenon known as Ellerman bombs (EBs). It is most common to observe EBs in the Hα and Hβ spectral lines. High-quality shorter-wavelength Balmer line observations of EBs are rare, but have the potential to provide the most highly resolved view on magnetic reconnection.
Aims. We aim to evaluate the Hε 3970 Å line as an EB diagnostic by analyzing high-quality observations in different Balmer lines.
Methods. Observations of different targets and viewing angles were acquired with the Swedish 1-m Solar Telescope. These observations sample EBs in different environments: active regions, the quiet Sun, and the penumbra and moat of a sunspot. We employed an automated detection method for quiet-Sun EBs based on k-means clustering.
Results. Ellerman bombs in the Hε line show similar characteristics as in the longer-wavelength Balmer lines: a higher intensity than in the surroundings, rapid variability, and a flame-like morphology. In a 24 min quiet-Sun time series, we detected 1674 EBs in the Hε line. This is 1.7 times more EBs than in Hβ. The quiet-Sun EBs measured in Hε are very similar to those in Hβ: They have similar lifetimes and a similar area, brightness, and spatial distribution. Most of the EBs detected in Hε are closer to the limb than their Hβ counterparts because the Hε line core EB emission is formed higher in the atmosphere than the Hβ EB wing emission.

Conclusions. We conclude that the Hε line is well suited for studying EBs, and consequently, for measuring the dynamics of magnetic reconnection in the solar atmosphere at the smallest scales. Our findings suggests that the deep atmosphere in the quiet Sun may host more than 750 000 reconnection events with an EB signature at any time. This is significantly more than what was found in earlier Hβ observations. **2020-08-07-16**

Ultra-high-resolution observations of plasmoid-mediated magnetic reconnection in the deep solar atmosphere⋆

Luc H. M. Rouppe van der **Voort**1,2, Michiel van Noort3 and Jaime de la Cruz Rodríguez4
A&A 673, A11 (**2023**)
https://www.aanda.org/articles/aa/pdf/2023/05/aa45933-23.pdf
Context. Magnetic reconnection in the deep solar atmosphere can give rise to enhanced emission in the Balmer hydrogen lines, a phenomenon referred to as Ellerman bombs.
Aims. To effectively trace magnetic reconnection below the canopy of chromospheric fibrils, we analyzed unique spectroscopic observations of Ellerman bombs in the Hα line.
Methods. We analyzed a 10 min data set of a young emerging active region observed with the prototype of the Microlensed Hyperspectral Imager (MiHI) at the Swedish 1-m Solar Telescope (SST). The MiHI instrument is an integral field spectrograph that is capable of achieving simultaneous ultra-high resolution in the spatial, temporal, and spectral domains. With the combination of the SST adaptive optics system and image restoration techniques, MiHI can deliver diffraction-limited observations if the atmospheric seeing conditions allow. The data set samples the Hα line over 4.5 Å with 10 mÅ pix−1, with 0.″065 pix−1 over a field of view of 8.″6 × 7.″7, and at a temporal cadence of 1.33 s. This constitutes a hyperspectral data cube that measures 132 × 118 spatial pixels, 456 spectral pixels, and 455 time steps.
Results. There were multiple sites with Ellerman bomb activity associated with strong magnetic flux emergence. The Ellerman bomb activity is very dynamic, showing rapid variability and a small-scale substructure. We found a number of plasmoid-like blobs with full-width-half-maximum sizes between 0.″1 and 0.″4 and moving with apparent velocities between 14 and 77 km s−1. Some of these blobs have Ellerman bomb spectral profiles with a single peak at a Doppler offset between 47 and 57 km s−1.
Conclusions. Our observations support the idea that fast magnetic reconnection in Ellerman bombs is mediated by the formation of plasmoids. These MiHI observations demonstrate that a microlens-based integral field spectrograph is capable of probing fundamental physical processes in the solar atmosphere. **24 August 2018, 11 August 2020**

High-resolution observations of the solar photosphere, chromosphere and transition region. A database of coordinated IRIS and SST observations

L.H.M. Rouppe van der **Voort**, B. De Pontieu, M. Carlsson, J. de la Cruz Rodriguez, S. Bose, G. Chintzoglou, A. Drews, C. Froment, M. Gosic, D.R. Graham, V.H. Hansteen, V.M.J. Henriques, S. A&A **2020**
https://arxiv.org/pdf/2005.14175.pdf
NASA's Interface Region Imaging Spectrograph (IRIS) provides high resolution observations of the solar atmosphere through UV spectroscopy and imaging. Since the launch of IRIS in June 2013, we have conducted systematic observation campaigns in coordination with the Swedish 1-m Solar Telescope (SST) on La Palma. The SST provides complementary high-resolution observations of the photosphere and chromosphere. The SST observations include spectro-polarimetric imaging in photospheric Fe I lines and spectrally-resolved imaging in the chromospheric Ca II 8542 A, H-alpha, and Ca II K lines. We present a database of co-aligned IRIS and SST datasets that is open for analysis to the scientific community. The database covers a variety of targets including active regions, sunspots, plage, quiet Sun, and coronal holes.

Imaging Polarimetry of the 2017 Solar Eclipse with the RIT Polarization Imaging Camera

Dmitry **Vorobiev**, Zoran Ninkov, Lee Bernard, Neal Brock
PASP (Publications of the Astronomical Society of the Pacific?) **2019**
https://arxiv.org/pdf/1909.12785.pdf
In the last decade, imaging polarimeters based on micropolarizer arrays have been developed for use in terrestrial remote sensing and metrology applications. Micropolarizer-based sensors are dramatically smaller and more mechanically robust than other polarimeters with similar spectral response and snapshot capability. To determine the suitability of these new polarimeters for astronomical applications, we developed the RIT Polarization Imaging Camera to investigate the performance of these devices, with a special attention to the low signal-to-noise regime. We characterized the device performance in the lab, by determining the relative throughput, efficiency, and orientation of every pixel, as a function of wavelength. Using the resulting pixel response model, we developed

demodulation procedures for aperture photometry and imaging polarimetry observing modes. We found that, using the current calibration, RITPIC is capable of detecting polarization signals as small as <0.3%. To demonstrate the stability of RITPIC's calibration and its extreme portability, we performed imaging polarimetry of the Solar corona in Madras, Oregon during the total Solar eclipse of 2017. The maximum polarization we measured was ~46%, which agrees well with the maximum value predicted for a Thomson scattering corona. Similarly, we found no strong deviations in the angle of linear polarization from the tangential direction. The relative ease of data collection, calibration, and analysis provided by these sensors suggest than they may become an important tool for a number of astronomical targets. **August 21, 2017**

Modeling Solar Oscillation Power Spectra. III. Spatiotemporal Spectra of Solar Granulation Velocity Field as Seen in HMI Velocity Measurements

Sergei V. **Vorontsov**1,2, Stuart M. Jefferies3, and Timothy P. Larson4,1
2024 ApJ 961 111
https://iopscience.iop.org/article/10.3847/1538-4357/ad12bd/pdf
We suggest a physically motivated model of the uncorrelated background, which can be used to improve the accuracy of helioseismic frequency measurements when the background contributes significantly to the formation of spectral lines of acoustic resonances. The basic assumption of our model is that the correlation length of the convective motions is small compared with the horizontal wavelength $R_\odot/\ell$ of the observations, where ℓ is the degree of the spherical harmonic $Y_\ell^m(\theta, \varphi)$. When applied to solar power spectra at frequencies below acoustic resonances, the model reveals a distinct sensitivity to solar rotation: advection of the convective velocity pattern brings spatial correlations in the apparent stochastic velocity field (temporal correlations in the corotating frame induce spatial correlations in the inertial frame). The induced spatiotemporal correlations manifest themselves as an antisymmetric component in the dependence of the convective noise power on azimuthal order m, which allows us to address the solar differential rotation. With 360 days of data obtained by the Helioseismic and Magnetic Imager on board the Solar Dynamics Observatory, we measure three components of the rotation rate as a function of latitude using only $\ell = 300$. This result indicates that the model suggests a new way of measuring solar subsurface rotation. This approach can complement traditional measurements based on correlation tracking.

Solar Polar Diamond Explorer (SPDEx): Understanding the Origins of Solar Activity Using a New Perspective

A. **Vourlidas**, P. C. Liewer, M. Velli, D. Webb
White paper submitted in response to ideas for the Next Generation Solar Physics Mission Concepts
2018
https://arxiv.org/ftp/arxiv/papers/1805/1805.04172.pdf
Our knowledge of the Sun, its atmosphere, long term activity and space weather potential is severely limited by the lack of good observations of the polar and far-side regions. Observations from a polar vantage point would revolutionize our understanding of the mechanism of solar activity cycles, polar magnetic field reversals, the internal structure and dynamics of the Sun and its atmosphere. Only with extended (many day) observations of the polar regions can the polar flows be determined down to the tachocline where the dynamo is thought to originate. Rapid short period polar orbits, using in situ and remote sensing instrumentation, distributed over a small number of spacecraft, will provide continuous 360o coverage of the solar surface and atmosphere in both longitude and latitude for years on end. This unprecedented full coverage will enable breakthrough studies of the physical connection between the solar interior, the solar atmosphere, the solar wind, solar energetic particles and the inner heliosphere at large. A potential implementation, the Solar Polar Diamond Explorer (SPDEx) built upon the Solar Polar Imager mission design, involves up to four small spacecraft in a 0.48-AU orbit with an inclination of 75o. The orbit is achieved using solar sails or ion engines, both technologies already demonstrated in space.

The Wide-Field Imager for Solar Probe Plus (WISPR)

Angelos **Vourlidas**, Russell A. Howard, Simon P. Plunkett, Clarence M. Korendyke, Arnaud F. . Thernisien, Dennis Wang, Nathan Rich, Michael T. Carter, Damien H. Chua, Dennis G. Socker, …show all 27
Space Science Reviews, Volume 204, Issue 1, pp 83–130 **2016**
http://link.springer.com/journal/11214/204/1?wt_mc=alerts.TOCjournals
The Wide-field Imager for Solar PRobe Plus (WISPR) is the sole imager aboard the Solar Probe Plus (SPP) mission scheduled for launch in 2018. SPP will be a unique mission designed to orbit as close as 7 million km (9.86 solar radii) from Sun center. WISPR employs a 95∘ radial by 58∘transverse field of view to image the fine-scale structure of the solar corona, derive the 3D structure of the large-scale corona, and determine whether a dust-free zone exists near the Sun. WISPR is the smallest heliospheric imager to date yet it comprises two nested wide-field telescopes with large-format (2 K × 2 K) APS CMOS detectors to optimize the performance for their respective fields of view

and to minimize the risk of dust damage, which may be considerable close to the Sun. The WISPR electronics are very flexible allowing the collection of individual images at cadences up to 1 second at perihelion or the summing of multiple images to increase the signal-to-noise when the spacecraft is further from the Sun. The dependency of the Thomson scattering emission of the corona on the imaging geometry dictates that WISPR will be very sensitive to the emission from plasma close to the spacecraft in contrast to the situation for imaging from Earth orbit. WISPR will be the first 'local' imager providing a crucial link between the large-scale corona and the in-situ measurements.

Charge exchange in fluid description of partially ionized plasmas

J. **Vranjes**, M. Kono, M. Luna

MNRAS **2015**

http://arxiv.org/pdf/1511.00875v1.pdf

The effects of charge exchange on waves propagating in weakly ionized plasmas are discussed. It is shown that for low-frequency processes, ions and neutrals should be treated as a single fluid with some effective charge on all of them. We have derived a new momentum equation which should be used in such an environment. As a result, the low-frequency magnetic waves can propagate even if particles are not magnetized, which is entirely due to the charge exchange and the fact that it is not possible to separate particles into two different populations as charged and neutral species. So there can be no friction force between ions and neutrals in the usual sense. The mean force per particle is proportional to the ionization ratio n_i/(n_i+ n_n). Regarding the application of the theory to the Alfvén wave propagation in the lower solar atmosphere, the results predict that the plane of displacement of the fluid must change by 90 degrees when an Alfvén wave propagates from the area where particles are un-magnetized (photosphere) to the area where they are magnetized (chromosphere). Because of the most accurate cross sections which we have here, it is possible to very accurately determine altitudes at which such rotation of the Alfvén wave takes place.

Energy in density gradient

J. **Vranjes**, M. Kono

Phys. Plasmas 22, 012105 (**2015**)

http://arxiv.org/pdf/1501.03730v1.pdf

Inhomogeneous plasmas and fluids contain energy stored in inhomogeneity and they naturally tend to relax into lower energy states by developing instabilities or by diffusion. But the actual amount of energy in such inhomogeneities has remained unknown. In the present work the amount of energy stored in a density gradient is calculated for several specific density profiles in a cylindric configuration. This is of practical importance for drift wave instability in various plasmas, and in particular in its application in models dealing with the heating of solar corona because the instability is accompanied with stochastic heating, so the energy contained in inhomogeneity is effectively transformed into heat. It is shown that even for a rather moderate increase of the density at the axis in magnetic structures in the corona by a factor 1.5 or 3, the amount of excess energy per unit volume stored in such a density gradient becomes several orders of magnitude greater than the amount of total energy losses per unit volume (per second) in quiet regions in the corona. Consequently, within the life-time of a magnetic structure such energy losses can easily be compensated by the stochastic drift wave heating.

Alfvén wave coupled with flow-driven fluid instability in interpenetrating plasmas

J. **Vranjes**

Phys. Plasmas 22, 052102 (**2015**)

http://arxiv.org/pdf/1510.05143v1.pdf

The Alfvén wave is analyzed in case of one quasineutral plasma propagating with some constant speed v0 through another static quasineutral plasma. A dispersion equation is derived describing the Alfvén wave coupled with the flow driven mode ω=kv0 and solutions are discussed analytically and numerically. The usual solutions for two oppositely propagating Alfvén waves are substantially modified due to the flowing plasma. More profound is modification of the solution propagating in the negative direction with respect to the magnetic field and the plasma flow. For a large enough flow speed (exceeding the Alfvén speed in the static plasma), this negative solution may become non-propagating, with frequency equal to zero. In this case it represents a spatial variation of the electromagnetic field. For greater flow speed it becomes a forward mode, and it may merge with the positive one. This merging of the two modes represents the starting point for a flow-driven instability, with two complex-

conjugate solutions. The Alfvén wave in interpenetrating plasmas is thus modified and coupled with the flow-driven mode and this coupled mode is shown to be growing when the flow speed is large enough. The energy for the instability is macroscopic kinetic energy of the flowing plasma. The dynamics of plasma particles caused by such a coupled wave still remains similar to the ordinary Alfvén wave. This means that well-known stochastic heating by the Alfvén wave may work, and this should additionally support the potential role of the Alfvén wave in the coronal heating.

Collisions, magnetization, and transport coefficients in the lower solar atmosphere

J. **Vranjes**1,2 and P. S. Krstic
A&A 554, A22 (**2013**)
Context. The lower solar atmosphere is an intrinsically multi-component and collisional environment with electron and proton collision frequencies in the range 108−1010 Hz, which may be considerably higher than the gyro-frequencies for both species. Collisions between different species are altitude dependent because of the variation in density and temperature of all species.
Aims. We aim to provide a reliable quantitative set of data for collision frequencies, magnetization, viscosity, and thermal conductivity for the most important species in the lower solar atmosphere. Having such data at hand is essential for any modeling that is aimed at describing realistic properties of the considered environment.
Methods. The relevant elastic and charge transfer cross sections in the considered range of collision energies are now accepted by the scientific community as known with unprecedented accuracy for the most important species that may be found in the lower solar atmosphere. These were previously calculated using a quantum-mechanical approach and were validated by laboratory measurements. Only with reliable collision data one can obtain accurate values for collision frequencies and coefficients of viscosity and thermal conductivity.
Results. We describe the altitude dependence of the parameters and the different physics of collisions between charged species, and between charged and neutral species. Regions of dominance of each type of collisions are clearly identified. We determine the layers within which either electrons or ions or both are unmagnetized. Protons are shown to be unmagnetized in the lower atmosphere in a layer that is at least 1000 km thick even for a kilo-Gauss magnetic field that decreases exponentially with altitude. In these layers the dynamics of charged species cannot be affected by the magnetic field, and this fact is used in our modeling. Viscosity and thermal conductivity coefficients are calculated for layers where ions are unmagnetized. We compare viscosity and friction and determine the regions of dominance of each of the phenomena.
Conclusions. We provide the most reliable quantitative values for most important parameters in the lower solar atmosphere to be used in analytical modeling and numerical simulations of various phenomena such as waves, transport and magnetization of particles, and the triggering mechanism of coronal mass ejections.

Observed Power and Frequency Variations of Solar Rossby Waves with Solar Cycles

M. **Waidele**, Junwei Zhao
ApJL **954**, L26 **2023**
https://arxiv.org/pdf/2308.07040.pdf
Several recent studies utilizing different helioseismic methods have confirmed the presence of large-scale vorticity waves known as solar Rossby waves within the Sun. Rossby waves are distinct from acoustic waves, typically with longer periods and lifetimes; and their general properties, even if only measured at the surface, may be used to infer properties of the deeper convection zone, such as the turbulent viscosity and entropy gradients which are otherwise difficult to observe. In this study, we utilize 12 years of inverted subsurface velocity fields derived from the SDO/HMI's time--distance and ring-diagram pipelines to investigate the propoerty of the solar equatorial Rossby waves. By covering the maximum and the decline phases of Solar Cycle 24, these datasets enable a systematic analysis of any potential cycle dependence of these waves. Our analysis provides evidence of a correlation between the average power of equatorial Rossby waves and the solar cycle, with stronger Rossby waves during the solar maximum and weaker waves during the minimum. Our result also shows that the frequency of the Rossby waves is lower during the magnetic active years, implying a larger retrograde drift relative to the solar rotation. Although the underlying mechanism that enhances the Rossby wave power and lowers its frequency during the cycle maximum is not immediately known, this observation has the potential to provide new insights into the interaction of large-scale flows with the solar cycle.

On Strengthening of the Solar f-mode Prior to Active Region Emergence Using the Fourier-Hankel Analysis

Matthias **Waidele**, Markus Roth, Nishant Singh, Petri Käpylä
Solar Phys. **2022**
https://arxiv.org/pdf/2202.11236.pdf

Recent results of Singh et al. (2016) show that the emergence of an active region (AR) can be seen in a strengthening of the f-mode power up to two days prior of the region's formation. In the original work, ring diagram analysis was used to estimate the power evolution. In this study, we make use of the Fourier-Hankel method, essentially testing the aforementioned results with an independent method. The data is acquired from SDO/HMI, studying the ARs 11158, 11072, 11105, 11130, 11242 and 11768. Investigating the total power as a function of time, we find a similar behavior to the original work, which is an enhancement of f-mode power about one to three days prior to AR emergence. Analysis of the absorption coefficient α, yielded by a Fourier-Hankel analysis, shows neither absorption ($\alpha>0$) nor emission ($\alpha<0$) of power during the enhancement. Finding no changes of the absorption coefficient (i.e. $\alpha=0$) is an important result, as it narrows down the possible physical interpretation of the original f-mode power enhancement, showing that no directional dependence (in the sense of inward and outward moving waves) is present.

Investigation of surface effects of simple flux tubes using numerical simulations

M. **Waidele**, M. Roth
ApJ, 889, 83 (**2020**)
https://arxiv.org/pdf/2001.11798.pdf
We use the SPARC code for MHD simulations with monolithic flux tubes of varying subsurface topology. Our studies involve the interactions of waves caused by a single source with subsurface magnetic fields. Mode conversion causing acoustic power to trickle downwards along the flux tube has been described before and can be visualized in our simulations. We show that this downward propagation causes the flux tube to act as an isolated source, creating a characteristic surface wavefield. Measuring this wavefield at the surface reveals subsurface properties of the magnetic field topology. Using time distance helioseismology, we demonstrate how to detect such a flux tube signal based on a group travel-time delay of $\Delta t=282.6$ sec due to the wave packet spending time subsurface as a slow mode wave. Although the amplitude is small and generally superimposed by the full wave field, it can be detected if assumptions about Δt are made. We demonstrate this for a simulation with solar like sources. This kind of study has the potential to reveal subsurface information of sunspots based on the analysis of a surface signal.

Coordination of the in situ payload of Solar Orbiter

A. P. **Walsh**1, T. S. Horbury2, M. Maksimovic3, C. J. Owen4, J. Rodríguez-Pacheco5, ….
A&A 642, A5 (**2020**)
https://doi.org/10.1051/0004-6361/201936894
https://www.aanda.org/articles/aa/pdf/2020/10/aa36894-19.pdf
Solar Orbiter's in situ coordination working group met frequently during the development of the mission with the goal of ensuring that its in situ payload has the necessary level of coordination to maximise science return. Here we present the results of that work, namely how the design of each of the in situ instruments (EPD, MAG, RPW, SWA) was guided by the need for coordination, the importance of time synchronisation, and how science operations will be conducted in a coordinated way. We discuss the mechanisms by which instrument sampling schemes are aligned such that complementary measurements will be made simultaneously by different instruments, and how burst modes are scheduled to allow a maximum overlap of burst intervals between the four instruments (telemetry constraints mean different instruments can spend different amounts of time in burst mode). We also explain how onboard autonomy, inter-instrument communication, and selective data downlink will be used to maximise the number of transient events that will be studied using high-resolution modes of all the instruments. Finally, we briefly address coordination between Solar Orbiter's in situ payload and other missions.

Rotation signal on the full disc of the solar chromosphere

M **Wan**, L H Deng, S G Zeng, Z J Yan, J L Xie, T T Xu, Y T Yu
MNRAS, Volume 536, Issue 1, January **2025**, Pages 871–878,
https://doi.org/10.1093/mnras/stae2669
https://watermark.silverchair.com/stae2669.pdf
The rotation signal on the full disc of the solar chromosphere was studied by using the Ca ii K normalized intensity from 938 Carrington rotation (CR) synoptic maps (from CR827 to CR1764) obtained from the Mount Wilson Observatory during the period of 1915 August 10 to 1985 July 7. In this study, our main focus is on the distribution characteristics of the rotation signal on the full disc of the solar chromosphere and its variation with the solar cycle. We found that the chromospheric rotation signal is more pronounced in the latitudinal belt of sunspot activity and tends to extend to higher latitudes, and the trend is essentially the same for each solar cycle. The chromospheric rotation signal is also found to have phase differences in latitudes. The period of the chromospheric rotation signal varies regularly in latitudes, but its phase variation is irregular. In addition, we found that the intensity background is lowest in the latitudinal belt of sunspot drift where the chromospheric rotation signal is generated, but it increases with latitude and tends to extend to higher latitudes. We discussed the possible mechanisms of the above analysis results and thought that the chromospheric rotation signal is mainly caused by sunspots and plages.

Differential rotation: the chromosphere to the quiet chromosphere

M **Wan**, P X Gao, J C Xu, X J Shi, N B Xiang, J L Xie

Monthly Notices of the Royal Astronomical Society, Volume 520, Issue 1, March **2023**, Pages 988–993, https://doi.org/10.1093/mnras/stad192

https://scholar.google.com/scholar_url?url=https://academic.oup.com/mnras/article-pdf/520/1/988/49058086/stad192.pdf

Synoptic maps of Ca II K-normalized intensity at ±40° latitude belt from Carrington rotations 827 (1915 August 10) to 1764 (1985 July 7) are utilized to investigate the long-term variation of the quiet chromospheric differential rotation within solar activity cycles through removing some large values of Ca II-normalized intensity. The equatorial rotation rate of the quiet chromosphere is found to be smaller than that of the chromosphere, and the absolute value of the parameter B is also found to be smaller for the quiet chromosphere than for the chromosphere on the whole, especially during periods of solar cycle maxima. Therefore, we induce that the differential of rotation rate in the quiet chromosphere seems to be enhanced by large-scale magnetic fields. The north–south asymmetry in the solar rotation is also investigated, and the asymmetry coefficients of the chromosphere and the quiet chromosphere are positively correlated in solar cycles 15–17, while they are negatively correlated in solar cycles 18–21.

Solar-cycle-related Variation of Differential Rotation of the Chromosphere

Miao **Wan**1,2 and Peng-xin Gao1,3,4

2022 ApJ 939 111

https://iopscience.iop.org/article/10.3847/1538-4357/ac930d/pdf

Solar-cycle-related variation of the solar chromospheric rotation is studied by analyzing the chromospheric rotation rate of 938 synoptic maps generated from the Ca ii K line at the Mount Wilson Observatory during the period of 1915 August 10 to 1985 July 7. The results obtained are as follows: (1) The parameters A (the equatorial rotation rate) and B (the latitudinal gradient of rotation) in the standard form of differential rotation both show a decreasing trend in the considered time frame, although A has weak statistical significance. (2) There is a significant negative correlation between the level of solar activity and parameter B, indicating that there seems to be a correlation between field strength and chromospheric differential rotation. (3) During solar cycles 15, 16, 19, 20, and 21, the southern hemisphere rotates faster, whereas in cycles 17 and 18, the northern hemisphere rotates faster. (4) There exists a significant negative correlation between the N–S asymmetry of the chromospheric rotation rate and that of solar activity, indicating that differential rotation of the chromosphere seems to be strengthened by stronger magnetic activity in a certain hemisphere. Possible explanations for the above results are given.

1/f Noise in the Heliosphere: A Target for PUNCH Science.

Wang, J., Matthaeus, W.H., Chhiber, R. et al.

Sol Phys 299, 169 (**2024**).

https://doi.org/10.1007/s11207-024-02401-z

https://link.springer.com/content/pdf/10.1007/s11207-024-02401-z.pdf

We present a broad review of 1/f noise observations in the heliosphere, and discuss and complement the theoretical background of generic 1/f models as relevant to NASA's Polarimeter to UNify the Corona and Heliosphere (PUNCH) mission. First observed in the voltage fluctuations of vacuum tubes, the scale-invariant 1/f spectrum has since been identified across a wide array of natural and artificial systems, including heart rate fluctuations and loudness patterns in musical compositions. In the solar wind the interplanetary magnetic field trace spectrum exhibits 1/f scaling within the frequency range from around \unit[2×10−6]Hz to around \unit[10−3]Hz at 1 au. One compelling mechanism for the generation of 1/f noise is the superposition principle, where a composite 1/f spectrum arises from the superposition of a collection of individual power-law spectra characterized by a scale-invariant distribution of correlation times. In the context of the solar wind, such a superposition could originate from scale-invariant reconnection processes in the corona. Further observations have detected 1/f signatures in the photosphere and corona at frequency ranges compatible with those observed at 1 au, suggesting an even lower altitude origin of 1/f spectrum in the solar dynamo itself. This hypothesis is bolstered by dynamo experiments and simulations that indicate inverse cascade activities, which can be linked to successive flux tube reconnections beneath the corona, and are known to generate 1/f noise possibly through nonlocal interactions at the largest scales. Conversely, models positing in situ generation of 1/f signals face causality issues in explaining the low-frequency portion of the 1/f spectrum. Understanding 1/f noise in the solar wind may inform central problems in heliospheric physics, such as the solar dynamo, coronal heating, the origin of the solar wind, and the nature of interplanetary turbulence.

High-resolution Observations of Clustered Dynamic Extreme-Ultraviolet Bright Tadpoles near the Footpoints of Corona Loops

Rui **Wang**, Ying D. Liu, L. P. Chitta, Huidong Hu, Xiaowei Zhao

Research in Astronomy and Astrophysics m **2024**

https://arxiv.org/pdf/2410.15789

An extreme ultraviolet (EUV) close-up view of the Sun offers unprecedented detail of heating events in the solar corona. Enhanced temporal and spatial images obtained by the Solar Orbiter during its first science perihelion enabled us to identify clustered EUV bright tadpoles (CEBTs) occurring near the footpoints of coronal loops. Combining SDO/AIA observations, we determine the altitudes of six distinct CEBTs by stereoscopy, ranging from ~1300 to 3300 km. We then notice a substantial presence of dark, cooler filamentary structures seemingly beneath the CEBTs, displaying periodic up-and-down motions lasting 3 to 5 minutes. This periodic behavior suggests an association of the majority of CEBTs with Type I spicules. Out of the ten selected CEBTs with fast downward velocity, six exhibit corrected velocities close to or exceeding 50 km s−1. These velocities notably surpass the typical speeds of Type I spicules. We explore the generation of such velocities. It indicates that due to the previous limited observations of spicules in the EUV wavelengths, they may reveal novel observational features beyond our current understanding. Gaining insights into these features contributes to a better comprehension of small-scale coronal heating dynamics. **2022-03-30**

An efficient, time-evolving, global MHD coronal model based on COCONUT

H. P. **Wang**, S. Poedts, A. Lani, M. Brchnelova, T. Baratashvili, L. Linan, F. Zhang, D. W. Hou, Y. H. Zhou

A&A **2024**

https://arxiv.org/pdf/2409.02043

Context. Magnetohydrodynamic (MHD) solar coronal models are critical in the Sun-to-Earth model chain and the most complex and computationally intensive component, particularly the time-evolving coronal models, typically driven by a series of time-evolving photospheric magnetograms. There is an urgent need to develop efficient and reliable time-evolving MHD coronal models to further improve our ability to predict space weather. Aims. COCONUT is a rapidly developing MHD coronal model. Adopting the efficient implicit algorithm makes it suitable for performing computationally intensive time-evolving coronal simulations. This paper aims to extend COCONUT to an efficient timeevolving MHD coronal model. Methods. In this MHD model, as usual, an implicit temporal integration algorithm is adopted to avoid the Courant-Friedrichs-Lewy (CFL) stability restriction and increase computational efficiency by large time steps. The Newton iteration method is applied within each time step to enhance the temporal accuracy. The unstructured geodesic mesh is used for flexibility in mesh division and to avoid degeneracy at the poles. Furthermore, an HLL Riemann solver with a self-adjustable dissipation term accommodates both low- and high-speed flows. A series of time-evolving photospheric magnetograms are utilized to drive the evolution of coronal structures from the solar surface to 25 Rs during two Carrington rotations (CRs) around the 2019 eclipse in an inertial coordinate system. It shows that COCONUT can mimic the coronal evolution during a full CR within 9 hours (1080 CPU cores, 1.5M cells). We also compare the simulation results of time-evolving versus quasi-steady-state coronal simulations in the thermodynamic MHD model to validate the time-evolving approach. Additionally, we evaluate the effect of time steps on the simulation results to find an optimal time step that simultaneously maintains high efficiency and necessary numerical stability and accuracy. Results. Consequently, we developed the first fully implicit time-evolving coronal model, and this highly efficient model is promising for timely and accurately simulating the time-evolving corona in practical space weather forecasting.

Toward a live homogeneous database of solar active regions based on SOHO/MDI and SDO/HMI synoptic magnetograms.II.parameters for solar cycle variability

Ruihui **Wang**, Jie Jiang, Yukun Luo

ApJ **971** 110 **2024**

https://arxiv.org/pdf/2405.06224

https://iopscience.iop.org/article/10.3847/1538-4357/ad5b5f/pdf

Solar active regions (ARs) determine solar polar fields and cause solar cycle variability within the framework of the Babcock-Leighton (BL) dynamo. The contribution of an AR to the polar field is measured by its dipole field, which results from flux emergence and subsequent flux transport over the solar surface. The dipole fields contributed by an AR before and after the flux transport are referred to as the initial and final dipole fields, respectively. For a better understanding and prediction of solar cycles, in this paper, we provide a database including AR's initial and final dipole fields and the corresponding results of their bipolar magnetic region (BMR) approximation from 1996 onwards. We also identify the repeated ARs and provide the optimized transport parameters. Based on our database, we find that although the commonly used BMR approximation performs well for the initial dipole field, it exhibits a significant deviation for the final dipole field. To accurately assess an AR's contribution to the polar field, the final dipole field with its real configuration should be applied. Despite the notable contributions of a few rogue ARs, approximately the top 500 ARs ordered by their final dipole fields are necessary to derive the polar field at the cycle minimum. While flux transport may increase or decrease the dipole field for an individual AR, its collective impact over all ARs in a cycle is a reduction in their total dipole field.

The Radial Interplanetary Field Strength at Sunspot Minimum as Polar Field Proxy and Solar Cycle Predictor

Y.-M. **Wang**1

2024 ApJL 961 L27

https://iopscience.iop.org/article/10.3847/2041-8213/ad1c65/pdf

The minimum value of the geomagnetic aa index has served as a remarkably successful predictor of solar cycle amplitude. This value is reached near or just after sunspot minimum, when both the near-Earth solar wind speed and interplanetary magnetic field (IMF) strength fall to their lowest values. At this time, the heliospheric current sheet is flattened toward the heliographic equator and the dominant source of the IMF is the Sun's axial dipole moment, which, in turn, has its source in the polar fields. As recognized previously, the success of aa min as solar cycle precursor provides support for dynamo models in which the sunspots of a given cycle are produced by winding up the poloidal field built up during the previous cycle. Because they are highly concentrated toward the poles by the surface meridional flow, the polar fields are difficult to measure reliably. Here we point out that the observed value of the radial IMF strength at solar minimum can be used to constrain the polar field measurements, and that this parameter, which is directly proportional to the Sun's axial dipole strength, may be an even better solar cycle predictor than geomagnetic activity.

Towards a live homogeneous database of solar active regions based on SOHO/MDI and SDO/HMI synoptic magnetograms. I. Automatic detection and calibration

Ruihui **Wang**, Jie Jiang, Yukun Luo

Astrophysical Journal Supplement Series **2023**

https://arxiv.org/pdf/2308.06914.pdf **File**

Recent studies indicate that a small number of rogue solar active regions (ARs) may have a significant impact on the end-of-cycle polar field and the long-term behavior of solar activity. The impact of individual ARs can be qualified based on their magnetic field distribution. This motivates us to build a live homogeneous AR database in a series of papers. As the first of the series, we develop a method to automatically detect ARs from 1996 onwards based on SOHO/MDI and SDO/HMI synoptic magnetograms. The method shows its advantages in excluding decayed ARs and unipolar regions and being compatible with any available synoptic magnetograms. The identified AR flux and area are calibrated based on the co-temporal SDO/HMI and SOHO/MDI data. The homogeneity and reliability of the database are further verified by comparing it with other relevant databases. We find that ARs with weaker flux have a weaker cycle dependence. Stronger ARs show the weaker cycle 24 compared with cycle 23. Several basic parameters, namely, location, area, and flux of negative and positive polarities of identified ARs are provided in the paper. This paves the way for AR's new parameters quantifying the impact on the long-term behavior of solar activity to be presented in the subsequent paper of the series. The constantly updated database covering more than two full solar cycles will be beneficial for the understanding and prediction of the solar cycle. The database and the detection codes are accessible online.

A comparative study of data-driven MHD simulations of solar coronal evolution with photospheric flows derived from two different approaches.

Xinyi **Wang**, Chaowei Jiang, Xueshang Feng, Boyi Wang, and Bo Chen

Front. Astron. Space Sci. 10: 1157304. **2023**

doi: 10.3389/fspas.2023.1157304

https://www.frontiersin.org/articles/10.3389/fspas.2023.1157304/pdf

Data-driven simulation proves to be a powerful tool in revealing the dynamic process of the solar corona, but it remains challenging to implement the driving boundary conditions in a self-consistent way and match the observables at the photosphere. Here, we test two different photospheric velocity-driven MHD simulations in studying the quasi-static evolution of solar active region NOAA 11158. The two simulations were identically initialized with an MHD equilibrium as relaxed from a non-linear force-free field extrapolation from a vector magnetogram. Then, we energized the MHD system by applying the time series of photospheric velocity at the bottom boundary as derived by two different codes, the DAVE4VM and PDFI, from the observed vector magnetograms. To mimic the small-scale flux cancellation on the photosphere, the magnetic diffusion at the bottom boundary was set to be inversely proportional to the local scale length of the magnetic field. The result shows the evolution curves of the total magnetic energy and unsigned magnetic flux generated by the PDFI velocity match the corresponding curves from the observations much better than those by the DAVE4VM one. The structure of the current layer and synthetic image in PDFI simulation also has a more reasonable consistency with SDO/AIA 131 Å observation. The only shortage of the PDFI velocity is its capability in reproducing the morphology of sunspots, as characterized by a slightly lower correlation coefficient for the bottom magnetic field in simulations and magnetograms. Overall, this study suggests the superiority of each method in the models driven by the bottom velocity, which represents a further step toward the goal of reproducing more realistically the evolution of coronal magnetic fields using data-driven modeling. **15 February 2011**

Implicit Solar Coronal Magnetohydrodynamic (MHD) Modeling with a Low-dissipation Hybridized AUSM-HLL Riemann Solver

In this paper, we develop a 3D implicit single-fluid magnetohydrodynamic (MHD) model to simulate the steady-state solar corona with a wide range of Mach numbers and low plasma β. We employ a low-dissipation advection upstream splitting method (AUSM) to calculate the convective flux in the regions of low Mach numbers for a high resolution, and hybridize the AUSM with Harten-Lax-van Leer Riemann solver in the regions of high Mach numbers to improve the solver's robustness. The inner boundary condition of no backflow is implemented by numerical flux. A reconstruction method based on the divergence-free radial basis function is adopted to enhance the divergence-free constraint of magnetic field. Also, an anisotropic thermal conduction term is considered; the positivity-preserving reconstruction method is used to prevent the presence of negative thermal pressure and plasma density, and the implicit lower-upper symmetric Gauss Seidel method is implemented for a better convergence rate. After establishing the implicit solar wind MHD model, we employ it to simulate steady-state solar coronal structures in Carrington rotations 2177 and 2212. The simulations demonstrate that the MHD model's computational efficiency is desirable, and the modeled results are basically in agreement with the solar coronal observations and the mapped in situ measurements from the OMNI archive. Consequently, this implicit MHD model is promising to simulate a complex plasma environment with high-intensity magnetic field and wide-ranging Mach numbers.

Undetected Minority-polarity Flux as the Missing Link in Coronal Heating

Y.-M. **Wang**
Solar Physics **volume 297**, Article number: 129 **2022**
https://arxiv.org/pdf/2206.11327.pdf
https://link.springer.com/content/pdf/10.1007/s11207-022-02060-y.pdf

During the last few decades, the most widely favored models for coronal heating have involved the in situ dissipation of energy, with footpoint shuffling giving rise to multiple current sheets (the "nanoflare" model) or to Alfv{é}n waves that leak into the corona and undergo dissipative interactions (the wave heating scenario). As has been recognized earlier, observations suggest instead that the energy deposition is concentrated at very low heights, with the coronal loops being filled with hot, dense material from below, which accounts for their overdensities and flat temperature profiles. While an obvious mechanism for footpoint heating would be reconnection with small-scale fields, this possibility seems to have been widely ignored because magnetograms show almost no minority-polarity flux inside active region (AR) plages. Here, we present further examples to support our earlier conclusions (1) that magnetograms greatly underrepresent the amount of minority-polarity flux inside plages and "unipolar" network, and (2) that small loops are a major constituent of \ion{Fe}{9} 17.1 nm moss. On the assumption that the emergence or churning rate of small-scale flux is the same inside plages as in mixed-polarity regions of the quiet Sun, we estimate the energy flux density associated with reconnection with the plage fields to be on the order of 107 erg cm−2 s−1, sufficient to heat the AR corona.

Variation in Cosmic-Ray Intensity Lags Sunspot Number: Implications of Late Opening of Solar Magnetic Field

Yuming **Wang**1,2,3, Jingnan Guo1,2, Gang Li4, Elias Roussos5, and Junwei Zhao6
2022 ApJ 928 157
https://iopscience.iop.org/article/10.3847/1538-4357/ac5896/pdf

Galactic cosmic rays (GCRs), the highly energetic particles that may raise critical health issues for astronauts in space, are modulated by solar activity, with their intensity lagging behind the variation in sunspot number (SSN) by about one year. Previously, this lag has been attributed to the combined effect of outward convecting solar wind and inward propagating GCRs. However, the lag's amplitude and its solar-cycle dependence are still not fully understood. By investigating the solar surface magnetic field, we find that the source of heliospheric magnetic field—the open magnetic flux on the Sun—already lags behind SSN before it convects into the heliosphere along with the solar wind. The delay during odd cycles is longer than that during sequential even cycles. Thus, we propose that the GCR lag is primarily due to the very late opening of the solar magnetic field with respect to SSN, though solar wind convection and particle transport in the heliosphere also matter. We further investigate the origin of the open flux from different latitudes of the Sun and find that the total open flux is significantly contributed by that from low latitudes, where coronal mass ejections frequently occur and also show an odd–even cyclic pattern. Our findings challenge existing theories, and may serve as the physical basis of long-term forecasts of radiation dose estimates for manned deep-space exploration missions.

Uncovering Intense Ancient Solar Activity from Naked-eye Observations of Egg-like Sunspots

Hongrui **Wang**1 and Huiduan Li1
2021 ApJ 921 159
https://doi.org/10.3847/1538-4357/ac2152
Ancient sunspot records written in classical Chinese provide important information regarding ancient solar activity. The Chinese recorded 14 observations of sunspots that resembled an egg (hereafter, egg record; the word egg is used to represent approximate sunspot sizes) before 1000 CE. However, the egg records in classical Chinese were too short to provide sufficient sunspot details. This study was conducted to decode egg records from 1769 and 1917 through telescopic sunspot observations. The results of our decoding show that egg-like sunspots were generally used by observers in East Asia to represent a very large sunspot group with an approximately elliptical outline. An egg record generally served as a marker of intense solar activity. Three egg records (in 1278, 1769, and 1917) were observed to be close to the solar maxima, with the time difference being smaller than 1 yr. Some egg records could thus be used to identify the solar maxima. The mean time difference between 10 egg records and the nearest solar maxima is 2 yr. Therefore, egg records can provide necessary information for uncovering additional intense solar activity from ancient times.

A New Reconstruction of the Sun's Magnetic Field and Total Irradiance since 1700

Y.-M. **Wang**1 and J. L. Lean3,2
2021 ApJ 920 100
https://doi.org/10.3847/1538-4357/ac1740
We model the Sun's large-scale magnetic field and total solar irradiance (TSI) since 1700 by combining flux transport simulations with empirical relationships between facular brightening, sunspot darkening, and the total photospheric flux. The photospheric field is evolved subject to the constraints that (1) the flux emergence rate scales as the yearly sunspot numbers, and (2) the polar field strength at solar minimum is proportional to the amplitude of the following cycle. Simulations are performed using both the recently revised sunspot numbers and an average of these numbers and the Hoyt–Schatten group numbers. A decrease (increase) in the polar field strength from one cycle to the next is simulated either by increasing (decreasing) the poleward flow speed, or by decreasing (increasing) the average axial tilts of active regions; the resulting photospheric field evolution is very similar whichever parameter is varied. Comparisons between irradiance data and both the simulated and observed photospheric field suggest that TSI and facular brightness increase less steeply with the field strength at solar minimum than at other phases of the cycle, presumably because of the dominance of small-scale ephemeral regions when activity is very low. This relative insensitivity of the irradiance to changes in the large-scale field during cycle minima results in a minimum-to-minimum increase of annual TSI from 1700 to 1964 (2008) of 0.2 (0.06) W m−2, a factor of 2–3 smaller than predicted in earlier reconstructions where the relation between facular brightness and field strength was assumed to be independent of cycle phase.

Naked emergence of an anti-Hale active region
I. Overall evolution and magnetic properties⋆

Jincheng **Wang**1,2,3, Xiaoli Yan1,3, Defang Kong1,3, Zhike Xue1,3, Liheng Yang1,3, Qiaoling Li1,4, Yan Zhang1,4 and Hao Li5,6
A&A 652, A55 (**2021**)
https://arxiv.org/abs/2106.02786
https://www.aanda.org/articles/aa/pdf/2021/08/aa40685-21.pdf
https://doi.org/10.1051/0004-6361/202140685
Aims. In order to understand the emergence of the active region, we investigate the emerging process and magnetic properties of a naked anti-Hale active region during the period between **August 24 to 25, 2018**.
Methods. Using the data from Helioseismic and Magnetic Imager on board the Soar Dynamic Observatory and the New Vacuum Solar Telescope, we calculated different evolving parameters (such as pole separation, tilt angle) and magnetic parameters (such as vertical electric current, force-free parameter, relative magnetic helicity) during the emergence of the active region. With these calculated parameters and some reasonable assumptions, we use two different methods to estimate the twist of the active region.
Results. The magnetic flux and pole separation continue increasing while the tilt angle exhibits a decreasing pattern during the emergence of the active region. The increase of the pole separation is mainly contributed as a result of the enhancement in the longitude direction. A power-law relationship between pole separation and total flux is found during the emergence of the active region. On the other hand, it is found that both the positive and negative electric currents increased equivalently and the average flux-weighted force-free parameter $\tilde{\alpha}$ remains almost consistently positive, on the order of ∼10−8 m−1. The relative magnetic helicity is mainly contributed by the shear term, while the relative magnetic helicity injection flux of the shear term changes its sign at the latter stage of the emergence.

The twist number of the whole active region remains on the order of 10−1 turns during the emergence of the active region.
Conclusions. We find that the magnetic flux tube with low twist also could emerge into the solar atmosphere.

Fast Magnetic Wave Could Heat the Solar Low-beta Chromosphere

Yikang **Wang**1, Takaaki Yokoyama2, and Haruhisa Iijima3,4
2021 ApJL 916 L10
https://arxiv.org/pdf/2107.13722
https://doi.org/10.3847/2041-8213/ac10c7
We perform two-dimensional radiative MHD simulation to investigate the propagation of MHD waves in the quiet region of the solar chromosphere. We identify the mode of the shock waves by using the relationship between gas pressure and magnetic pressure across the shock front and calculate their corresponding heating rate through the entropy jump to obtain a quantitative understanding of the wave-heating process in the chromosphere. Our result shows that the fast magnetic wave is significant in heating the low-beta chromosphere. The low-beta fast magnetic waves are generated from high-beta fast acoustic waves via mode conversion crossing the equipartition layer. Efficient mode conversion is achieved by large attacking angles between the propagation direction of the shock waves and the chromospheric magnetic field.

Algebraic quantification of an active region's contribution to the solar cycle

Zi-Fan **Wang**, Jie Jiang, Jing-Xiu Wang
A&A 650, A87 **2021**
https://arxiv.org/pdf/2104.04307.pdf
https://www.aanda.org/articles/aa/pdf/2021/06/aa40407-21.pdf
https://doi.org/10.1051/0004-6361/202140407
The solar dipole moment at cycle minimum is considered to be the most successful precursor for the amplitude of the subsequent cycle. Numerical simulations of the surface flux transport (SFT) model are widely used to effectively predict the dipole moment at cycle minimum. Recently an algebraic method has been proposed to quickly predict the contribution of an active region (AR) to the axial dipole moment at cycle minimum instead of SFT simulations. However, the method assumes a bipolar magnetic region (BMR) configuration of ARs. Actually most ARs are asymmetric in configuration of opposite polarities, or have more complex configurations. Such ARs evolve significantly differently from that of BMR approximations. We propose a generalized algebraic method to describe the axial dipole contribution of an AR with an arbitrary configuration, and evaluate its effectiveness compared to the BMR-based method. We employ mathematical deductions to obtain the generalized method. We compare the results of the generalized method with SFT simulations of observed ARs, artificially created BMRs, and ARs with more complex configurations. We also compare the results with that from the BMR-based method. The generalized method is equivalent to the SFT model, and precisely predicts the ARs' contributions to the dipole moment. The method has a much higher computational efficiency than SFT simulations. Although the BMR-based method has similar computational efficiency as the generalized method, it is only accurate for symmetric bipolar ARs. The BMR-based method systematically overestimates the dipole contributions of asymmetric bipolar ARs, and randomly miscalculate the contributions of more complex ARs. The generalized method provides a quick and precise quantification of an AR's contribution to the solar cycle evolution, which paves the way for the application into the physics-based solar cycle prediction.

Aurora Sightings Observed in Chinese History Caused by CIRs or Great-storm CMEs

Guowei **Wang**1,2, Shuo Yao1, Yiqun Yu3, Dong Wei3, Fei Di1, Xiujuan Bao1, Shihong Zhang1, and Jianjun Liu2
2021 ApJ 908 187
https://doi.org/10.3847/1538-4357/abd0fe
https://iopscience.iop.org/article/10.3847/1538-4357/abd0fe/pdf
Auroras observed at middle and low geographic latitudes are related to external inputs and varying geomagnetic fields. This work aims to exclude corotating interaction region (CIR) storms and identify strong coronal mass ejection (CME) storms according to historical auroral records when the geomagnetic field varies substantially. An existing catalog of the aurora records in Chinese history reported by Zeng & Jin from 193 B.C. to 1911 A.D. is used. Archaeomagnetic field models are adopted to estimate the variation of the dipole field. According to the empirical relation between the equatorward boundary of the auroral oval, Dst index, and geomagnetic field intensity, the auroras caused by CIRs can be excluded, and those caused by strong CMEs are identified. After 1500 A.D., China's magnetic latitude decreased substantially due to the pole shift. This shift provides a better opportunity to investigate the existence of great-level storms. These great-storm CMEs occurred in both solar maximum and minimum. The space weather modeling framework is used to calculate the cusp area and the downward ion flux through the cusp for varied geomagnetic field and solar wind. For the present solar wind condition and tilt angle <15°, stronger

geomagnetic field tends to generate a larger cusp area and higher ion flux through the cusp. For the weaker solar wind in the Maunder minimum, the ion flux is lower, but the cusp area is similar to that at present.

Slow-Mode Magnetoacoustic Waves in Coronal Loops **Review**

Tongjiang **Wang**, Leon Ofman, Ding Yuan, Fabio Reale, Dmitrii Y. Kolotkov, Abhishek K. Srivastava
Space Science Reviews **2021**
https://arxiv.org/pdf/2102.11376.pdf

Rapidly decaying long-period oscillations often occur in hot coronal loops of active regions associated with small (or micro-) flares. This kind of wave activity was first discovered with the SOHO/SUMER spectrometer from Doppler velocity measurements of hot emission lines, thus also often called "SUMER" oscillations. They were mainly interpreted as global (or fundamental mode) standing slow magnetoacoustic waves. In addition, increasing evidence has suggested that the decaying harmonic type of pulsations detected in light curves of solar and stellar flares are likely caused by standing slow-mode waves. The study of slow magnetoacoustic waves in coronal loops has become a topic of particular interest in connection with coronal seismology. We review recent results from SDO/AIA and Hinode/XRT observations that have detected both standing and reflected intensity oscillations in hot flaring loops showing the physical properties (e.g., oscillation periods, decay times, and triggers) in accord with the SUMER oscillations. We also review recent advances in theory and numerical modeling of slow-mode waves focusing on the wave excitation and damping mechanisms. MHD simulations in 1D, 2D and 3D have been dedicated to understanding the physical conditions for the generation of a reflected propagating or a standing wave by impulsive heating. Various damping mechanisms and their analysis methods are summarized. Calculations based on linear theory suggest that the non-ideal MHD effects such as thermal conduction, compressive viscosity, and optically thin radiation may dominate in damping of slow-mode waves in coronal loops of different physical conditions. Finally, an overview is given of several important seismological applications such as determination of transport coefficients and heating function.

Small-scale Flux Emergence, Coronal Hole Heating, and Flux-tube Expansion: A Hybrid Solar Wind Model

Y.-M. **Wang**
2020 ApJ 904 199
https://doi.org/10.3847/1538-4357/abbda6

Extreme-ultraviolet images from the Solar Dynamics Observatory often show loop-like fine structure to be present where no minority-polarity flux is visible in magnetograms, suggesting that the rate of ephemeral region (ER) emergence inside "unipolar" regions has been underestimated. Assuming that this rate is the same inside coronal holes as in the quiet Sun, we show that interchange reconnection between ERs and open field lines gives rise to a solar wind energy flux that exceeds 105 erg cm−2 s−1 and that scales as the field strength at the coronal base, consistent with observations. In addition to providing ohmic heating in the low corona, these reconnection events may be a source of Alfvén waves with periods ranging from the granular timescale of ~10 minutes to the supergranular/plume timescale of many hours, with some of the longer-period waves being reflected and dissipated in the outer corona. The asymptotic wind speed depends on the radial distribution of the heating, which is largely controlled by the rate of flux-tube expansion. Along the rapidly diverging flux tubes associated with slow wind, heating is concentrated well inside the sonic point (1) because the outward conductive heat-flux density and thus the outer coronal temperatures are reduced, and (2) because the net wave energy flux is dissipated at a rate proportional to the local Alfvén speed. In this "hybrid" solar wind model, reconnection heats the lower corona and drives the mass flux, whereas waves impart energy and momentum to the outflow at greater distances.

Solar modulation of cosmic proton and helium with AMS-02

Bing-Bing **Wang**, Xiao-Jun Bi, Kun Fang, Sujie Lin, Peng-Fei Yin
2020
https://arxiv.org/pdf/2011.12531.pdf

We investigate the solar modulation effect with the long time cosmic ray proton and helium spectrum measured by AMS-02 on the time scale of a Bartels rotation (27 days) between May 2011 and May 2017. The time-span covers the negative heliospheric magnetic field polarity cycle, the polarity reversal period and the positive polarity cycle. The unprecedented accuracy of AMS-02 observation data provide a good opportunity to improve the understanding of the time dependent solar modulation effect. In this work, a two-dimensional solar modulation model is used to compute the propagation of cosmic rays in the heliosphere. Some important ingredients of the model which reflect the global heliospherical environment are taken from the observations. The propagation equation is numerically solved with the pubic Solarprop code. We find that the drift effect is suppressed during the high solar activity period but nearly recovered in the first half of 2017. The time-dependent rigidity dependence of the mean free path is critical to reproduce the observations between August 2012 and October 2015.

Activity Complexes and A Prominent Poleward Surge During Solar Cycle 24

Zi-Fan **Wang**, Jie Jiang, Jie Zhang, Jing-Xiu Wang

ApJ **904** 62 **2020**

https://arxiv.org/pdf/2009.12483.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/abbc1e/pdf

https://doi.org/10.3847/1538-4357/abbc1e

Long-lasting activity complexes (ACs), characterised as a series of closely located, continuously emerging solar active regions (ARs), are considered generating prominent poleward surges from observations. The surges lead to significant variations of the polar field, which are important for the modulation of solar cycles. We aim to study a prominent poleward surge during solar cycle 24 on the southern hemisphere, and analyse its originating ACs and the effect on the polar field evolution. We automatically identify and characterize ARs based on synoptic magnetograms from the Solar Dynamic Observatory. We assimilate these ARs with realistic magnetic configuration into a surface flux transport model, and simulate the creation and migration of the surge. Our simulations well reproduce the characteristics of the surge and show that the prominent surge is mainly caused by the ARs belonging to two ACs during Carrington Rotations 2145-2159 (December 2013-January 2015). The surge has a strong influence on the polar field evolution of the southern hemisphere during the latter half of cycle 24. Without the about one-year-long flux emergence in the form of ACs, the polar field around the cycle minimum would have remained at a low level and even reversed to the polarity at cycle 23 minimum. Our study also shows that the long-lived unipolar regions due to the decay of the earlier emerging ARs cause an intrinsic difficulty of automatically identifying and precisely quantifying later emerging ARs in ACs.

HMI Science Nuggets №149 Dec **2020** http://hmi.stanford.edu/hminuggets/?p=3420

High-resolution Observations of Small-scale Flux Emergence by GST

Jiasheng **Wang**1,2,3, Chang Liu1,2,3, Wenda Cao1,2,3, and Haimin Wang1,2,3

2020 ApJ 900 84

https://doi.org/10.3847/1538-4357/aba696

https://arxiv.org/pdf/2009.06717

Recent observations demonstrated that emerging flux regions, which constitute the early stage of solar active regions, consist of emergence of numerous small-scale magnetic elements. They in turn interact, merge, and form mature sunspots. However, observations of fine magnetic structures on photosphere with subarcsecond resolution are very rare due to limitations of observing facilities. In this work, taking advantage of the high resolution of the 1.6 m Goode Solar Telescope, we jointly analyze vector magnetic fields, continuum images, and Hα observations of NOAA AR 12665 on **2017 July 13**, with the goal of understanding the signatures of small-scale flux emergence, as well as their atmospheric responses as they emerge through multiple heights in the photosphere and chromosphere. Under such a high resolution of $0\farcs1$–$0\farcs2$, our results confirm two kinds of small-scale flux emergence: magnetic flux sheet emergence associated with the newly forming granules, and the traditional magnetic flux loop emergence. With direct imaging in the broadband TiO, we observe that both types of flux emergence are associated with darkening of granular boundaries, while only flux sheets elongate granules along the direction of emerging magnetic fields and expand laterally. With a life span of 10 ~ 15 minutes, the total emerged vertical flux is on the order of 10^{18} Mx for both types of emergence. The magnitudes of the vertical and horizontal fields are comparable in the flux sheets, while the former is stronger in flux loops. Hα observations reveal transient brightenings in the wings in the events of magnetic loop emergence, which are most probably the signatures of Ellerman bombs.

Solar 11-Year Cycle Signal in Stratospheric Nitrogen Dioxide—Similarities and Discrepancies Between Model and NDACC Observations

Shuhui **Wang**, King-Fai Li, Diana Zhu, Stanley P. Sander, Yuk L. Yung, Andrea Pazmino & Richard Querel

Solar Physics volume 295, Article number: 117 (**2020**)

https://link.springer.com/content/pdf/10.1007/s11207-020-01685-1.pdf

NOx (NO2 and NO) plays an important role in controlling stratospheric ozone. Understanding the change in stratospheric NOx and its global pattern is important for predicting future changes in ozone and the corresponding implications on the climate. Stratospheric NOx is mainly produced by the reaction of N2O with the photochemically produced O(1D) and, therefore, it is expected to vary with changes in solar UV irradiance during the solar cycle. Previous studies on this topic, often limited by the relatively short continuous data, show puzzling results. The effect of the 1991 Pinatubo eruption might have caused interference in the data analysis. In this study, we examine the NO2 vertical column density (VCD) data from the Network for the Detection of Atmospheric Composition Change (NDACC). Data collected at 16 stations with continuous long-term observations covering the most recent Solar Cycles 23 and 24 were analyzed. We found positive correlations between changes in NO2 VCD and solar Lyman-αα over nine stations (mostly in the Northern Hemisphere) and negative correlations over three stations

(mostly in the Southern Hemisphere). The other four stations do not show significant NO2 solar-cycle signal. The varying NO2 responses from one location to another are likely due to different geo-locations (latitude and altitude). In particular, two high-altitude stations show the strongest positive NO2 solar-cycle signals. Our 1D chemical-transport model calculations help explain the altitude dependence of NO2 response to the solar cycle. NO2 solar-cycle variability is suggested to play an important role controlling O3 at an altitude range from ≈20 km≈20 km to near 60 km, while OH solar-cycle variability controls O3 at 40 – 90 km. While observations show both positive and negative NO2 responses to solar forcing, the 1D model predicts negative NO2 responses to solar UV changes throughout the middle atmosphere. 3D global model results suggest complex roles of dynamics in addition to photochemistry. The energetic particle-induced NO2 variabilities could also contribute significantly to the NO2 variability during solar cycles.

Concept of the Solar Ring Mission: Overview

Yuming **Wang**, Haisheng Ji, Yamin Wang, Lidong Xia, Chenglong Shen, Jingnan Guo, Quanhao Zhang, Zhenghua Huang, Kai Liu, Xiaolei Li, Rui Liu, Jingxiu Wang, Shui Wang
Science China Technological Sciences, **2020**
https://arxiv.org/pdf/2003.12728.pdf
The concept of the Solar Ring mission was gradually formed from L5/L4 mission concept, and the proposal of its pre-phase study was funded by the National Natural Science Foundation of China in November 2018 and then by the Strategic Priority Program of Chinese Academy of Sciences in space sciences in May 2019. Solar Ring mission will be the first attempt to routinely monitor and study the Sun and inner heliosphere from a full 360-degree perspective in the ecliptic plane. The current preliminary design of the Solar Ring mission is to deploy six spacecraft, grouped in three pairs, on a sub-AU orbit around the Sun. The two spacecraft in each group are separated by about 30 degrees and every two groups by about 120 degrees. This configuration with necessary science payloads will allow us to establish three unprecedented capabilities: (1) determine the photospheric vector magnetic field with unambiguity, (2) provide 360-degree maps of the Sun and the inner heliosphere routinely, and (3) resolve the solar wind structures at multiple scales and multiple longitudes. With these capabilities, the Solar Ring mission aims to address the origin of solar cycle, the origin of solar eruptions, the origin of solar wind structures and the origin of severe space weather events. The successful accomplishment of the mission will advance our understanding of the star and the space environment that hold our life and enhance our capability of expanding the next new territory of human. **3-4 April 2010, 1–2 August 2010, 2014-10-23, 10–16 September 2017**

Simulation of Alfvén Wave Propagation in the Magnetic Chromosphere with Radiative Loss: Effects of Nonlinear Mode Coupling on Chromospheric Heating

Yikang **Wang** and Takaaki Yokoyama
2020 ApJ 891 110
https://doi.org/10.3847/1538-4357/ab70b2
https://arxiv.org/pdf/2003.05796.pdf
We perform magnetohydrodynamic simulations to investigate the propagation of Alfvén waves in the magnetic chromosphere. We use the 1.5D expanding flux tube geometry setting and transverse perturbation at the bottom to generate the Alfvén wave. Compared with previous studies, our expansion is that we include the radiative loss term introduced by Carlsson & Leenaarts. We find that when an observation-based transverse wave generator is applied, the spatial distribution of the time-averaged radiative loss profile in our simulation is consistent with that in the classic atmospheric model. In addition, the energy flux in the corona is larger than the required value for coronal heating in the quiet region. Our study shows that the Alfvén wave-driven model has the potential to simultaneously explain chromospheric heating and how energy is transported to the corona.

Are Large Sunspots Dominant in Naked-eye Sunspot Observations for 1819–1918?

Hongrui **Wang** and Huiduan Li
2020 ApJ 890 134
https://doi.org/10.3847/1538-4357/ab6ddb
This article explores the sizes of sunspots as determined by naked-eye sunspot observations (NSOs). The international sunspot number (ISN), the group sunspot number, and the Greenwich photo-heliographic results (GPR) were utilized. According to the ISN results, 64% of NSOs from 1819 to 1918 have been identified as large sunspots. We found that the sunspot sizes had been considerably underestimated using the ISN data (compared to using the GPR data). About 40% of NSOs from 1819 to 1918 have been identified as giant sunspots, which have ranks of sunspot areas smaller than 5%. The results in this article indicate that the majority of NSOs are large sunspots. This calls into question the previous understanding that NSOs include sunspots of all sizes above the visibility limit.

Do Records of Sunspot Sightings Provide Reliable Indicators of Solar Maxima for 1613 – 1918?

Hongrui **Wang**, Huiduan Li
Solar Physics October **2019**, 294:138
https://link.springer.com/content/pdf/10.1007%2Fs11207-019-1528-1.pdf
Records of Sunspot Sightings (RSS) which were obtained by the naked eye without the aid of the telescope are essential to find the solar activity in the distant past. Intense solar activity or the solar maxima had been identified by using the RSS for several decades. However, the performance of the RSS as the indicators of the solar maxima has rarely been discussed with quantitative analysis. The RSS from 1613 to 1918 are accessed as the indicators of the solar maxima, by using the time difference between each RSS and the specific solar maxima. The results have shown that about 33% of the sunspot sightings were obtained within one year of the solar maxima and about 51% of the sunspot sightings were obtained within 2 years of the solar maxima. The average time error of identifying the solar maxima by the RSS is 2.52 years, during the period 1613 – 1918. If a certain amount of time error could be tolerated for the identification of the solar maxima, the RSS could be generally used as indicators of the solar maxima.

Flat-fielding of Full-disk Solar Images with a Gaussian-type Diffuser

Yiran **Wang**, Xianyong Bai, Siqing Liu, Yuanyong Deng, Zhiyong Zhang, Yueqiang Sun
Solar Physics September **2019**, 294:127
https://link.springer.com/content/pdf/10.1007%2Fs11207-019-1527-2.pdf
Full-disk solar chromospheric and photospheric images are widely used to monitor solar activity. Flat-fielding is a basic step during scientific data production. Here, a Gaussian-type diffuser is used to measure the flat-field of full-disk solar chromospheric and photospheric images. The effectiveness of the method is verified by theoretical simulation and practical measurement. First, the uniformity of the light source generated by the Gaussian diffuser and the sunlight, with a field of view the same as the full-disk solar image, is calculated. The full width at half maximum (FWHM) of the scatter angle of the Gaussian diffuser is one degree, such that the light source presents a Gaussian distribution. After the correction of the Gaussian background, the uniformity of the area light source is 99.6%, which can be regarded as a uniform area light source. Second, experiments are conducted on full-disk solar telescopes at Huairou solar observing station and Yangbajing station. The diffuser covers the entire entrance aperture when taking flat-field frames. Through qualitative and quantitative analysis of experimental results, it is confirmed that a revised flat-field frame can modify uniformity caused by various aspects of the telescope, including vignetting, non-uniformities of filters, and contamination of optical components.

Further Evidence for Looplike Fine Structure inside "Unipolar" Active Region Plages

Y.-M. **Wang**, I. Ugarte-Urra, J. W. Reep
The Astrophysical Journal, 885, 34 (**2019**)
https://arxiv.org/ftp/arxiv/papers/2104/2104.06633.pdf
Earlier studies using extreme-ultraviolet images and line-of-sight magnetograms from the Solar Dynamics Observatory (SDO) have suggested that active region (AR) plages and strong network concentrations often have small, looplike features embedded within them, even though no minority-polarity flux is visible in the corresponding magnetograms. Because of the unexpected nature of these findings, we have searched the SDO database for examples of inverted-Y structures rooted inside "unipolar" plages, with such jetlike structures being interpreted as evidence for magnetic reconnection between small bipoles and the dominant-polarity field. Several illustrative cases are presented from the period 2013--2015, all of which are associated with transient outflows from AR "moss." The triangular or dome-shaped bases have horizontal dimensions of ~2--4 Mm, corresponding to ~1--3 granular diameters. We also note that the spongy-textured Fe IX 17.1 nm moss is not confined to plages, but may extend into regions where the photospheric field is relatively weak or even has mixed polarity. We again find a tendency for bright coronal loops seen in the 17.1, 19.3, and 21.1 nm passbands to show looplike fine structure and compact brightenings at their footpoints. These observations provide further confirmation that present-day magnetograms are significantly underrepresenting the amount of minority-polarity flux inside AR plages and again suggest that footpoint reconnection and small-scale flux cancellation may play a major role in coronal heating, both inside and outside ARs. **2013 April 30, 2013 May 4, 2013 May 5, 2014 September 14, 2014 December 1, 2014 December 13–15, 2015 April 18, 2015 May 5, 2015 October 23, 2015 November 5, 2015 December 19**

Surface Flux Transport and the Evolution of the Sun's Polar Fields **Review**

Y.-M. **Wang**
Space Science Reviews **2017**, Volume 210, Issue 1–4, pp 351–365
The evolution of the polar fields occupies a central place in flux transport (Babcock–Leighton) models of the solar cycle. We discuss the relationship between surface flux transport and polar field evolution, focusing on two main issues: the latitudinal profile of the meridional flow and the axial tilts of active regions. Recent helioseismic observations indicate that the poleward flow speed peaks at much lower latitudes than inferred from magnetic feature tracking, which includes the effect of supergranular diffusion and thus does not represent the actual bulk

flow. Employing idealized simulations, we demonstrate that flow profiles that peak at mid latitudes give rise to overly strong and concentrated polar fields. We discuss the differences between magnetic and white-light measurements of tilt angles, noting the large uncertainties inherent in the sunspot group measurements and their tendency to underestimate the actual tilts. We find no clear evidence for systematic cycle-to-cycle variations in Joy's law during cycles 21–23. Finally, based on the observed evolution of the Sun's axial dipole component and polar fields up to the end of 2015, we predict that cycle 25 will be similar in amplitude to cycle 24.

Variation of Coronal Activity from the Minimum to Maximum of Solar Cycle 24 using Three Dimensional Coronal Electron Density Reconstructions from STEREO/COR1

Tongjiang **Wang**, Nelson L. Reginald, Joseph M. Davila, O. Chris St. Cyr, William T. Thompson
Solar Phys. 292:97 **2017**
https://arxiv.org/pdf/1706.05116.pdf

Three dimensional electron density distributions in the solar corona are reconstructed for 100 Carrington Rotations (CR 2054−2153) during 2007/03−2014/08 using the spherically symmetric method from polarized white-light observations with the STEREO/COR1. These three-dimensional electron density distributions are validated by comparison with similar density models derived using other methods such as tomography and a MHD model as well as using data from SOHO/LASCO-C2. Uncertainties in the estimated total mass of the global corona are analyzed based on differences between the density distributions for COR1-A and -B. Long-term variations of coronal activity in terms of the global and hemispheric average electron densities (equivalent to the total coronal mass) reveal a hemispheric asymmetry during the rising phase of Solar Cycle 24, with the northern hemisphere leading the southern hemisphere by a phase shift of 7−9 months. Using 14-CR (~13-month) running averages, the amplitudes of the variation in average electron density between Cycle 24 maximum and Cycle 23/24 minimum (called the modulation factors) are found to be in the range of 1.6−4.3. These modulation factors are latitudinally dependent, being largest in polar regions and smallest in the equatorial region. These modulation factors also show a hemispheric asymmetry, being somewhat larger in the southern hemisphere. The wavelet analysis shows that the short-term quasi-periodic oscillations during the rising and maximum phases of Cycle 24 have a dominant period of 7−8 months. In addition, it is found that the radial distribution of mean electron density for streamers at Cycle 24 maximum is only slightly larger (by ~30%) than at cycle minimum. **1–15 May 2013**

Initial In-flight Results: The Total Solar Irradiance Monitor on the FY-3C Satellite, an Instrument with a Pointing System

Hongrui **Wang**, Jin Qi, Huiduan Li, Wei Fang
Solar Physics January **2017**, 292:9

The total solar irradiance (TSI) has been recorded daily since October 2013 by the Total Solar Irradiance Monitor (TSIM) onboard the FY-3C satellite, which is mainly designed for Earth observation. The TSIM has a pointing system to perform solar tracking using a sun sensor. The TSI is measured by two electrical substitution radiometers with traceability to the World Radiation Reference. The TSI value measured with the TSIM on 2 October 2013 is \(1364.88~\mbox{W}\,\mbox{m}^{-2}\) with an uncertainty of \(1.08~\mbox{W}\,\mbox{m}^{-2}\). Short-term TSI variations recorded with the TSIM show good agreement with SOHO/VIRGO and SORCE/TIM. The data quality and accuracy of FY-3C/TSIM are much better than its predecessors on the FY-3A and FY-3B satellites, which operated in a scanning mode.

Instrument Description: The Total Solar Irradiance Monitor on the FY-3C Satellite, an Instrument with a Pointing System

Hongrui **Wang**, Yupeng Wang, Xin Ye, Dongjun Yang, Kai Wang, Huiduan Li, Wei Fang
Solar Physics January **2017**, 292:8

The Total Solar Irradiance Monitor (TSIM) onboard the nadir Feng Yun-3C (FY-3C) satellite provides measurements of the total solar irradiance with accurate solar tracking and sound thermal stability of its heat sink. TSIM/FY-3C mainly consists of the pointing system, the radiometer package, the thermal control system, and the electronics. Accurate solar tracking is achieved by the pointing system, which greatly improves the science data quality when compared with the previous TSIM/FY-3A and TSIM/FY-3B. The total solar irradiance (TSI) is recorded by TSIM/FY-3C about 26 times each day, using a two-channel radiometer package. One channel is used to perform routine observation, and the other channel is used to monitor the degradation of the cavity detector in the routine channel. From the results of the ground test, the incoming irradiance is measured by the routine channel (AR1) with a relative uncertainty of 592 ppm. A general description of the TSIM, including the instrument modules, uncertainty evaluation, and its operation, is given in this article.

Simulation of Quiet-Sun Hard X-rays Related to Solar Wind Superhalo Electrons

Wen **Wang**, Linghua Wang, Säm Krucker, and Iain Hannah
Solar Phys. Volume 291, Issue 5, pp 1357-1367 **2016**
http://arxiv.org/pdf/1605.06339.pdf
In this paper, we propose that the accelerated electrons in the quiet Sun could collide with the solar atmosphere to emit Hard X-rays (HXRs) via non-thermal bremsstrahlung, while some of these electrons would move upwards and escape into the interplanetary medium, to form a superhalo electron population measured in the solar wind. After considering the electron energy loss due to Coulomb collisions and the ambipolar electrostatic potential, we find that the sources of the superhalo could only occur high in the corona (at a heliocentric altitude >~ 1.9 R⊙ (the mean radius of the Sun), to remain a power-law shape of electron spectrum as observed by STEREO at 1AU near solar minimum (Wang et al., 2012). The modeled quiet-Sun HXRs related to the superhalo electrons fit well to a power-law spectrum, f ~ ε^(-γ), with an index γ ≈ 2.0"2.3 (3.3"3.7) at 10?100 keV, for the warm/cold thick-target (thin-target) emissions produced by the downward-traveling (upward-traveling) accelerated electrons. These simulated quiet-Sun spectra are significantly harder than the observed spectra of most solar HXR flares. Assuming that the quiet-Sun sources cover 5% of the solar surface, the modeled thin-target HXRs are more than six orders of magnitude weaker than the RHESSI upper limit for quiet-Sun HXRs (Hannah et al., 2010). Using the thick-target model for the downward-traveling electrons, the RHESSI upper limit restricts the number of downward-traveling electrons to at most ≈3 times the number of escaping electrons. This ratio is fundamentally different from what is observed during solar flares associated with escaping electrons where the fraction of downward-traveling electrons dominates by a factor of 100 to 1000 over the escaping population.

Coronal Mass Ejections and the Solar Cycle Variation of the Sun's Open Flux

Y.-M. **Wang** and N. R. Sheeley, Jr.
2015 ApJ 809 L24
The strength of the radial component of the interplanetary magnetic field (IMF), which is a measure of the Sun's total open flux, is observed to vary by roughly a factor of two over the 11 year solar cycle. Several recent studies have proposed that the Sun's open flux consists of a constant or "floor" component that dominates at sunspot minimum, and a time-varying component due to coronal mass ejections (CMEs). Here, we point out that CMEs cannot account for the large peaks in the IMF strength which occurred in 2003 and late 2014, and which coincided with peaks in the Sun's equatorial dipole moment. We also show that near-Earth interplanetary CMEs, as identified in the catalog of Richardson and Cane, contribute at most ~30% of the average radial IMF strength even during sunspot maximum. We conclude that the long-term variation of the radial IMF strength is determined mainly by the Sun's total dipole moment, with the quadrupole moment and CMEs providing an additional boost near sunspot maximum. Most of the open flux is rooted in coronal holes, whose solar cycle evolution in turn reflects that of the Sun's lowest-order multipoles.

Correlation Between CME Occurrence Rate and Current Helicity in the Global Magnetic Field of Solar Cycle 23

Chuanyu **Wang**, Mei Zhang
Solar Phys. **2015**
We investigate the correlation between the occurrence rate of the monthly coronal mass ejection (CME) and the magnitude of the current helicity in global magnetic field on the photosphere of solar cycle 23. We used the technique introduced by Pevtsov and Latushko (Astrophys. J. 528, 999,2000) to retrieve the vector magnetic field from longitudinal full-disk magnetograms, but applied a different method to calculate the current helicity and focused on the evolution of the magnitude of current helicity over a full solar cycle. We found that there is a close relationship between the variation of the current helicity in the global magnetic field and that of the monthly CME occurrence rate. This provides further evidence to support that helicity is an important ingredient for solar eruptions.

Solar Cycle Variation of the Sun's Low-Order Magnetic Multipoles: Heliospheric Consequences **Review**

Y.-M. **Wang**
Space Science Reviews December **2014**, Volume 186, Issue 1-4, pp 387-407
The Sun's dipole and quadrupole components play a central role in the solar cycle evolution of the interplanetary magnetic field (IMF). The long-term variation of the radial IMF component approximately tracks that of the total dipole moment, with additional contributions coming near sunspot maximum from the quadrupole moment and from CMEs. The axial and equatorial components of the dipole vary out of phase with each other over the solar cycle. The equatorial dipole, whose photospheric sources are subject to rotational shearing, decays on a timescale of ∼1 yr and must be continually regenerated by new sunspot activity; its fluctuating strength depends not only on the activity level, but also on the longitudinal phase relationships among the active regions. During cycles 21–23, the equatorial dipole and IMF reached their peak strength ∼2 yrs after sunspot maximum; conversely, large dips or "Gnevyshev gaps" occurred when active regions emerged longitudinally out of phase with each other. The 10Be-inferred phase shift in the IMF variation during the Maunder Minimum may be explained by a decrease in the amplitude of the equatorial dipole relative to the axial dipole, due either to a systematic weakening of the emerging bipoles or to an increase in their tilt angles. In mid-2012, during the polarity reversal of cycle 24, the nonaxisymmetric quadrupole component became so dominant that the heliospheric current sheet (HCS) split into two cylindrical components. Hemispheric asymmetries in sunspot activity give rise to an axisymmetric quadrupole component, which has combined with the axial dipole to produce a systematic southward displacement of the HCS since cycle 20.

Total Solar Irradiance Monitor for the FY-3B Satellite – Space Experiments and Primary Data Corrections

Hongrui **Wang**, Huiduan Li, Jin Qi, Wei Fang
Solar Phys., February **2015**, Volume 290, Issue 2, pp 645-655
We present space experiments of the Total Solar Irradiance Monitor (TSIM) on the FY-3B satellite. The total solar irradiance (TSI) has been measured by TSIM/FY-3B continuously for nearly four years, with some short data gaps. Overlapping measurements of the TSI are provided by the TSIM, with three electrical substitution radiometers that are mounted with different alignment angles onto the leading face of the satellite. TSI measurements are normalized to a distance of 1 AU and zero velocity with respect to the Sun. The relative uncertainty in the TSI measurements is 910 parts per million. TSI values measured with TSIM/FY-3B are around 1365 W m−2, slightly lower than VIRGO/SOHO and higher than TIM/SORCE values. Most of the time, it is found that short time-scale variations in TSI detected by TSIM/FY-3B agree with other space TSI instruments.

Validation of Spherically Symmetric Inversion by Use of a Tomographic Reconstructed Three-Dimensional Electron Density of the Solar Corona

Tongjiang **Wang**, Joseph M. Davila
Solar Phys., 2014
http://arxiv.org/pdf/1404.5925v1.pdf
Determination of the coronal electron density by the inversion of white-light polarized brightness (pB) measurements by coronagraphs is a classic problem in solar physics. An inversion technique based on the spherically symmetric geometry (Spherically Symmetric Inversion, SSI) was developed in the 1950s, and has been widely applied to interpret various observations. However, to date there is no study about uncertainty estimation of this method. In this study we present the detailed assessment of this method using a three-dimensional (3D) electron density in the corona from 1.5 to 4 Rsun as a model, which is reconstructed by tomography method from STEREO/COR1 observations during solar minimum in February 2008. We first show in theory and observation that the spherically symmetric polynomial approximation (SSPA) method and the Van de Hulst inversion technique are equivalent. Then we assess the SSPA method using synthesized pB images from the 3D density model, and find that the SSPA density values are close to the model inputs for the streamer core near the plane of the sky (POS) with differences generally less than a factor of two or so; the former has the lower peak but more spread in both longitudinal and latitudinal directions than the latter. We estimate that the SSPA method may resolve the coronal density structure near the POS with angular resolution in longitude of about 50 degrees. Our results confirm the suggestion that the SSI method is applicable to the solar minimum streamer (belt) as stated in some previous studies. In addition, we demonstrate that the SSPA method can be used to reconstruct the 3D coronal density, roughly in agreement with that by tomography for a period of low solar activity. We suggest that the SSI method is complementary to the 3D tomographic technique in some cases, given that the development of the latter is still an ongoing research effort.

Is Solar Cycle 24 Producing More Coronal Mass Ejections Than Cycle 23?

Y.-M. **Wang** and R. Colaninno
2014 ApJ 784 L27
Although sunspot numbers are roughly a factor of two lower in the current cycle than in cycle 23, the rate of coronal mass ejections (CMEs) appears to be at least as high in 2011-2013 as during the corresponding phase of the previous cycle, according to three catalogs that list events observed with the Large Angle and Spectrometric Coronagraph (LASCO). However, the number of CMEs detected is sensitive to such factors as the image cadence and the tendency (especially by human observers) to under-/overcount small or faint ejections during periods of high/low activity. In contrast to the total number, the total mass of CMEs is determined mainly by larger events. Using the mass measurements of 11,000 CMEs given in the manual CDAW catalog, we find that the mass loss rate remains well correlated with the sunspot number during cycle 24. In the case of the automated CACTus and SEEDS catalogs, the large increase in the number of CMEs during cycle 24 is almost certainly an artifact caused by the near-doubling of the LASCO image cadence after mid-2010. We confirm that fast CMEs undergo a much stronger solar-cycle variation than slow ones, and that the relative frequency of slow and less massive CMEs increases with decreasing sunspot number. We conclude that cycle 24 is not only producing fewer CMEs than cycle 23, but that these ejections also tend to be slower and less massive than those observed one cycle earlier.

On the Strength of the Hemispheric Rule and the Origin of Active-region Helicity

Y.-M. **Wang**
2013 ApJ 775 L46
Vector magnetograph and morphological observations have shown that the solar magnetic field tends to have negative (positive) helicity in the northern (southern) hemisphere, although only ~60%-70% of active regions appear to obey this "hemispheric rule." In contrast, at least ~80% of quiescent filaments and filament channels that form during the decay of active regions follow the rule. We attribute this discrepancy to the difficulty in determining the helicity sign of newly emerged active regions, which are dominated by their current-free component; as the transverse field is canceled at the polarity inversion lines, however, the axial component becomes dominant there, allowing a more reliable determination of the original active-region chirality. We thus deduce that the hemispheric rule is far stronger than generally assumed, and cannot be explained by stochastic processes. Earlier studies have shown that the twist associated with the axial tilt of active regions is too small to account for the observed helicity; here, both tilt and twist are induced by the Coriolis force acting on the diverging flow in the emerging flux tube. However, in addition to this east-west expansion about the apex of the loop, each of its legs must expand continually in cross section during its rise through the convection zone, thereby acquiring a further twist through the Coriolis force. Since this transverse pressure effect is not limited by drag or tension forces, the final twist depends mainly on the rise time, and may be large enough to explain the observed active-region helicity.

ASYMMETRIC SUNSPOT ACTIVITY AND THE SOUTHWARD DISPLACEMENT OF THE HELIOSPHERIC CURRENT SHEET

Y.-M. **Wang**1 and E. Robbrecht
2011 ApJ 736 136
Observations of the interplanetary magnetic field (IMF) have suggested a statistical tendency for the heliospheric current sheet (HCS) to be shifted a few degrees southward of the heliographic equator during the period 1965-2010, particularly in the years near sunspot minimum. Using potential-field source-surface extrapolations and photospheric flux-transport simulations, we demonstrate that this southward displacement follows from Joy's law and the observed hemispheric asymmetry in the sunspot numbers, with activity being stronger in the southern (northern) hemisphere during the declining (rising) phase of cycles 20-23. The hemispheric asymmetry gives rise to an axisymmetric quadrupole field, whose equatorial zone has the sign of the leading-polarity flux in the dominant hemisphere; during the last four cycles, the polarity of the IMF around the equator thus tended to match that of the north polar field both before and after polar field reversal. However, large fluctuations are introduced by the nonaxisymmetric field components, which depend on the longitudinal distribution of sunspot activity in either hemisphere. Consistent with this model, the HCS showed an average northward displacement during cycle 19, when the "usual" alternation was reversed and the northern hemisphere became far more active than the southern hemisphere during the declining phase of the cycle. We propose a new method for determining the north-south displacement of the HCS from coronal streamer observations.

Is there more global solar activity on the Sun?

J. X. **Wang**1, Y.Z. Zhang1, G.P. Zhou1, Y.Y. Wen1 and J. Jiang2

Solar and Stellar Variability: Impact on Earth and Planets, Proceedings IAU Symposium No. 264, **2009**, p. 251-256, A.G. Kosovichev, A.H. Andrei & J.-P. Rozelot, eds.
Y:\obridko\otchet09
There appear indications of more global activity on the Sun which is larger, much beyond the scale of solar active regions (ARs). These indications include formation, flaring and eruption of the trans-equatorial loops seen in EUV and X-rays, formation and eruption of transequatorial filaments, global magnetic connectivity in EUV dimming associated with halo-coronal mass ejections, wide spread of radio burst sources in meter wavelength in the solar corona, and quasi-simultaneous magnetic flux emergence in both hemispheres seen during some major solar events. With examples of a few major events in the last solar cycle we discuss the possibility that there is large or global-scale activity on the Sun. Its spatial scale is many times larger than that of AR and temporal scale is over 10 hours. The exemplified trans-equatorial loops are anchored in ARs and their activity is temporally associated with flares in ARs too. In some sense the flares in ARs appear either as a part of or a precursor of the more global activity. It is likely that the combination of the flares in ARs and the associated global activity is responsible to the major solar-terrestrial events. More efforts in understanding the global activity are undertaken.

Multi-Fluid Simulations of Upper Chromospheric Magnetic Reconnection with Helium-Hydrogen mixture

Q. M. **Wargnier**, J. Martinez-Sykora, V. H. Hansteen, B. De Pontieu
ApJ **2022**
https://arxiv.org/pdf/2211.02157.pdf
Our understanding of magnetic reconnection (MR) under chromospheric conditions remains limited. Recent observations have demonstrated the important role of ion-neutral interactions in the dynamics of the chromosphere. Furthermore, the comparison between spectral profiles and synthetic observations of reconnection events suggest that current MHD approaches appear to be inconsistent with observations. First, collisions and multi-thermal aspects of the plasma play a role in these regions. Second, hydrogen and helium ionization effects are relevant to the energy balance of the chromosphere. This work investigates multi-fluid multi-species (MFMS) effects on MR in conditions representative of the upper chromosphere using the multi-fluid Ebysus code. We compare an MFMS approach based on a helium-hydrogen mixture with a two-fluid MHD model based on hydrogen only. The simulations of MRs are performed in a Lundquist number regime high enough to develop plasmoids and instabilities. We study the evolution of the MR and compare the two approaches including the structure of the current sheet and plasmoids, the decoupling of the particles, the evolution of the heating mechanisms, and the composition. The presence of helium species leads to more efficient heating mechanisms than the two-fluid case. This scenario, which is out of reach of the two-fluid or single-fluid models, can reach transition region temperatures starting from upper chromospheric thermodynamic conditions, representative of a quiet Sun scenario. The different dynamics between helium and hydrogen species could lead to chemical fractionation and, under certain conditions, enrichment of helium in the strongest outflows. This could be of significance for recent observations of helium enrichment in the solar wind in switchbacks and CMEs.

Investigating Global Convective Dynamos with Mean-field Models: Full Spectrum of Turbulent Effects Required

Jörn **Warnecke**1, Matthias Rheinhardt2, Mariangela Viviani1,3, Frederick A. Gent2,4, Simo Tuomisto2, and Maarit J. Käpylä1,2,5
2021 ApJL 919 L13
https://doi.org/10.3847/2041-8213/ac1db5
The role of turbulent effects for dynamos in the Sun and stars continues to be debated. Mean-field (MF) theory provides a broadly used framework to connect these effects to fundamental magnetohydrodynamics. While inaccessible observationally, turbulent effects can be directly studied using global convective dynamo (GCD) simulations. We measure the turbulent effects in terms of turbulent transport coefficients, based on the MF framework, from an exemplary GCD simulation using the test-field method. These coefficients are then used as an input into an MF model. We find a good agreement between the MF and GCD solutions, which validates our theoretical approach. This agreement requires all turbulent effects to be included, even those which have been regarded as unimportant so far. Our results suggest that simple dynamo models, as are commonly used in the solar and stellar community, relying on very few, precisely fine-tuned turbulent effects, may not be representative of the full dynamics of dynamos in global convective simulations and astronomical objects.

Consistent transport properties in multicomponent two-temperature magnetized plasmas *Application to the Sun atmosphere*

Q. **Wargnier**1, A. Alvarez Laguna1,2, J. B. Scoggins1, N. N. Mansour4, M. Massot1 and T. E. Magin1,2,3
A&A 635, A87 (**2020**)
https://www.aanda.org/articles/aa/pdf/2020/03/aa34686-18.pdf
Aims. We present a fluid model that has been developed for multicomponent two-temperature magnetized plasmas in chemical non-equilibrium for the partially to fully ionized collisional regimes. We focus on transport phenomena with the aim of representing the atmosphere of the Sun.
Methods. This study is based on an asymptotic fluid model for multicomponent plasmas derived from kinetic theory, yielding a rigorous description of the dissipative effects. The governing equations and consistent transport properties are obtained using a multiscale Chapman-Enskog perturbative solution to the Boltzmann equation based on a dimensional analysis. The mass disparity between free electrons and heavy particles is accounted for, as well as the influence of the electromagnetic field. We couple this model to the Maxwell equations for the electromagnetic field and derive the generalized Ohm's law for multicomponent plasmas. The model inherits a well-identified mathematical structure leading to an extended range of validity for the Sun's atmospheric conditions. We compute consistent transport properties by means of a spectral Galerkin method using the Laguerre-Sonine polynomial approximation. Two non-vanishing polynomial terms are used when deriving the transport systems for electrons, whereas only one term is retained for heavy particles.
Results. In a simplified framework where the plasma is fully ionized, we compare the transport properties for the lower solar atmosphere to conventional expressions for magnetized plasmas attributed to Braginskii, showing a good agreement between both results. For more general partially ionized conditions, representative of the lower solar atmosphere, we compute the muticomponent transport properties corresponding to the species diffusion velocities, heavy-particle and electron heat fluxes, and viscous stress tensor of the model for a helium-hydrogen mixture in local thermodynamic equilibrium. The model is assessed for the 3D radiative magnetohydrodynamic simulation of a pore at the Sun photosphere. The resistive term is found to dominate mainly the dynamics of the electric field at the pore location. The battery term for heavy particles appears to be higher at the pore location and at some intergranulation boundaries.

Small-scale and large-scale dynamos in global convection simulations of solar-like stars

Jörn **Warnecke**, Maarit J. Korpi-Lagg, Matthias Rheinhard, Mariangela Viviani, Ameya Prabhu
A&A **2024**
https://arxiv.org/pdf/2406.08967
It has been recently shown that a small-scale dynamo (SSD) instability could be possible in solar-like low magnetic Prandtl number Pm plasmas. It has been proposed that the presence of SSD can potentially have a significant impact on the dynamics of the large-scale dynamo (LSD) in the stellar convection zones. Studying these two dynamos, SSD and LSD, together in a global magnetoconvection model requires high-resolution simulations and large amounts of computational resources. Starting from a well-studied global convective dynamo model that produces cyclic magnetic fields, we systematically increased the resolution and lowered the diffusivities to enter the regime of Reynolds numbers that allow for the excitation of SSD on top of the LSD. We studied how the properties of convection, generated differential rotation profiles, and LSD solutions change with the presence of SSD. We performed convective dynamo simulations in a spherical wedge with the Pencil Code. The resolutions of the models were increased in 4 steps by a total factor of 16 to achieve maximal fluid and magnetic Reynolds numbers of over 500. We found that the differential rotation is strongly quenched by the presence of the LSD and SSD. Even though the small-scale magnetic field only mildly decreases increasing Re, the large-scale field strength decreases significantly. We do not find the SSD dynamo significantly quenching the convective flows as claimed recently by other authors; in contrast, the convective flows first grow and then saturate for increasing Re. Furthermore, the angular momentum transport is highly affected by the presence of small-scale magnetic fields, which are mostly generated by LSD. These fields not only change the Reynolds stresses, but also generate dynamically important Maxwell stresses. The LSD evolution in terms of its pattern and field distribution is rather independent of the increase in Rm.

Numerical evidence for a small-scale dynamo approaching solar magnetic Prandtl numbers

Jörn **Warnecke**, Maarit J. Korpi-Lagg, Frederick A. Gent, Matthias Rheinhardt
Nature **2023** (2021)
https://arxiv.org/pdf/2306.03991.pdf
Magnetic fields on small scales are ubiquitous in the universe. Though they can often be observed in detail, their generation mechanisms are not fully understood. One possibility is the so-called small-scale dynamo (SSD). Prevailing numerical evidence, however, appears to indicate that an SSD is unlikely to exist at very low magnetic Prandtl numbers (PrM) such as are present in the Sun and other cool stars. We have performed high-resolution simulations of isothermal forced turbulence employing the lowest PrM values so far achieved. Contrary to earlier findings, the SSD turns out to be not only possible for PrM down to 0.0031, but even becomes increasingly easier to

excite for PrM below ≃0.05. We relate this behaviour to the known hydrodynamic phenomenon referred to as the bottleneck effect. Extrapolating our results to solar values of PrM indicates that an SSD would be possible under such conditions.

Investigating global convective dynamos with mean-field models: full spectrum of turbulent effects required

Jörn **Warnecke**, Matthias Rheinhardt, Mariangela Viviani, Frederick Gent, Simo Tuomisto, Maarit J. Käpylä

ApJL **2021**

https://arxiv.org/pdf/2105.07708.pdf

Turbulent effects are argued to be essential for dynamos in the Sun and stars. While inaccessible observationally, they can be directly studied using global convective dynamo (GCD) simulations. We measure these turbulent effects, in terms of turbulent transport coefficients, from an exemplary GCD simulation using the test-field method. These coefficients are then used as an input into a mean-field (MF) model. We find a good agreement between the MF and GCD solutions, which validates our theoretical approach. This agreement requires all turbulent effects to be included, even those which have been regarded unimportant so far. Our results suggest that simple dynamo models as are commonly used in the solar and stellar community, relying on very few, precisely fine-tuned turbulent effects, may not be representative of the full dynamics of GCDs in astronomical objects.

On the influence of magnetic helicity on X-rays emission of solar and stellar coronae

Jörn **Warnecke**, Hardi Peter, (Max-Planck-Institut für Sonnensystemforschung)

A&A **2019**

https://arxiv.org/pdf/1910.06896.pdf

Observation of solar-like stars show a clear relation between X-ray emission and their rotation. Higher stellar rotation can lead to a larger magnetic helicity production in stars. We aim to understand the relation between magnetic helicity on the surface of a star to their coronal X-ray emission. We use 3D MHD simulations to model the corona of the solar-like stars. We take an observed magnetogram as in photospheric activity input, and inject different values of magnetic helicity. We use synthesis emission to calculate the X-ray emission flux of each simulation and investigate how this scales with injected magnetic helicity. We find that for larger injected magnetic helicities an increase in temperature and an increase in X-ray emission. The X-ray emission scaled cubicly with the injected helicity. We can related this to increase of horizontal magnetic field and therefore higher Poynting flux at the coronal base. Using typical scaling of magnetic helicity production with stellar rotation, we can explain the increase of X-ray emission with rotation only by an increase of magnetic helicity at the surface of a star.

Data-driven model of the solar corona above an active region

Jörn **Warnecke**, Hardi Peter (Max-Planck-Institut f\"ur Sonnensystemforschung)

A&A letters **2019**

https://arxiv.org/pdf/1903.00455.pdf

In this study we aim to reproduce the structure of the corona above a solar active region as seen in the extreme ultraviolet (EUV) using a three-dimensional magnetohydrodynamic (3D MHD) model. The 3D MHD data-driven model solves the induction equation and the mass, momentum and energy balance. To drive the system, we feed the observed evolution of the magnetic field in the photosphere of the active region AR 12139 into the bottom boundary. This creates a hot corona above the cool photosphere in a self-consistent way. We synthesize the coronal EUV emission from the densities and temperatures in the model and compare this to the actual coronal observations. We are able to reproduce the overall appearance and key features of the corona in this active region. The model shows long loops, fan loops, compact loops and diffuse emission forming at the same locations at similar times as in the observation. Furthermore, the low intensity contrast of the model loops in EUV matches the observations. In our model the energy input into the corona is similar as in the scenarios of fieldline-braiding or fluxtube tectonics, i.e. through the driving of the vertical magnetic field by horizontal photospheric motions. The success of our model shows the central role this process plays for the structure, dynamics and heating of the corona. **16 August 2014**

Non-Fourier description of heat flux evolution in 3D MHD simulations of the solar corona

Jörn **Warnecke** (1), Sven Bingert

Geophysical and Astrophysical Fluid Dynamics **2018**

https://arxiv.org/pdf/1811.01572.pdf

The hot loop structures in the solar corona can be well modeled by three dimensional magnetohydrodynamic simulations, where the corona is heated by field line braiding driven at the photosphere. To be able to reproduced the emission comparable to observations, one has to use realistic values for the Spitzer heat conductivity, which puts a large constrain on the time step of these simulations and therefore make them computationally expensive. Here, we present a non-Fourier description of the heat flux evolution, which allow us to speed up the simulations

significantly. Together with the semi-relativistic Boris correction, we are able to limit the time step constrain of the Alfvén speed and speed up the simulations even further. We discuss the implementation of these two methods to the \PC and present their implications on the time step, and the temperature structures, the ohmic heating rate and the emission in simulations of the solar corona. We find that with the use of the non-Fourier description of the heat flux evolution and the Boris correction, we can increase the time step of the simulation significantly without moving far away from the reference solution. However, for too low values of the Alfvén speed limit, the simulation moves away from the reference solution und produces much higher temperatures and stronger emission structures.

Dynamo cycles in global convection simulations of solar-like stars

Jörn **Warnecke** (Max-Planck-Institut für Sonnensystemforschung)

A&A **2017**

https://arxiv.org/pdf/1712.01248.pdf

Several solar-like stars exhibit magnetic activity similar to the Sun. We want to understand the rotational dependency of these activity cycle periods. We use three dimensional magnetohydrodynamical simulations of global convective dynamo models of solar-like stars to investigate the rotational dependency of dynamos. We further apply the test-field method to determine the α effect in these simulations. We find dynamo with clear oscillating mean magnetic fields for moderately and rapidly rotating runs. For slower rotation, the field is constant or exhibit irregular cycles. In the moderately and rapidly rotating regime the cycle periods increase weakly with rotation. This behavior can be well explained with a Parker-Yoshimura dynamo wave traveling equatorward. Even though the α effect becomes stronger for increasing rotation, the shear decreases steeper, causing this weak dependence on rotation. Similar as other numerical studies, we find no indication of activity branches as suggested by Brandenburg et al. (1998). However, our simulation seems to agree more with the transitional branch suggested by Distefano et al. (2017). If the Sun exhibit a dynamo wave similar as we find in our simulations, it would operate deep inside the convection zone.

Influence of a coronal envelope as a free boundary to global convective dynamo simulations

J. **Warnecke**1,2, P. J. Käpylä3,2,1,4, M. J. Käpylä1,2 and A. Brandenburg

A&A 596, A115 (**2016**)

Aims. We explore the effects of an outer stably stratified coronal envelope on rotating turbulent convection, differential rotation, and large-scale dynamo action in spherical wedge models of the Sun.
Methods. We solve the compressible magnetohydrodynamic equations in a two-layer model with unstable stratification below the surface, representing the convection zone, and a stably stratified coronal envelope above. The interface represents a free surface. We compare our model to models that have no coronal envelope.
Results. The presence of a coronal envelope is found to modify the Reynolds stress and the Λ effect resulting in a weaker and non-cylindrical differential rotation. This is related to the reduced latitudinal temperature variations that are caused by and dependent on the angular velocity. Some simulations develop a near-surface shear layer that we can relate to a sign change in the meridional Reynolds stress term in the thermal wind balance equation. Furthermore, the presence of a free surface changes the magnetic field evolution since the toroidal field is concentrated closer to the surface. In all simulations, however, the migration direction of the mean magnetic field can be explained by the Parker-Yoshimura rule, which is consistent with earlier findings.
Conclusions. A realistic treatment of the upper boundary in spherical dynamo simulations is crucial for the dynamics of the flow and magnetic field evolution.

Bipolar region formation in stratified two-layer turbulence

Jörn **Warnecke** (1,2), Illa R. Losada (2,3), Axel Brandenburg (2,3,4,5), Nathan Kleeorin (6,2), Igor Rogachevskii

A&A **2016**

https://arxiv.org/pdf/1502.03799v4.pdf

This work presents an extensive study of the previously discovered formation of bipolar flux concentrations in a two-layer model. We interpret the formation process in terms of negative effective magnetic pressure instability (NEMPI), which is a possible mechanism to explain the origin of sunspots. In our simulations, we use a Cartesian domain of isothermal stratified gas that is divided into two layers. In the lower layer, turbulence is forced with transverse nonhelical random waves, whereas in the upper layer no flow is induced. A weak uniform magnetic field is imposed in the entire domain at all times. In this study we vary the stratification by changing the gravitational acceleration, magnetic Reynolds number, strength of the imposed magnetic field, and size of the domain to investigate their influence on the formation process. Bipolar magnetic structure formation takes place over a large range of parameters. The magnetic structures become more intense for higher stratification until the density contrast becomes around 100 across the turbulent layer. For the Reynolds numbers considered, magnetic flux concentrations are generated at magnetic Prandtl number between 0.1 and 1. The magnetic field in bipolar regions increases with

higher imposed field strength until the field becomes comparable to the equipartition field strength of the turbulence. A larger horizontal extent enables the flux concentrations to become stronger and more coherent. The size of the bipolar structures turns out to be independent of the domain size. In the case of bipolar region formation, we find an exponential growth of the large-scale magnetic field, which is indicative of a hydromagnetic instability. Additionally, the flux concentrations are correlated with strong large-scale downward and converging flows. These findings imply that NEMPI is responsible for magnetic flux concentrations.

Cause of equatorward migration in global convective dynamo simulations

Jörn **Warnecke** (1,2), Petri J. Käpylä (3,2), Maarit J. Käpylä (2), Axel Brandenburg
ApJL, **2014**

We present results from four convectively-driven stellar dynamo simulations in spherical wedge geometry. All of these simulations produce cyclic and migrating mean magnetic fields. Through detailed comparisons we show that the migration direction can be explained by an αΩ dynamo wave following the Parker--Yoshimura rule. We conclude that the equatorward migration in this and previous work is due to a positive (negative) α effect in the northern (southern) hemisphere and a negative radial gradient of Ω outside the inner tangent cylinder of these models. This idea is supported by a strong correlation between negative radial shear and toroidal field strength in the region of equatorward propagation.

A Multicomponent Magnetic Proxy for Solar Activity

Harry P. **Warren**,Linton E. Floyd,Lisa A. Upton
Space Weather **Volume19, Issue12** e2021SW002860 **2021**
https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2021SW002860
https://doi.org/10.1029/2021SW002860

We present a new, multicomponent magnetic proxy for solar activity derived from full disk magnetograms that can be used in the specification and forecasting of the Sun's radiative output. To compute this proxy we project Carrington maps, such as the synchronic Carrington maps computed with the Advective Flux Transport (AFT) surface flux transport model, to heliographic cartesian coordinates and determine the total unsigned flux as a function of absolute magnetic flux density. Performing this calculation for each day produces an array of time series, one for each flux density interval. Since many of these time series are strongly correlated, we use principal component analysis to reduce them to a smaller number of uncorrelated time series. We show that the first few principal components accurately reproduce widely used proxies for solar activity, such the the 10.7 cm radio flux and the Mg core-to-wing ratio. This suggests that these magnetic time series can be used as a proxy for irradiance variability for emission formed over a wide range of temperatures.

Observation and Modeling of High-temperature Solar Active Region Emission during the High-resolution Coronal Imager Flight of 2018 May 29

Harry P. **Warren**, Jeffrey W. Reep, Nicholas A. Crump, Ignacio Ugarte-Urra, David H. Brooks, Amy R. Winebarger, Sabrina Savage, Bart De Pontieu, Hardi Peter, Jonathan W. Cirtain, Leon Golub, Ken Kobayashi, David McKenzie, Richard Morton, Laurel Rachmeler, Paola Testa, Sanjiv Tiwari, and Robert Walsh
2020 ApJ 896 51
https://doi.org/10.3847/1538-4357/ab917c

Excellent coordinated observations of NOAA active region 12712 were obtained during the flight of the High-resolution Coronal Imager (Hi-C) sounding rocket on **2018 May 29**. This region displayed a typical active region core structure with relatively short, high-temperature loops crossing the polarity inversion line and bright "moss" located at the footpoints of these loops. The differential emission measure (DEM) in the active region core is very sharply peaked at about 4 MK. Further, there is little evidence for impulsive heating events in the moss, even at the high spatial resolution and cadence of Hi-C. This suggests that active region core heating is occurring at a high frequency and keeping the loops close to equilibrium. To create a time-dependent simulation of the active region core, we combine nonlinear force-free extrapolations of the measured magnetic field with a heating rate that is dependent on the field strength and loop length and has a Poisson waiting time distribution. We use the approximate solutions to the hydrodynamic loop equations to simulate the full ensemble of active region core loops for a range of heating parameters. In all cases, we find that high-frequency heating provides the best match to the observed DEM. For selected field lines, we solve the full hydrodynamic loop equations, including radiative transfer in the chromosphere, to simulate transition region and chromospheric emission. We find that for heating scenarios consistent with the DEM, classical signatures of energy release, such as transition region brightenings and chromospheric evaporation, are weak, suggesting that they would be difficult to detect.

Sparse Bayesian Inference and the Temperature Structure of the Solar Corona

Harry P. **Warren**, Jeff M. Byers, Nicholas A. Crump
ApJ **2016**

https://arxiv.org/pdf/1610.05972v1.pdf
Measuring the temperature structure of the solar atmosphere is critical to understanding how it is heated to high temperatures. Unfortunately, the temperature of the upper atmosphere cannot be observed directly, but must be inferred from spectrally resolved observations of individual emission lines that span a wide range of temperatures. Such observations are "inverted" to determine the distribution of plasma temperatures along the line of sight. This inversion is ill-posed and, in the absence of regularization, tends to produce wildly oscillatory solutions. We introduce the application of sparse Bayesian inference to the problem of inferring the temperature structure of the solar corona. Within a Bayesian framework a preference for solutions that utilize a minimum number of basis functions can be encoded into the prior and many ad hoc assumptions can be avoided. We demonstrate the efficacy of the Bayesian approach by considering a test library of 40 assumed temperature distributions.

Transition Region Abundance Measurements During Impulsive Heating Events

Harry P. **Warren**, David H. Brooks, George A. Doschek, Uri Feldman
ApJ 824 56 **2016**
http://arxiv.org/pdf/1512.04447v1.pdf
It is well established that elemental abundances vary in the solar atmosphere and that this variation is organized by first ionization potential (FIP). Previous studies have shown that in the solar corona low-FIP elements, such as Fe, Si, Mg, and Ca, are generally enriched relative to high-FIP elements, such as C, N, O, Ar, and Ne. In this paper we report on measurements of plasma composition made during impulsive heating events observed at transition region temperatures with the Extreme Ultraviolet Imaging Spectrometer (EIS) on Hinode. During these events the intensities of O IV, V, and VI emission lines are enhanced relative to emission lines from Mg V, VI, and VII and Si VI and VII and indicate a composition close to that of the photosphere. Long-lived coronal fan structures, in contrast, show an enrichment of low-FIP elements. We conjecture that the plasma composition is an important signature of the coronal heating process, with impulsive heating leading to the evaporation of unfractionated material from the lower layers of the solar atmosphere and higher frequency heating leading to long-lived structures and the accumulation of low-FIP elements in the corona.

The Effect of the Chromospheric Temperature on Coronal Heating

Haruka **Washinoue**, Munehito Shoda, Takeru K. Suzuki
ApJ **938** 126 **2022**
https://arxiv.org/pdf/2209.10156
https://iopscience.iop.org/article/10.3847/1538-4357/ac91c8/pdf
Recent observational and numerical studies show a variety of thermal structures in the solar chromosphere. Given that the thermal interplay across the transition region is a key to coronal heating, it is worth investigating how different thermal structures of the chromosphere yield different coronal properties. In this work, by MHD simulations of Alfvén-wave heating of coronal loops, we study how the coronal properties are affected by the chromospheric temperature. To this end, instead of solving the radiative transfer equation, we employ a simple radiative loss function so that the chromospheric temperature is easily tuned. When the chromosphere is hotter, because the chromosphere extends to a larger height, the coronal part of the magnetic loop becomes shorter, which enhances the conductive cooling. A larger loop length is therefore required to maintain the high-temperature corona against the thermal conduction. From our numerical simulations we derive a condition for the coronal formation with respect to the half loop length lloop in a simple form: lloop>aTmin+lth, where Tmin is the minimum temperature in the atmosphere and parameters a and lth have negative dependencies on the coronal field strength. Our conclusion is that the chromospheric temperature has a non-negligible impact on coronal heating for loops with small length and weak coronal field. In particular, the enhanced chromospheric heating could prevent the formation of the corona.

Catastrophic cooling in optically thin plasmas

Tim **Waters**, Amanda Stricklan
ApJ **2024**
https://arxiv.org/pdf/2408.15869
The solar corona is the prototypical example of a low density environment heated to high temperatures by external sources. The plasma cools radiatively, and because it is optically thin to this radiation, it becomes possible to model the density, velocity, and temperature structure of the system by modifying the MHD equations to include energy source terms that approximate the local heating and cooling rates. The solutions can be highly inhomogeneous and even multiphase because the well known linear instability associated with these source terms, thermal instability, leads to a catastrophic heating and cooling of the plasma in the nonlinear regime. Here we show that there is a separate, much simpler instance of catastrophic heating and cooling accompanying these source terms that can rival thermal instability in dynamical importance. The linear stability criterion is the isochoric one identified by Parker (1953), and we demonstrate that cooling functions derived from collisional ionization equilibrium are highly prone

to violating this criterion. If catastrophic cooling instability can act locally in global simulations, then it is an alternative mechanism for forming condensations, and due to its nonequilibrium character, it may be relevant to explaining a host of phenomena associated with the production of cooler gas in hot, low density plasmas.

25 Years of Self-organized Criticality: Concepts and Controversies **Review**

Nicholas W. **Watkins** , Gunnar Pruessner, Sandra C. Chapman, Norma B. Crosby, Henrik J. Jensen

Space Science Reviews January **2016**, Volume 198, Issue 1, pp 3-44 **Open Access**

Introduced by the late Per Bak and his colleagues, self-organized criticality (SOC) has been one of the most stimulating concepts to come out of statistical mechanics and condensed matter theory in the last few decades, and has played a significant role in the development of complexity science. SOC, and more generally fractals and power laws, have attracted much comment, ranging from the very positive to the polemical. The other papers (Aschwanden et al. in Space Sci. Rev., 2014, this issue; McAteer et al. in Space Sci. Rev., 2015, this issue; Sharma et al. in Space Sci. Rev. 2015, in preparation) in this special issue showcase the considerable body of observations in solar, magnetospheric and fusion plasma inspired by the SOC idea, and expose the fertile role the new paradigm has played in approaches to modeling and understanding multiscale plasma instabilities. This very broad impact, and the necessary process of adapting a scientific hypothesis to the conditions of a given physical system, has meant that SOC as studied in these fields has sometimes differed significantly from the definition originally given by its creators. In Bak's own field of theoretical physics there are significant observational and theoretical open questions, even 25 years on (Pruessner 2012). One aim of the present review is to address the dichotomy between the great reception SOC has received in some areas, and its shortcomings, as they became manifest in the controversies it triggered. Our article tries to clear up what we think are misunderstandings of SOC in fields more remote from its origins in statistical mechanics, condensed matter and dynamical systems by revisiting Bak, Tang and Wiesenfeld's original papers.

Erratum: Space Science Reviews January **2016**, Volume 198, Issue 1, p 45

Solar Cycle Related Changes in the Helium Ionization Zones of the Sun

Courtney B. **Watson**, Sarbani Basu

ApJL **903** L29 **2020**

https://arxiv.org/pdf/2010.11215.pdf

https://doi.org/10.3847/2041-8213/abc348

Helioseismic data for solar cycles 23 and 24 have shown unequivocally that solar dynamics changes with solar activity. Changes in solar structure have been more difficult to detect. Basu & Mandel (2004) had claimed that the then available data revealed changes in the HeII ionization zone of the Sun. The amount of change, however, indicated the need for larger than expected changes in the magnetic fields. Now that helioseismic data spanning two solar cycles are available, we have redone the analysis using improved fitting techniques. We find that there is indeed a change in the region around the HeII ionization zone that is correlated with activity. Since the data sets now cover two solar cycles, the time variation is easily discernible.

A Multi-instrument Analysis of Sunspot Umbrae

F. T. **Watson**, M. J. Penn, and W. Livingston

2014 ApJ 787 22

The recent solar minimum and rise phase of solar cycle 24 have been unlike any period since the early 1900s. This article examines some of the properties of sunspot umbrae over the last 17 yr with three different instruments on the ground and in space: MDI, HMI and BABO. The distribution of magnetic fields and their evolution over time is shown and reveals that the field distribution in cycle 24 is fundamentally different from that in cycle 23. The annual average umbral magnetic field is then examined for the 17 yr observation period and shows a small decrease of 375 G in sunspot magnetic fields over the period 1996-2013, but the mean intensity of sunspot umbrae does not vary significantly over this time. A possible issue with sample sizes in a previous study is then explored to explain disagreements in data from two of the source instruments. All three instruments show that the relationship between umbral magnetic fields and umbral intensity agrees with past studies in that the umbral intensity decreases as the field strength increases. This apparent contradiction can be explained by the range of magnetic field values measured for a given umbral intensity being larger than the measured 375 G change in umbral field strength over time.

Evolution of sunspot properties during solar cycle 23

F. T. **Watson**1, L. Fletcher1 and S. Marshall

A&A 533, A14 (**2011**)

Context. The long term study of the Sun is necessary if we are to determine the evolution of sunspot properties and thereby inform modeling of the solar dynamo, particularly on scales of a solar cycle.

Aims. We aim to determine a number of sunspot properties over cycle 23 using the uniform database provided by the SOHO Michelson Doppler Imager data. We focus in particular on their distribution on the solar disk, maximum magnetic field and umbral/penumbral areas. We investigate whether the secular decrease in sunspot maximum magnetic field reported in Kitt Peak data is present also in MDI data.
Methods. We have used the Sunspot Tracking And Recognition Algorithm (STARA) to detect all sunspots present in the SOHO Michelson Doppler Imager continuum data giving us 30 084 separate detections. We record information on the sunspot locations, area and magnetic field properties as well as corresponding information for the umbral areas detected within the sunspots, and track them through their evolution.
Results. We find that the total visible umbral area is 20−40% of the total visible sunspot area regardless of the stage of the solar cycle. We also find that the number of sunspots observed follows the Solar Influences Data Centre international sunspot number with some interesting deviations. Finally, we use the magnetic information in our catalogue to study the long term variation of magnetic field strength within sunspot umbrae and find that it increases and decreases along with the sunspot number. However, if we were to assume a secular decrease as was reported in the Kitt Peak data and take into account sunspots throughout the whole solar cycle we would find the maximum umbral magnetic fields to be decreasing by 23.6 ± 3.9 Gauss per year, which is far less than has previously been observed by other studies (although measurements are only available for solar cycle 23). If we only look at the declining phase of cycle 23 we find the decrease in sunspot magnetic fields to be 70 Gauss per year.

LYRA Mid-Term Periodicities

L. **Wauters**, M. Dominique, I. E. Dammasch
Solar Phys. Volume 291, Issue 7, pp 2135–2144 **2016**
The spectra of the PROBA2/LYRA data, similarly to every other solar time series, show predominant periodicities that can be of solar or instrumental origin. In this article, we compare the main periodicities characterizing the LYRA spectrum to those found in the sunspot number, in the 10.7 cm flux, in an X-ray flare index, and in the sunspot area evolution. We focused on the 2010 to 2014 time range, for which the LYRA data are available, although we also briefly address the evolution of the main periodicities in the longer range. The mid-term periodicities at ∼28∼28, ∼44∼44, ∼54∼54, ∼59∼59, ∼100∼100, ∼110∼110, and ∼150∼150 days appear as highly significant in several analyzed datasets. The consistency of distinct periodicities between datasets provides characteristics for the global Sun. This consistency also strengthens the reliability of LYRA data.

The Polar Field Reversal Process over Five Solar Cycles.

Webb, D.F., Emery, B.A., Gibson, S.E. et al.
Sol Phys 299, 27 (**2024**).
https://doi.org/10.1007/s11207-024-02273-3
https://link.springer.com/content/pdf/10.1007/s11207-024-02273-3.pdf
We examine the process during which the solar magnetic field reverses polarity around each solar maximum. We use the McIntosh Archive (McA) of solar synoptic maps over five consecutive solar cycles, SCs 19 – 23, or from 1955 to 2009. This data set allows us to track features such as filaments, polarity inversion lines (PILs), coronal hole (CH) boundaries, and sunspots over many consecutive Carrington rotations (CRs) and solar cycles (SCs). The McA allows tracking of the evolution of the polar magnetic regions and how the rush-to-the-pole (RttP) patterns occur during the period when the polar fields reverse around each activity maximum. We use the McA dataset to determine the timing and lags among these events around the maximum of each SC in each hemisphere: the sunspot number peak, the polarity reversal, the disappearance of the polar crown filaments and PILs, the poleward movement of midlatitude CHs of new-cycle polarity behind the primary PIL, the first appearance of polar CHs of new-cycle polarity, and the earliest persistent complete coverage of each pole by a CH. The goal is to use the RttPs and CH boundary mapping to better constrain solar interior and dynamo models. The end of the PIL RttP, the end of the RttP of the poleward boundary of new-cycle polarity midlatitude CHs, and the first appearance of new-cycle polar CHs are nearly coincident and follow the polarity reversals in each hemisphere by about 1 year. We also show the lag times relative to “terminator” times, which denote when the toroidal magnetic flux built during a given cycle is canceled across the equator, thus beginning the rise of new-cycle flux. This occurs after the start of the RttPs of the polar CH boundaries and near the start of the primary and secondary PIL RttPs. The start of the RttP of the poleward boundary of the new-cycle, midlatitude CH that leads to the new polar CH always occurs later than the terminator time, so the terminator is located near the beginning of the ascending phase.

Global solar magnetic field evolution over 4 solar cycles: Use of the McIntosh archive.

Webb, D.F., Gibson, S.E., Hewins, I.M., McFadden, R.H., Emery, B.A., Malanushenko, A., Kuchar, T.A.:
Front. Astron. Space Sci. 5, 23. **2018**, DOI. ADS.
https://www.frontiersin.org/articles/10.3389/fspas.2018.00023/full
The McIntosh Archive consists of a set of hand-drawn solar Carrington maps created by Patrick McIntosh from 1964 to 2009. McIntosh used mainly Hα, He-I 10830 Å and photospheric magnetic measurements from both

ground-based and NASA satellite observations. With these he traced polarity inversion lines (PILs), filaments, sunspots and plage and, later, coronal holes over a ~45-year period. This yielded a unique record of synoptic maps of features associated with the large-scale solar magnetic field over four complete solar cycles. We first discuss how these and similar maps have been used in the past to investigate long-term solar variability. Then we describe our work in preserving and digitizing this archive, developing a digital, searchable format, and creating a website and an archival repository at NOAA's National Centers for Environmental Information (NCEI). Next we show examples of how the data base can be utilized for scientific applications. Finally, we present some preliminary results on the solar-cycle evolution of the solar magnetic field, including the polar field reversal process, the evolution of active longitudes, and the role of differential solar rotation.

New Views of Global Solar Magnetic Field Evolution Over Four Solar Cycles

D. F. Webb

RHESSI Science Nuggets #331 Sept **2018**

Is There a CME Rate Floor? CME and Magnetic Flux Values for the Last Four Solar Cycle Minima

D. F. **Webb**1, R. A. Howard2, O. C. St. Cyr3, and A. Vourlidas4

2017 ApJ 851 142

http://sci-hub.tw/10.3847/1538-4357/aa9b81

The recent prolonged activity minimum has led to the question of whether there is a base level of the solar magnetic field evolution that yields a "floor" in activity levels and also in the solar wind magnetic field strength. Recently, a flux transport model coupled with magneto-frictional simulations has been used to simulate the continuous magnetic field evolution in the global solar corona for over 15 years, from 1996 to 2012. Flux rope eruptions in the simulations are estimated (Yeates), and the results are in remarkable agreement with the shape of the SOlar Heliospheric Observatory/Large Angle and Spectrometric Coronagraph Experiment coronal mass ejection (CME) rate distribution. The eruption rates at the two recent minima approximate the observed-corrected CME rates, supporting the idea of a base level of solar magnetic activity. In this paper, we address this issue by comparing annual averages of the CME occurrence rates during the last four solar cycle minima with several tracers of the global solar magnetic field. We conclude that CME activity never ceases during a cycle, but maintains a base level of 1 CME every 1.5 to ~3 days during minima. We discuss the sources of these CMEs. **1996 May-July, 2008 December - 2009 February**

The McIntosh Archive consists of hand-drawn solar Carrington maps created by Patrick McIntosh from 1964 to 2009, using Hα, He 10830 Å, and photospheric magnetic measurements to trace polarity inversion lines, filaments, sunspots, and plage and coronal holes, yielding a unique 45 year record of the evolution of the solar magnetic field. We discuss our efforts to preserve and digitize this archive.

A Time–Distance Helioseismology Method for Quasi-Linear Geometries

Shea A. Hess **Webber**, W. Dean Pesnell

Solar Physics October **2019**, 294:151

https://link.springer.com/content/pdf/10.1007%2Fs11207-019-1547-y.pdf

Helioseismology is the study of the solar interior, through which we extract flow and wave-speed information from Doppler velocity observations at the surface. Local helioseismology involves the study of small regions on the solar disk and is used to create a detailed picture of the interior in that particular region. Perturbations in the flow and wave-speed results indicate, e.g. magnetic-flux or temperature variations. There are multiple methods used in local-helioseismic research, but all current local-helioseismic techniques assume a point-source perturbation. For this study, we develop a new time–distance (TD) helioseismic methodology that can exploit the quasi-linear geometry of an elongated feature, allowing us to i) improve the signal-to-noise ratio of the TD results, and ii) greatly decrease the number of calculations required and therefore the computing time of the TD analysis. Ultimately, the new method

will allow us to investigate solar features with magnetic-field configurations previously unexplored. We validate our new technique using a simple ff-mode wave simulation, comparing results of point-source and linear perturbations. Results indicate that local-helioseismic analysis is dependent on the geometry of the system and can be improved by taking the magnetic-field configuration into account.

Understanding Active Region Emergence and Origins on the Sun and Other Cool Stars

Review

Maria A. **Weber**, Hannah Schunker, Laurène Jouve, Emre Işık
Space Science Reviews 219, Article number: 63 (**2023**)
https://arxiv.org/pdf/2306.06536.pdf
https://link.springer.com/content/pdf/10.1007/s11214-023-01006-5.pdf
The emergence of active regions on the Sun is an integral feature of the solar dynamo mechanism. However, details about the generation of active-region-scale magnetism and the journey of this magnetic flux to the photosphere are still in question. Shifting paradigms are now developing for the source depth of the Sun's large-scale magnetism, the organization of this magnetism into fibril flux tubes, and the role of convection in shaping active-region observables. Here we review the landscape of flux emergence theories and simulations, highlight the role flux emergence plays in the global dynamo process, and make connections between flux emergence on the Sun and other cool stars. As longer-term and higher fidelity observations of both solar active regions and their associated flows are amassed, it is now possible to place new constraints on models of emerging flux. We discuss the outcomes of statistical studies which provide observational evidence that flux emergence may be a more passive process (at least in the upper convection zone); dominated to a greater extent by the influence of convection and to a lesser extent by buoyancy and the Coriolis force acting on rising magnetic flux tubes than previously thought. We also discuss how the relationship between stellar rotation, fractional convection zone depth, and magnetic activity on other stars can help us better understand flux emergence processes. Looking forward, we identify open questions regarding magnetic flux emergence that we anticipate can be addressed in the next decade with further observations and simulations.

Dynamo Processes Constrained by Solar and Stellar Observations

Maria A. **Weber**
Proceedings of IAUS 340 **2018**
https://arxiv.org/pdf/1804.05904.pdf
Our understanding of stellar dynamos has largely been driven by the phenomena we have observed of our own Sun. Yet, as we amass longer-term datasets for an increasing number of stars, it is clear that there is a wide variety of stellar behavior. Here we briefly review observed trends that place key constraints on the fundamental dynamo operation of solar-type stars to fully convective M dwarfs, including: starspot and sunspot patterns, various magnetism-rotation correlations, and mean field flows such as differential rotation and meridional circulation. We also comment on the current insight that simulations of dynamo action and flux emergence lend to our working knowledge of stellar dynamo theory. While the growing landscape of both observations and simulations of stellar magnetic activity work in tandem to decipher dynamo action, there are still many puzzles that we have yet to fully understand.

Comment on the Article by Thuillier et al.“The Infrared Solar Spectrum Measured by the SOLSPEC Spectrometer onboard the International Space Station”

M. **Weber**
Solar Phys. **2015**
Thuillier et al. (Solar Phys., 2015, DOI:10.1007/s11207-015-0704-1) discuss the apparent discrepancy between the ATLAS-3 composite solar spectral irradiances (SSI) covering the ultraviolet/visible/near-infrared (NIR) spectral region with more recent SSI measurements in the NIR. Recent measurements from IRSPERAD, CAVIAR, SCIAMACHY, SOLSPEC/ISS (the SOLAR2 spectrum from 2008), and unadjusted SIM show that above about 1600 nm, SSI is lower by about 8 % with respect to ATLAS-3. A new correction is presented in Thuillier et al. (2015) that leads to SOLSPEC/ISS (SOLAR2rev) which is in better agreement with ATLAS-3. SOLSPEC/ISS SSI underwent a +10 % change from 2008 to 2010, leading to better agreement with ATLAS-3, but it remains unclear which year provided the proper radiometric level, 2008 (SOLAR2) or 2010 (SOLAR2rev) as no link to pre-launch calibration is established. Before interpreting the NIR SSI observations using our current physical understanding (constraints by the total solar irradiance and solar models), the cause for the discrepancy between the early ATLAS-3 and all recent measurements (without a-posteriori adjustments) needs to be understood considering instrument and calibration performance alone.

Flux Tubes in Turbulent Solar-like Convection

M. A. **Weber**, Y. Fan

Solar Phys. **2015**

We study the combined effects of convection and radiative diffusion on the evolution of thin magnetic flux tubes in the solar interior. Radiative diffusion is the primary supplier of heat to convective motions in the lower convection zone, and it results in a heat input per unit volume of magnetic flux tubes that has been ignored by many previous thin flux tube studies. We use a thin flux tube model subject to convection taken from a rotating spherical shell of turbulent, solar-like convection as described by Weber, Fan, and Miesch (Astrophys. J. 741, 11, 2011; Solar Phys. 287, 239, 2013), now taking into account the influence of radiative heating on 1022 Mx flux tubes, corresponding to flux tubes of large active regions. Our simulations show that flux tubes of ≤ 60 kG that are subject to solar-like convective flows do not anchor in the overshoot region, but rather drift upward because of the increased buoyancy of the flux tube earlier in its evolution, which results from including radiative diffusion. Flux tubes of magnetic field strengths ranging from 15 kG to 100 kG have rise times of ≤ 0.2 years and exhibit a Joy's Law tilt-angle trend. Our results suggest that radiative heating is an effective mechanism by which flux tubes can escape from the stably stratified overshoot region. Moreover, flux tubes do not necessarily need to be anchored in the overshoot region to produce emergence properties similar to those of active regions on the Sun.

An Automated Algorithm for Identifying and Tracking Transverse Waves in Solar Images

Micah J. **Weberg**, Richard J. Morton, and James A. McLaughlin

2018 ApJ 852 57

http://sci-hub.tw/10.3847/1538-4357/aa9e4a

https://arxiv.org/ftp/arxiv/papers/1807/1807.04842.pdf

Recent instrumentation has demonstrated that the solar atmosphere supports omnipresent transverse waves, which could play a key role in energizing the solar corona. Large-scale studies are required in order to build up an understanding of the general properties of these transverse waves. To help facilitate this, we present an automated algorithm for identifying and tracking features in solar images and extracting the wave properties of any observed transverse oscillations. We test and calibrate our algorithm using a set of synthetic data, which includes noise and rotational effects. The results indicate an accuracy of 1%–2% for displacement amplitudes and 4%–10% for wave periods and velocity amplitudes. We also apply the algorithm to data from the Atmospheric Imaging Assembly on board the Solar Dynamics Observatory and find good agreement with previous studies. Of note, we find that 35%–41% of the observed plumes exhibit multiple wave signatures, which indicates either the superposition of waves or multiple independent wave packets observed at different times within a single structure. The automated methods described in this paper represent a significant improvement on the speed and quality of direct measurements of transverse waves within the solar atmosphere. This algorithm unlocks a wide range of statistical studies that were previously impractical. **2010 May 23, 2010 Oct 06, 2012 Mar 27**

On the plasma flow inside magnetic tornadoes on the Sun

Sven **WEDEMEYER**1,∗ and Oskar STEINER2,3

Publ. Astron. Soc. Japan (**2014**) 66 (SP1), S10 (1–8)

http://pasj.oxfordjournals.org/content/66/SP1/S10.full.pdf+html

https://watermark.silverchair.com/psu086.pdf

High-resolution observations with the Swedish 1-m Solar Telescope (SST) and the Solar Dynamics Observatory (SDO) reveal rotating magnetic field structures that extend from the solar surface into the chromosphere and the corona. These so-called magnetic tornadoes are primarily detected as rings or spirals of rotating plasma in the Ca II 854.2nm line core (also known as chromospheric swirls). Detailed numerical simulations show that the observed chromospheric plasma motion is caused by the rotation of magnetic field structures, which again are driven by photospheric vortex flows at their footpoints. Under the right conditions, two vortex flow systems are stacked on top of each other.We refer to the lower vortex, which extends from the low photosphere into the convection zone, as intergranular vortex flow (IVF). Once amagnetic field structure is co-located with an IVF, the rotation is mediated into the upper atmospheric layers and an atmospheric vortex flow (AVF, or magnetic tornado) is generated. In contrast to the recent work by Shelyag et al. (2013, ApJ, 776, L4), we demonstrate that particle trajectories in a simulated magnetic tornado indeed follow spirals and argue that the properties of the trajectories decisively depend on the location in the atmosphere and the strength of the magnetic field.

Dynamo induced by time-periodic force

Xing **Wei**

2018 ApJL 855 L7

https://arxiv.org/pdf/1802.08284.pdf
http://sci-hub.tw/http://iopscience.iop.org/2041-8205/855/1/L7/
To understand the dynamo driven by time-dependent flow, e.g. turbulence, we investigate numerically the dynamo induced by time-periodic force in rotating magnetohydrodynamic flow and focus on the effect of force frequency on the dynamo action. It is found that the dynamo action depends on the force frequency. When the force frequency is near resonance the force can drive dynamo but when it is far away from resonance dynamo fails. In the frequency range near resonance to support dynamo, the force frequency at resonance induces a weak magnetic field and magnetic energy increases as the force frequency deviates from the resonant frequency. This is opposite to the intuition that a strong flow at resonance will induce a strong field.

No evidence for synchronization of the solar cycle by a "clock"

E. **Weisshaar**1, R. H. Cameron2 and M. Schüssler2
A&A 671, A87 (**2023**)
https://www.aanda.org/articles/aa/pdf/2023/03/aa44997-22.pdf
The length of the solar activity cycle fluctuates considerably. The temporal evolution of the corresponding cycle phase, that is, the deviation of the epochs of activity minima or maxima from strict periodicity, provides relevant information concerning the physical mechanism underlying the cyclic magnetic activity. An underlying strictly periodic process (akin to a perfect "clock"), with the observer seeing a superposition of the perfect clock and a small random phase perturbation, leads to long-term phase stability in the observations. Such behavior would be expected if cycles were synchronized by tides caused by orbiting planets or by a hypothetical torsional oscillation in the solar radiative interior. Alternatively, in the absence of such synchronization, phase fluctuations accumulate and a random walk of the phase ensues, which is a typical property of randomly perturbed dynamo models. Based on the sunspot record and the reconstruction of solar cycles from cosmogenic 14C, we carried out rigorous statistical tests in order to decipher whether there exists phase synchronization or random walk. Synchronization is rejected at significance levels of between 95% (28 cycles from sunspot data) and beyond 99% (84 cycles reconstructed from 14C), while the existence of random walk in the phases is consistent with all data sets. This result strongly supports randomly perturbed dynamo models with little inter-cycle memory.

Energy goes up... but doesn't come back down! Coronal heating?

Brian **Welsch**
RHESSI Science Nugget, No. 236, Sept **2014**
http://sprg.ssl.berkeley.edu/~tohban/wiki/index.php/Energy_goes_up..._but_doesn't_come_back_down!_Coronal_heating%3F
In a "straightened" corona, the magnetic field runs between two photospheric planes, in which footpoints of the coronal fields are anchored. Photospheric convective motions can braid coronal fields, inducing electric currents in the corona. Such currents imply the presence of free magnetic energy in the corona, i.e, energy that can be released by dissipating the currents.

Did solar flares cook up life on Earth?

Wendel, J.
Eos, 97, doi:10.1029/2016EO052815. 23 May **2016.**
https://eos.org/articles/did-solar-flares-cook-up-life-on-earth
Researchers at NASA have found that when the Sun was half a billion years old, large solar flares—larger than any recorded by humans—could have changed the very chemistry of Earth's atmosphere. What's more, bombardment of the planet by high-energy particles from those jets of superhot solar plasma might have prompted organic molecules considered precursors to life to form from simpler inorganic molecules then abundant on primordial Earth.

Defining the Middle Corona **Review**

Matthew J. **West**, Daniel B. Seaton, David B. Wexler, John C. Raymond, +++
Solar Physics volume 298, Article number: 78 (**2023**)
https://link.springer.com/content/pdf/10.1007/s11207-023-02170-1.pdf
The middle corona, the region roughly spanning heliocentric distances from 1.5 to 6 solar radii, encompasses almost all of the influential physical transitions and processes that govern the behavior of coronal outflow into the heliosphere. The solar wind, eruptions, and flows pass through the region, and they are shaped by it. Importantly, the region also modulates inflow from above that can drive dynamic changes at lower heights in the inner corona. Consequently, the middle corona is essential for comprehensively connecting the corona to the heliosphere and for developing corresponding global models. Nonetheless, because it is challenging to observe, the region has been poorly studied by both major solar remote-sensing and in-situ missions and instruments, extending back to the Solar and Heliospheric Observatory (SOHO) era. Thanks to recent advances in instrumentation, observational processing techniques, and a realization of the importance of the region, interest in the middle corona has increased. Although the region cannot be intrinsically separated from other regions of the solar atmosphere, there has emerged a need to define the region in terms of its location and extension in the solar atmosphere, its composition, the physical

transitions that it covers, and the underlying physics believed to shape the region. This article aims to define the middle corona, its physical characteristics, and give an overview of the processes that occur there. **21 Aug 2017, 29 Apr 2021, 15 Feb 2022**

A Review of the Extended EUV Corona Observed by the Sun Watcher with Active Pixels and Image Processing (SWAP) Instrument

Matthew J. **West**, Daniel B. Seaton, Elke D'Huys, +++
Solar Physics volume 297, Article number: 136 (**2022**)
https://link.springer.com/content/pdf/10.1007/s11207-022-02063-9.pdf
The Sun Watcher with Active Pixels and Image Processing (SWAP) instrument onboard ESA's PRoject for On Board Autonomy 2 (PROBA2) has provided the first uncompressed, high-cadence, continuous, large field-of-view observations of the extended extreme-ultraviolet (EUV) corona for over a complete solar cycle. It has helped shape our understanding of this previously understudied region, and pioneered research into the middle corona. In this article, we present a review of all publications that have utilized these observations to explore the extended EUV corona, highlighting the unique contributions made by SWAP. The review is broadly divided into three main sections of SWAP-based studies about: i) long-lived phenomena, such as streamers, pseudo-streamers, and coronal fans; ii) dynamic phenomena, such as eruptions, jets, EUV waves, and shocks; iii) coronal EUV emission generation. We also highlight SWAP's imaging capabilities, techniques that have been applied to observations to enhance the off-limb observations and its legacy.

LUCI onboard Lagrange, the next generation of EUV space weather monitoring

Matthew J. **West**1,2*, Christian Kintziger3, Margit Haberreiter4, Manfred Gyo4, David Berghmans1, Samuel Gissot1, Valeria Büchel4, Leon Golub5, Sergei Shestov1,6 and Jackie A. Davies
J. Space Weather Space Clim. **2020**, 10, 49
https://www.swsc-journal.org/articles/swsc/pdf/2020/01/swsc200056.pdf
https://doi.org/10.1051/swsc/2020052
Lagrange eUv Coronal Imager (LUCI) is a solar imager in the Extreme UltraViolet (EUV) that is being developed as part of the Lagrange mission, a mission designed to be positioned at the L5 Lagrangian point to monitor space weather from its source on the Sun, through the heliosphere, to the Earth. LUCI will use an off-axis two mirror design equipped with an EUV enhanced active pixel sensor. This type of detector has advantages that promise to be very beneficial for monitoring the source of space weather in the EUV. LUCI will also have a novel off-axis wide field-of-view, designed to observe the solar disk, the lower corona, and the extended solar atmosphere close to the Sun–Earth line. LUCI will provide solar coronal images at a 2–3 min cadence in a pass-band centred on 19.5. Observations made through this pass-band allow for the detection and monitoring of semi-static coronal structures such as coronal holes, prominences, and active regions; as well as transient phenomena such as solar flares, limb coronal mass ejections (CMEs), EUV waves, and coronal dimmings. The LUCI data will complement EUV solar observations provided by instruments located along the Sun–Earth line such as PROBA2-SWAP, SUVI-GOES and SDO-AIA, as well as provide unique observations to improve space weather forecasts. Together with a suite of other remote-sensing and in-situ instruments onboard Lagrange, LUCI will provide science quality operational observations for space weather monitoring.

The need for active region disconnection in 3D kinematic dynamo simulations

T. **Whitbread**, A. R. Yeates, A. Muñoz-Jaramillo
A&A 627, A168 **2019**
https://arxiv.org/pdf/1907.02762.pdf
In this paper we address a discrepancy between the surface flux evolution in a 3D kinematic dynamo model and a 2D surface flux transport model that has been closely calibrated to the real Sun. We demonstrate that the difference is due to the connectivity of active regions to the toroidal field at the base of the convection zone, which is not accounted for in the surface-only model. Initially, we consider the decay of a single active region, firstly in a simplified Cartesian 2D model and subsequently the full 3D model. By varying the turbulent diffusivity profile in the convection zone, we find that increasing the diffusivity - so that active regions are more rapidly disconnected from the base of the convection zone - improves the evolution of the surface field. However, if we simulate a full solar cycle, we find that the dynamo is unable to sustain itself under such an enhanced diffusivity. This suggests that in order to accurately model the solar cycle, we must find an alternative way to disconnect emerging active regions, whilst conserving magnetic flux.

How many active regions are necessary to predict the solar dipole moment?

T. **Whitbread**, A. R. Yeates, A. Muñoz-Jaramillo
ApJ **2018**
https://arxiv.org/pdf/1807.01617.pdf

We test recent claims that the polar field at the end of Cycle 23 was weakened by a small number of large, abnormally oriented regions, and investigate what this means for solar cycle prediction. We isolate the contribution of individual regions from magnetograms for Cycles 21, 22 and 23 using a 2D surface flux transport model, and find that although the top ~10% of contributors tend to define sudden large variations in the axial dipole moment, the cumulative contribution of many weaker regions cannot be ignored. In order to recreate the axial dipole moment to a reasonable degree, many more regions are required in Cycle 23 than in Cycles 21 and 22 when ordered by contribution. We suggest that the negative contribution of the most significant regions of Cycle 23 could indeed be a cause of the weak polar field at the following cycle minimum and the low-amplitude Cycle 24. We also examine the relationship between a region's axial dipole moment contribution and its emergence latitude, flux, and initial axial dipole moment. We find that once the initial dipole moment of a given region has been measured, we can predict the long-term dipole moment contribution using emergence latitude alone.

How Many Active Regions Are Necessary to Predict the Solar Dipole Moment?

T. **Whitbread**1, A. R. Yeates1, and A. Muñoz-Jaramillo
2018 ApJ 863 116
http://sci-hub.tw/http://iopscience.iop.org/article/10.3847/1538-4357/aad17e/meta
We test recent claims that the polar field at the end of Cycle 23 was weakened by a small number of large, abnormally oriented regions, and investigate what this means for solar cycle prediction. We isolate the contribution of individual regions from magnetograms for Cycles 21, 22, and 23 using a 2D surface flux transport model, and find that although the top ~10% of contributors tend to define sudden large variations in the axial dipole moment, the cumulative contribution of many weaker regions cannot be ignored. Parameter optimization for surface flux transport models

T. **Whitbread**, A. R. Yeates, A. Muñoz-Jaramillo, G. J. D. Petrie
A&A 607, A76 **2017**
https://arxiv.org/pdf/1708.01098.pdf
Accurate prediction of solar activity calls for precise calibration of solar cycle models. Consequently we aim to find optimal parameters for models which describe the physical processes on the solar surface, which in turn act as proxies for what occurs in the interior and provide source terms for coronal models. We use a genetic algorithm to optimize surface flux transport models using National Solar Observatory (NSO) magnetogram data for Solar Cycle 23. This is applied to both a 1D model that inserts new magnetic flux in the form of idealized bipolar magnetic regions, and also to a 2D model that assimilates specific shapes of real active regions. The genetic algorithm searches for parameter sets (meridional flow speed and profile, supergranular diffusivity, initial magnetic field, and radial decay time) that produce the best fit between observed and simulated butterfly diagrams, weighted by a latitude-dependent error structure which reflects uncertainty in observations. Due to the easily adaptable nature of the 2D model, the optimization process is repeated for Cycles 21, 22, and 24 in order to analyse cycle-to-cycle variation of the optimal solution. We find that the ranges and optimal solutions for the various regimes are in reasonable agreement with results from the literature, both theoretical and observational. The optimal meridional flow profiles for each regime are almost entirely within observational bounds determined by magnetic feature tracking, with the 2D model being able to accommodate the mean observed profile more successfully. Differences between models appear to be important in deciding values for the diffusive and decay terms. In like fashion, differences in the behaviours of different solar cycles lead to contrasts in parameters defining the meridional flow and initial field strength.

Acoustic response in the transition region to transverse oscillations in a solar coronal loop

S. J. **White** and E. Verwichte
A&A 670, A1 (**2023**)
https://www.aanda.org/articles/aa/pdf/2023/02/aa44873-22.pdf
Context. Magnetohydrodynamic (MHD) waves play an important role in the dynamics and heating of the solar corona. Transverse (Alfvénic) oscillations of loops commonly occur in response to solar eruptions and are mostly studied in isolation. However, acoustic coupling has been shown to be readily observable in the form of propagating intensity variations at the loop footpoints.

Aims. We extend the modelling of wave coupling between a transverse loop oscillation and slow magnetoacoustic waves in a structured loop to include a lower atmosphere.
Methods. We achieve this with combined analytical modelling and fully non-linear MHD simulations.
Results. Transverse loop oscillations result in the excitation of propagating slow waves from the top of the transition region and the lower boundary. The rate of excitation for the upward propagating waves at the lower boundary is smaller than for waves at the top of the transition region due to the reduced local sound speed. Additionally, slow waves are found to propagate downwards from the transition region, which reflect at the lower boundary and interfere with the upward propagating waves. Resonances are present in the normal mode analysis but these do not appear in the simulations. Due to the presence of the transition region, additional longitudinal harmonics lead to a narrower slow wave profile. The slow wave field is anti-symmetric in the direction of wave polarisation, which highlights the importance that the loop orientation has on the observability of these waves. The ponderomotive effect must be accounted for when interpreting intensity oscillations. Evidence is found for an additional short-period oscillation, which is likely a hybrid mode.

Sounding Rocket Observations of Active Region Soft X-Ray Spectra Between 0.5 and 2.5 nm Using a Modified SDO/EVE Instrument

Seth **Wieman**, Thomas Woods, Andrew Jones, Christopher Moore
Solar Phys. **2016**

Spectrally resolved measurements of individual solar active regions (ARs) in the soft X-ray (SXR) range are important for studying dynamic processes in the solar corona and their associated effects on the Earth's upper atmosphere. They are also a means of evaluating atomic data and elemental abundances used in physics-based solar spectral models. However, very few such measurements are available. We present spectral measurements of two individual ARs in the 0.5 to 2.5 nm range obtained on the NASA 36.290 sounding rocket flight of **21 October 2013** (at about 18:30 UT) using the *Solar Aspect Monitor* (SAM), a channel of the *Extreme Ultaviolet Variability Experiment* (EVE) payload designed for underflight calibrations of the orbital EVE on the *Solar Dynamics Observatory* (SDO). The EVE rocket instrument is a duplicate of the EVE on SDO, except the SAM channel on the rocket version was modified in 2012 to include a freestanding transmission grating to provide spectrally resolved images of the solar disk with the best signal to noise ratio for the brightest features, such as ARs. Calibrations of the EVE sounding rocket instrument at the *National Institute of Standards and Technology Synchrotron Ultraviolet Radiation Facility* (NIST/SURF) have provided a measurement of the SAM absolute spectral response function and a mapping of wavelength separation in the grating diffraction pattern. We discuss techniques (incorporating the NIST/SURF data) for determining SXR spectra from the dispersed AR images as well as the resulting spectra for NOAA ARs 11877 and 11875 observed on the 2013 rocket flight. In comparisons with physics-based spectral models using the CHIANTI v8 atomic database we find that both AR spectra are in good agreement with isothermal spectra (4 MK), as well as spectra based on an AR differential emission measure (DEM) included with the CHIANTI distribution, with the exception of the relative intensities of strong Fe xvii lines associated with 2p62p6–2p53s2p53s and 2p62p6–2p53d2p53d transitions at about 1.7 nm and 1.5 nm, respectively. The ratio of the Fe xvii lines suggests that the AR 11877 is hotter than the AR 11875. This result is confirmed with analysis of the active regions imaged by *X-ray Telescope* (XRT) onboard *Hinode*.

Resolving Differences in Absolute Irradiance Measurements Between the SOHO/CELIAS/SEM and the SDO/EVE

S. R. **Wieman**, L. V. Didkovsky, D. L. Judg
Solar Physics, Volume 289, Issue 8, pp 2907-2925, **2014**,

The Solar EUV Monitor (SEM) onboard SOHO has measured absolute extreme ultraviolet (EUV) and soft X-ray solar irradiance nearly continuously since January 1996. The EUV Variability Experiment (EVE) on SDO, in operation since April of 2010, measures solar irradiance in a wide spectral range that encompasses the band passes (26−34 nm and 0.1−50 nm) measured by SOHO/SEM. However, throughout the mission overlap, irradiance values from these two instruments have differed by more than the combined stated uncertainties of the measurements. In an effort to identify the sources of these differences and eliminate them, we investigate in this work the effect of reprocessing the SEM data using a more accurate SEM response function (obtained from synchrotron measurements with a SEM sounding-rocket clone instrument taken after SOHO was already in orbit) and time-dependent, measured solar spectral distributions – i.e., solar reference spectra that were unavailable prior to the launch of the SDO. We find that recalculating the SEM data with these improved parameters reduces mean differences with the EVE measurements from about 20 % to less than 5 % in the 26−34 nm band, and from about 35 % to about 15 % for irradiances in the 0.1−7 nm band extracted from the SEM 0.1−50 nm channel.

The Dependence of Joy's Law as a Function of Flux Emergence Phase

Lucy **Will**, Aimee A. Norton, Jon Todd Hoeksema

ApJ **976** 20 **2024**

https://arxiv.org/pdf/2310.20171.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/ad82e3/pdf

Data from the Michelson Doppler Imager (MDI) and Helioseismic and Magnetic Imager (HMI) are analyzed from 1996 to 2023 to investigate tilt angles (γ) of bipolar magnetic regions and Joy's Law for Cycles 23, 24, and a portion of 25. The HMI radial magnetic field (Br) and MDI magnetogram (Blos) data are used to calculate (γ) using the flux-weighted centroids of the positive and negative polarities. Each AR is only sampled once. The analysis includes only Beta (β)-class active regions since computing γ of complex active regions is less meaningful. During the emergence of the ARs, we find that the average tilt angle ($\bar{\gamma}$) increases from 3.30∘±0.75 when 20\% of the flux has emerged to 6.79∘±0.66 when the ARs are at their maximum flux. Cycle 24 had a larger average tilt $\bar{\gamma}24=6.67\pm0.66$ than Cycle 23, $\bar{\gamma}23=5.11\pm0.61$. There are persistent differences in $\bar{\gamma}$ in the hemispheres with the southern hemisphere having higher $\bar{\gamma}$ in Cycles 23 and 24 but the errors are such that these differences are not statistically significant.

A Test of the Active Day Fraction Method of Sunspot Group Number Calibration: Dependence on the Level of Solar Activity

Teemu **Willamo**, Ilya G. Usoskin, Gennady A. Kovaltsov

Solar Phys. 293:69 **2018**

https://arxiv.org/pdf/1803.10501.pdf

The method of active day fraction (ADF) was proposed recently to calibrate different solar observers to the standard observational conditions. The result of the calibration may depend on the overall level of solar activity during the observational period. This dependency is studied quantitatively using data of the Royal Greenwich Observatory, by formally calibrating synthetic pseudo-observers to the full reference dataset. It is shown that the sunspot group number is precisely estimated by the ADF method for periods of moderate activity, may be slightly underestimated by 0.5\,--\,1.5 groups (≤10\,\%) for strong and very strong activity, and is strongly overestimated by up to 2.5 groups (≤30\,\%) for weak--moderate activity. The ADF method becomes unapplicable for the periods of grand minima of activity. In general, the ADF method tends to overestimate the overall level of activity and to reduce the long-term trends.

Updated sunspot group number reconstruction for 1749–1996 using the active day fraction method⋆

T. **Willamo**1, I. G. Usoskin2,3 and G. A. Kovaltsov

A&A 601, A109 (**2017**)

https://arxiv.org/pdf/1705.05109.pdf

Aims. Sunspot number series are composed from observations of hundreds of different observers that require careful normalization to standard conditions. Here we present a new normalized series of the number of sunspot groups for the period 1749–1996.

Methods. The reconstruction is based on the active day fraction (ADF) method, which is slightly updated with respect to previous works, and a revised database of sunspot group observations.

Results. Stability of some key solar observers has been evaluated against the composite series. The Royal Greenwich Observatory dataset appears relatively stable since the 1890s but is approximately 10% too low before that. A declining trend of 10–15% in the quality of Wolfer's observations is found between the 1880s and 1920s, suggesting that using him as the reference observer may lead to additional uncertainties. Wolf (small telescope) appears relatively stable between the 1860s and 1890s, without any obvious trend. The new reconstruction reflects the centennial variability of solar activity as evaluated using the singular spectrum analysis method. It depicts a highly significant feature of the modern grand maximum of solar activity in the second half of the 20th century, being a factor 1.33–1.77 higher than during the 18 and 19th centuries.

Conclusions. The new series of the sunspot group numbers with monthly and annual resolution is provided forming a basis for new studies of the solar variability and solar dynamo for the last 250 yr.

Monthly values of the reconstructed sunspot are available at the CDS via anonymous ftp to cdsarc.u-strasbg.fr (130.79.128.5) or via http://cdsarc.u-strasbg.fr/viz-bin/qcat?J/A+A/601/A109

Evidence for and Analysis of Multiple Hidden Coronal Strands in Cross-Sectional Emission Profiles: Further Results from NASA's High-resolution Solar Coronal Imager

Thomas **Williams**, Robert W. Walsh, Hardi Peter, Amy R. Winebarger
ApJ **902** 90 **2020**
https://arxiv.org/pdf/2009.02210.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/abb60a/pdf
https://doi.org/10.3847/1538-4357/abb60a
Previous work utilising NASA's High-resolution Coronal Imager (Hi-C 2.1) 17.2 nm observations revealed that, even at the increased spatial scales available in the data-set, there may be evidence for coronal structures that are still not fully resolved. In this follow-up study, cross-section slices of coronal strands are taken across the Hi-C 2.1 field-of-view. Following previous loop width studies, the background emission is removed to isolate the coronal strands. The resulting intensity variations are reproduced by simultaneously fitting multiple Gaussian profiles using a non-linear least-squares curve fitting method. In total, 183 Gaussian profiles are examined for possible structures that are hinted at in the data. The full width at half maximum (FWHM) is determined for each Gaussian, which are then collated and analysed. The most frequent structural widths are ≈450-575 km with 47% of the strand widths beneath NASA's Solar Dynamics Observatory Atmospheric Imaging Assembly (AIA) resolving scale (600-1000 km). Only 17% reside beneath an AIA pixel width (435 km) with just 6% of the strands at the Hi-C 2.1 resolving scale (≈220-340 km). These results suggest that non-Gaussian shaped cross-sectional emission profiles observed by Hi-C 2.1 are the result of multiple strands along the integrated line-of-sight that can be resolved, rather than being the result of even finer sub-resolution elements. **29th May 2018**

Is the High-Resolution Coronal Imager Resolving Coronal Strands? Results from AR 12712

Thomas **Williams**, Robert W. Walsh, Amy R. Winebarger, David H. Brooks, Jonathan W. Cirtain, Bart Depontieu, Leon Golub, Ken Kobayashi, David E. Mckenzie, Richard J. Morton, Hardi Peter, Laurel A. Rachmeler, Sabrina L. Savage, Paola Testa, Sanjiv K. Tiwari, Harry P. Warren, Benjamin J. Watkinson
2020 *ApJ* **892** 134
https://arxiv.org/pdf/2001.11254.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ab6dcf/pdf
Following the success of the first mission, the High-Resolution Coronal Imager (Hi-C) was launched for a third time (Hi-C 2.1) on **29th May 2018** from the White Sands Missile Range, NM, USA. On this occasion, 329 seconds of 17.2 nm data of target active region AR 12712 was captured with a cadence of ~4s, and a plate scale of 0.129"/pixel. Using data captured by Hi-C 2.1 and co-aligned observations from SDO/AIA 17.1 nm we investigate the widths of 49 coronal strands. We search for evidence of substructure within the strands that is not detected by AIA, and further consider whether these strands are fully resolved by Hi-C 2.1. With the aid of Multi-Scale Gaussian Normalization (MGN), strands from a region of low-emission that can only be visualized against the contrast of the darker, underlying moss are studied. A comparison is made between these low-emission strands with those from regions of higher emission within the target active region. It is found that Hi-C 2.1 can resolve individual strands as small as ~202km, though more typical strands widths seen are ~513km. For coronal strands within the region of low-emission, the most likely width is significantly narrower than the high-emission strands at ~388km. This places the low-emission coronal strands beneath the resolving capabilities of SDO/AIA, highlighting the need of a permanent solar observatory with the resolving power of Hi-C.

Fluctuations of Supergranulation Verified Through Spectral Analysis of HMI Doppler Images

Peter E. **Williams**1, W. Dean Pesnell2, John G. Beck3, and Shannon Lee
HMI Science Nuggets #35, Jan **2015**
http://hmi.stanford.edu/hminuggets/?p=1118
We tested the influence of stochastic processes by performing similar analyses on simulated Doppler data and also by producing time series models of the growth and decay of supergranules. While both models exhibited size fluctuations, they did not tend to have a regular 3-5 day oscillation component. So while stochastic mechanisms do influence the variation of supergranule characteristics, our results suggest that an underlying harmonic element is also evident.

Time-Series Analysis of Supergranule Characteristics at Solar Minimum

Peter E. **Williams**, W. Dean Pesnell
Solar Physics, April **2014**, Volume 289, Issue 4, pp 1101-1113
Sixty days of Doppler images from the Solar and Heliospheric Observatory (SOHO) / Michelson Doppler Imager (MDI) investigation during the 1996 and 2008 solar minima have been analyzed to show that certain supergranule characteristics (size, size range, and horizontal velocity) exhibit fluctuations of three to five days. Cross-correlating parameters showed a good, positive correlation between supergranulation size and size range, and a moderate, negative correlation between size range and velocity. The size and velocity do exhibit a moderate, negative

correlation, but with a small time lag (less than 12 hours). Supergranule sizes during five days of co-temporal data from MDI and the Solar Dynamics Observatory (SDO) / Helioseismic Magnetic Imager (HMI) exhibit similar fluctuations with a high level of correlation between them. This verifies the solar origin of the fluctuations, which cannot be caused by instrumental artifacts according to these observations. Similar fluctuations are also observed in data simulations that model the evolution of the MDI Doppler pattern over a 60-day period. Correlations between the supergranule size and size range time-series derived from the simulated data are similar to those seen in MDI data. A simple toy-model using cumulative, uncorrelated exponential growth and decay patterns at random emergence times produces a time-series similar to the data simulations. The qualitative similarities between the simulated and the observed time-series suggest that the fluctuations arise from stochastic processes occurring within the solar convection zone. This behavior, propagating to surface manifestations of supergranulation, may assist our understanding of magnetic-field-line advection, evolution, and interaction.

Comparisons of Supergranule Characteristics During the Solar Minima of Cycles 22/23 and 23/24

Peter E. **Williams** and W. Dean Pesnell

Solar Physics, Volume 270, Number 1, 125-136, **2011**

Supergranulation is a component of solar convection that manifests itself on the photosphere as a cellular network of around 35 Mm across, with a turnover lifetime of 1–2 days. It is strongly linked to the structure of the magnetic field. The horizontal, divergent flows within supergranule cells carry local field lines to the cell boundaries, while the rotational properties of supergranule upflows may contribute to the restoration of the poloidal field as part of the dynamo mechanism, which controls the solar cycle. The solar minimum at the transition from cycle 23 to 24 was notable for its low level of activity and its extended length. It is of interest to study whether the convective phenomena that influence the solar magnetic field during this time differed in character from periods of previous minima. This study investigates three characteristics (velocity components, sizes and lifetimes) of solar supergranulation. Comparisons of these characteristics are made between the minima of cycles 22/23 and 23/24 using MDI Doppler data from 1996 and 2008, respectively. It is found that whereas the lifetimes are equal during both epochs (around 18 h), the sizes are larger in 1996 (35.9 ± 0.3 Mm) than in 2008 (35.0 ± 0.3 Mm), while the dominant horizontal velocity flows are weaker (139 ± 1 m s−1 in 1996; 141 ± 1 m s−1 in 2008). Although numerical differences are seen, they are not conclusive proof of the most recent minimum being inherently unusual.

Linear MHD Wave Propagation in Time-Dependent Flux Tube III. Leaky Waves in Zero-Beta Plasma

A. **Williamson** , R. Erdélyi

Solar Phys. January **2016**, Volume 291, Issue 1, pp 175-185 **Open Access**

In this article, we evaluate the time-dependent wave properties and the damping rate of propagating fast magneto-hydrodynamic (MHD) waves when energy leakage into a magnetised atmosphere is considered. By considering a cold plasma, initial investigations into the evolution of MHD wave damping through this energy leakage will take place. The time-dependent governing equations have been derived previously in Williamson and Erdélyi (2014a, Solar Phys. 289, 899 – 909) and are now solved when the assumption of evanescent wave propagation in the outside of the waveguide is relaxed. The dispersion relation for leaky waves applicable to a straight magnetic field is determined in both an arbitrary tube and a thin-tube approximation. By analytically solving the dispersion relation in the thin-tube approximation, the explicit expressions for the temporal evolution of the dynamic frequency and wavenumber are determined. The damping rate is, then, obtained from the dispersion relation and is shown to decrease as the density ratio increases. By comparing the decrease in damping rate to the increase in damping for a stationary system, as shown, we aim to point out that energy leakage may not be as efficient a damping mechanism as previously thought.

Resonant Damping of Propagating Kink Waves in Time-Dependent Magnetic Flux Tube

A. **Williamson**, R. Erdélyi

Solar Physics November **2014**, Volume 289, Issue 11, pp 4105-4115

We explore the notion of resonant absorption in a dynamic time-dependent magnetised plasma background. Very many works have investigated resonance in the Alfvén and slow MHD continua under both ideal and dissipative MHD regimes. Jump conditions in static and steady systems have been found in previous works, connecting solutions at both sides of the resonant layer. Here, we derive the jump conditions in a temporally dependent, magnetised, inhomogeneous plasma background to leading order in the Wentzel–Kramers–Billouin (WKB) approximation. Next, we exploit the results found in Williamson and Erdélyi (Solar Phys. 289, 899, 2014) to describe the evolution of the jump condition in the dynamic model considered. The jump across the resonant point is

shown to increase exponentially in time. We determined the damping as a result of the resonance over the same time period and investigated the temporal evolution of the damping itself. We found that the damping coefficient, as a result of the evolution of the resonance, decreases as the density gradient across the transitional layer decreases. This has the consequence that in such time-dependent systems resonant absorption may not be as efficient as time progresses.

The Greenwich Photo-heliographic Results (1874 – 1885): Observing Telescopes, Photographic Processes, and Solar Images

D. M. **Willis**, M. N. Wild, G. M. Appleby, L. T. Macdonald

Solar Phys. Volume 291, Issue 9, pp 2553–2586 **2016**

Potential sources of inhomogeneity in the sunspot measurements published by the Royal Observatory, Greenwich, during the early interval 1874 – 1885 are examined critically. Particular attention is paid to inhomogeneities that might arise because the sunspot measurements were derived from solar photographs taken at various contributing solar observatories, which used different telescopes, experienced different seeing conditions, and employed different photographic processes. The procedures employed in the Solar Department at the Royal Greenwich Observatory (RGO), Herstmonceux, during the final phase of sunspot observations provide a modern benchmark for interpreting the early sunspot measurements. The different observing telescopes used at the contributing solar observatories during the interval 1874 – 1885 are discussed in detail, using information gleaned from the official RGO publications and other relevant historical documents. Likewise, the different photographic processes employed at the different solar observatories are reviewed carefully. The procedures used by RGO staff to measure the positions and areas of sunspot groups on photographs of the Sun having a nominal radius of either four or eight inches are described. It is argued that the learning curve for the use of the Kew photoheliograph at the Royal Observatory, Greenwich, actually commenced in 1858, not 1874. The RGO daily number of sunspot groups is plotted graphically and analysed statistically. Similarly, the changes of metadata at each solar observatory are shown on the graphical plots and analysed statistically. It is concluded that neither the interleaving of data from the different solar observatories nor the changes in metadata invalidates the RGO count of the number of sunspot groups, which behaves as a quasi-homogeneous time series. Furthermore, it is emphasised that the correct treatment of days without photographs is quite crucial to the correct calculation of Group Sunspot Numbers.

Re-examination of the Daily Number of Sunspot Groups for the Royal Observatory, Greenwich (1874 – 1885)

D. M. **Willis**, M. N. Wild, J. S. Warburton

Solar Phys. **2016**

The daily number of sunspot groups on the solar disk, as recorded by the programme of sunspot observations performed under the aegis of the Royal Observatory, Greenwich, UK, and subsequently the Royal Greenwich Observatory (RGO), is re-examined for the interval 1874 – 1885. The motivation for this re-examination is the key role that the RGO number of sunspot groups plays in the calculation of Group Sunspot Numbers (Hoyt and Schatten in *Solar Phys.* **179**, 189, 1998a;*Solar Phys.* **181**, 491, 1998b). A new dataset has been derived for the RGO daily number of sunspot groups in the interval 1874 – 1885. This new dataset attempts to achieve complete consistency between the sunspot data presented in the three main sections of the RGO publications and also incorporates all known errata and additions. It is argued that days for which no RGO solar photograph was acquired originally should be regarded, without exception, as being days without meaningful sunspot data. The daily number of sunspot groups that Hoyt and Schatten assign to days without RGO photographs is frequently just a lower limit. Moreover, in the absence of a solar photograph, the daily number of sunspot groups is inevitably uncertain because of the known frequent occurrence of sunspot groups that exist for just a single day. The elimination of days without photographs changes the list of inter-comparison days on which both the primary RGO observer and a specified secondary comparison observer saw at least one sunspot group. The resulting changes in the personal correction factors of secondary observers then change the personal correction factors of overlapping tertiary observers, *etc*. In this way, numerical changes in the personal correction factors of secondary observers propagate away from the interval 1874 – 1885, thereby potentially changing the arithmetical calculation of Group Sunspot Numbers over an appreciably wider time interval.

A Quarter Century of Wind Spacecraft Discoveries **Review**

https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2020RG000714 **File**
The Wind spacecraft, launched on November 1, 1994, is a critical element in NASA's Heliophysics System Observatory (HSO) - a fleet of spacecraft created to understand the dynamics of the Sun-Earth system. The combination of its longevity (>25 years in service), its diverse complement of instrumentation, and high resolution and accurate measurements has led to it becoming the "standard candle" of solar wind measurements. Wind has over 55 selectable public data products with over ~1,100 total data variables (including OMNI data products) on SPDF/CDAWeb alone. These data have led to paradigm shifting results in studies of statistical solar wind trends, magnetic reconnection, large-scale solar wind structures, kinetic physics, electromagnetic turbulence, the Van Allen radiation belts, coronal mass ejection topology, interplanetary and interstellar dust, the lunar wake, solar radio bursts, solar energetic particles, and extreme astrophysical phenomena such as gamma-ray bursts. This review introduces the mission and instrument suites then discusses examples of the contributions by Wind to these scientific topics that emphasize its importance to both the fields of heliophysics and astrophysics.

Identifying Observables that can Differentiate Between Impulsive and Footpoint Heating: Time Lags and Intensity Ratios

Amy R. **Winebarger**, Roberto Lionello, Cooper Downs, Zoran Mikic, Jon Linker
2018
https://arxiv.org/pdf/1806.05374.pdf
Two potential heating scenarios have been suggested to explain coronal loop observations. One scenario is that the loops are formed of many strands, each heated independently by a series of small-scale impulsive heating events, or nanoflares. Another hypothesis is that the heating is quasi-steady and highly-stratified, i.e., "footpoint heating". The goal of this paper is to identify observables that can be used to differentiate between these two heating scenarios. For footpoint heating, we vary the heating magnitude and stratification, for impulsive heating, we vary the heating magnitude. We use one-dimensional hydrodynamic codes to calculate the resulting temperature and density evolution. We convolve the temperature and density with the response functions of four EUV channels of the Atmospheric Imaging Assembly and one filter channel of Hinode's X-ray Telescope. We consider two principal diagnostics: the time lag between the appearance of the loop in two different channels, and the ratio of the peak intensities of the loop in the two channels. We find 1) that footpoint heating can predict longer time lags than impulsive heating in some channel pairs, 2) that footpoint heating can predict zero or negative time lags in some channel pairs, 3) the intensity ratio expected from impulsive heating is confined to a narrower range than footpoint heating, and 4) the range of temperatures expected in impulsive heating is broader than the range of temperatures expected in footpoint heating. This preliminary study identifies observables that may be useful in discriminating between heating models in future work.

Information Theoretic Approach to Discovering Causalities in the Solar Cycle

Simon **Wing**1, Jay R. Johnson2, and Angelos Vourlidas
2018 ApJ 854 85
http://sci-hub.tw/http://iopscience.iop.org/0004-637X/854/2/85/
The causal parameters and response lag times of the solar cycle dynamics are investigated with transfer entropy, which can determine the amount of information transfer from one variable to another. The causal dependency of the solar cycle parameters is bidirectional. The transfer of information from the solar polar field to the sunspot number (SSN) peaks at lag time (τ) ~ 30–40 months, but thereafter it remains at a persistently low level for at least 400 months (~3 solar cycles) for the period 1906–2014. The latter may lend support to the idea that the polar fields from the last three or more solar cycles can affect the production of the SSN of the subsequent cycle. There is also a similarly long-term information transfer from the SSN to the polar field. Both the meridional flow speed and flux emergence (proxied by the SSN) transfer information to the polar field, but one transfers more information than the other, depending on the lag times. The meridional flow speed transfers more information than the SSN to the polar field at τ ~ 28–30 months and at τ ~ 90–110 months, which may be consistent with some flux transfer dynamo models and some surface flux transport models. However, the flux emergence transfers more information than the meridional flow to the polar field at τ ~ 60–80 months, which may be consistent with a recently developed surface flux transport model. The transfer of information from the meridional flow to the SSN peaks at τ ~ 110–120 months (~1 solar cycle).
HMI Science Nuggets #89 Feb **2018** http://hmi.stanford.edu/hminuggets/?p=2316

Comparing SSN Index to X-ray Flare and Coronal Mass Ejection Rates from Solar Cycles 22-24

Lisa M. **Winter**, Rick Pernak, K.S. Balasubramaniam
Solar Phys. **2016**
http://arxiv.org/pdf/1605.00503v1.pdf
The newly revised sunspot number series allows for placing historical geoeffective storms in the context of several hundred years of solar activity. Using statistical analyses of the Geostationary Operational Environmental Satellites (GOES) X-ray observations from the past ~30 years and the Solar and Heliospheric Observatory (SOHO) Large Angle and Spectrometric Coronagraph (LASCO) Coronal Mass Ejection (CME) catalog (1996-present), we present sunspot-number-dependent flare and CME rates. In particular, we present X-ray flare rates as a function of sunspot number for the past three cycles. We also show that the 1-8 AA X-ray background flux is strongly correlated with sunspot number across solar cycles. Similarly, we show that the CME properties (e.g., proxies related to the CME linear speed and width) are also correlated with sunspot number for SC 23 and 24. These updated rates will enable future predictions for geoeffective events and place historical storms in the context of present solar activity.

Estimate of Solar Maximum using the 1-8 ÅGeostationary Operational Environmental Satellites X-ray Measurements

L.M. **Winter** (AER), K. S. Balasubramaniam
ApJL, 793 L45 **2014**
http://arxiv.org/pdf/1409.2763v1.pdf
We present an alternate method of determining the progression of the solar cycle through an analysis of the solar X-ray background. Our results are based on the NOAA Geostationary Operational Environmental Satellites (GOES) X-ray data in the 1-8 \AAband from 1986 - present, covering solar cycles 22, 23, and 24. The X-ray background level tracks the progression of the solar cycle through its maximum and minimum. Using the X-ray data, we can therefore make estimates of the solar cycle progression and date of solar maximum. Based upon our analysis, we conclude that the Sun reached its hemisphere-averaged maximum in Solar Cycle 24 in late 2013. This is within six months of the NOAA prediction of a maximum in Spring 2013.

OBSERVATIONAL EVIDENCE FOR VARIATIONS OF THE ACOUSTIC CUTOFF FREQUENCY WITH HEIGHT IN THE SOLAR ATMOSPHERE

A. **Wiśniewska**1, Z. E. Musielak1,2, J. Staiger1, and M. Roth
2016 ApJ 819 L23
Direct evidence for the existence of an acoustic cutoff frequency in the solar atmosphere is given by observations performed by using the HELioseismological Large Regions Interferometric DEvice operating on the Vacuum Tower Telescope located on Tenerife. The observational results demonstrate variations of the cutoff with atmospheric heights. The observed variations of the cutoff are compared to theoretical predictions made by using five acoustic cutoff frequencies that have been commonly used in helioseismology and asteroseismology. The comparison shows that none of the theoretical predictions is fully consistent with the observational data. The implication of this finding is far reaching as it urgently requires either major revisions of the existing methods of finding acoustic cutoff frequencies or developing new methods that would much better account for the physical picture underlying the concept of cutoff frequencies in inhomogeneous media.

The Daniel K. Inouye Solar Telescope (DKIST)/Visible Broadband Imager (VBI)

Friedrich **Wöger**, Thomas Rimmele, Andrew Ferayorni, Andrew Beard, Brian S. Gregory, Predrag Sekulic & Steven L. Hegwer
Solar Physics volume 296, Article number: 145 (**2021**)
https://link.springer.com/content/pdf/10.1007/s11207-021-01881-7.pdf
https://doi.org/10.1007/s11207-021-01881-7
The Daniel K. Inouye Solar Telescope (DKIST) is a ground-based observatory for observations of the solar atmosphere featuring an unprecedented entrance aperture of four meters. To address its demanding scientific goals, DKIST features innovative and state-of-the-art instrument subsystems that are fully integrated with the facility and designed to be capable of operating mostly simultaneously. An important component of DKIST's first-light instrument suite is the Visible Broadband Imager (VBI). The VBI is an imaging instrument that aims to acquire images of the solar photosphere and chromosphere with high spatial resolution and high temporal cadence to investigate the to-date smallest detectable features and their dynamics in the solar atmosphere. VBI observations of

unprecedented spatial resolution ultimately will be able to inform modern numerical models and thereby allow new insights into the physics of the plasma motion at the smallest scales measurable by DKIST. The VBI was designed to deliver images at various wavelengths and at the diffraction limit of DKIST. The diffraction limit is achieved by using adaptive optics in conjunction with post-facto image-reconstruction techniques to remove residual effects of the terrestrial atmosphere. The first images of the VBI demonstrate that DKIST's optical system enables diffraction-limited imaging across a large field of view of various layers in the solar atmosphere. These images allow a first glimpse at the exciting scientific discoveries that will be possible with DKIST's VBI.

Wave heating of the solar atmosphere without shocks

D. **Wójcik**, B. Kuźma, K. Murawski and Z. E. Musielak
A&A 635, A28 (**2020**)
https://doi.org/10.1051/0004-6361/201936938
Context. We investigate the wave heating problem of a solar quiet region and present its plausible solution without involving shock formation.
Aims. We aim to use numerical simulations to study wave propagation and dissipation in the partially ionized solar atmosphere, whose model includes both neutrals and ions.
Methods. We used a 2.5D two-fluid model of the solar atmosphere to study the wave generation and propagation. The source of these waves is the solar convection located beneath the photosphere.
Results. The energy carried by the waves is dissipated through ion-neutral collisions, which replace shocks used in some previous studies as the main source of local heating in quiet regions.
Conclusions. We show that the resulting wave dissipation is sufficient to balance radiative and thermal energy losses, and to sustain a quasi-stationary atmosphere whose averaged temperature profile agrees well with the observationally based semi-empirical model of Avrett & Loeser (2008, ApJS, 175, 229).

Partially Ionized Solar Atmosphere: Two-fluid Waves and Their Cutoffs

D. **Wójcik**1, K. Murawski1, and Z. E. Musielak2
2019 ApJ 882 32
https://doi.org/10.3847/1538-4357/ab3224
A novel model of the solar atmosphere that accounts for partially ionized plasma is developed and used to study the propagation of magnetoacoustic-gravity waves, which are generated by solar granulation. The model includes neutrals in otherwise ionized plasma and therefore the considered waves are two-fluid waves. Numerical simulations of these waves allow computing their cutoff period and its variations in the solar atmosphere. The results of these computations are compared to the observational data collected by Wiśniewska et al. and Kayshap et al., and a good agreement between the theory and observations is obtained. This first theoretical confirmation of the observational data profoundly shows the importance of effects caused by partially ionized plasma on the behavior of waves in the solar atmosphere, and on the origin of solar chromospheric oscillations. It is also suggested that theoretically predicted differences between the behavior of ions and neutrals can be verified by some currently operating solar missions.

Two-fluid Numerical Simulations of the Origin of the Fast Solar Wind

D. **Wójcik**1, B. Kuźma1, K. Murawski1, and A. K. Srivastava
2019 ApJ 884 127
https://doi.org/10.3847/1538-4357/ab26b1
With the use of our JOANNA code, which solves radiative equations for ion + electron and neutral fluids, we perform realistic 2.5D numerical simulations of plasma outflows associated with the solar granulation. These outflows exhibit physical quantities that are consistent, to the order of magnitude, with the observational findings for mass and energy losses in the upper chromosphere, transition region, and inner corona, and they may originate the fast solar wind.

Acoustic waves in two-fluid solar atmosphere model: cut-off periods, chromospheric cavity, and wave tunnelling

D **Wójcik** K Murawski Z E Musielak
MNRAS 481, Issue 1, 21 November **2018**, Pages 262–267
We perform numerical simulations of acoustic waves in a two-fluid model of quiet region of the solar atmosphere. The two-fluid model describes partially ionized (non-magnetized) solar plasma, whose main components are neutral atoms, protons, and electrons. The waves are excited by a monochromatic driver, which operates at the bottom of the solar photosphere. Our numerical results show that the driver excites ion and neutral acoustic waves whose propagation is affected by the gravity. As a result, the acoustic waves with periods higher than a local acoustic cut-off period are evanescent, while lower waveperiods are free to reach the solar corona. Acoustic waves, which are evanescent in the photosphere and low chromosphere, tunnel their energy into the upper chromosphere and the

transition region. The wave propagation to the solar corona is affected by partial wave reflection that occurs in the transition region, and is responsible for formation of a cavity, where the waves are trapped. Fourier power analysis of temporal characteristic of plasma quantities reveals that a spectrum of various periods is generated. While oscillations traced in ion and neutral velocities look very similar, dynamics of mass densities of ions and neutrals differs a lot. The obtained results clearly show that the two-fluid model provides new insights into the acoustic wave propagation in a more realistic (partially ionized) quiet region of the solar atmosphere.

Numerical Simulations of Torsional Alfvén Waves in Axisymmetric Solar Magnetic Flux Tubes

D. **Wójcik**, K. Murawski, Z. E. Musielak, P. Konkol, A. Mignone
Solar Physics February **2017**, 292:31
http://link.springer.com/article/10.1007/s11207-017-1058-7
We numerically investigate Alfvén waves propagating along an axisymmetric and non-isothermal solar flux tube embedded in the solar atmosphere. The tube magnetic field is current-free and diverges with height, and the waves are excited by a periodic driver along the tube magnetic field lines. The main results are that the two wave variables, the velocity and magnetic field perturbations in the azimuthal direction, behave differently as a result of gradients of the physical parameters along the tube. To explain these differences in the wave behavior, the time evolution of the wave variables and the resulting cutoff period for each wave variable are calculated and used to determine regions in the solar chromosphere where strong wave reflection may occur.

Solar Irradiance Variability, Influenced by r Modes

Charles L. **Wolff**
2019 ApJ 870 20
A spectrum of the four-decade solar irradiance record has a prominent cluster of power for periodicities near 1 yr. Correlating irradiance with a bandpass filter showed that periodicity values were not constant, but varied sinusoidally with each cycle lasting 14 ± 1 yr. The large modulation amplitude makes solar frequencies ≥1 yr−1 hard to detect at the solar surface. After removing the modulation, a Lomb–Scargle spectrum exposed two true periodicities: 1.006 and 0.920 yr. They are interpreted as the synodic rotation periods of r modes of lowest angular degree ($\ell = 1$). The first propagates in the stable interior and the second in the convective envelope perturbed by its several flow fields. The rotational beat period of the two modes is about 10.9 yr. This is close to the average length of a solar cycle and possibly controls this average. The 1.006 yr periodicity dominates most of the filtered irradiance record but an abrupt change to about 0.8 yr occurs in mid-2010. Also found was evidence for higher-degree r modes ($\ell = 2$ to 8) and a curious sawtooth modulation with a recurrence period of 2.6 yr.

Naked eye observation of the 2017 total solar eclipse: a more complete understanding of the white-light corona

Richard **Woo**
Monthly Notices of the Royal Astronomical Society, Volume 485, Issue 3, May **2019**, Pages 4122–4127,
https://doi.org/10.1093/mnras/stz703
sci-hub.se/10.1093/mnras/stz703
The **2017 August 21** total solar eclipse offered a rare opportunity to scientifically view and capture naked eye observation of the corona. Filling this observational gap has led to a more complete understanding of the white-light corona, because it clarified and reconciled differences in the brightness distributions that are visually observed, imaged (photographed), and measured. Crucial to these new results has been the fortuitous similarity of naked eye observation of the 2017 eclipse to that of 1932. The latter was captured by the unmatched skills of artist–painter Howard Russell Butler in his recently rediscovered painting. Without this remarkable painting, it would not have been possible to either convey confirmation of the illusion or meaningfully explain the role and relevance of naked eye observation to understanding more completely the white-light corona.

First Results for Solar Soft X-Ray Irradiance Measurements from the Third-generation Miniature X-Ray Solar Spectrometer

Thomas N. **Woods**1, Bennet Schwab1, Robert Sewell1, Anant Kumar Telikicherla Kandala2, James Paul Mason +++
2023 ApJ 956 94
https://iopscience.iop.org/article/10.3847/1538-4357/acef13/pdf
Three generations of the Miniature X-ray Solar Spectrometer (MinXSS) have flown on small satellites with the goal "to explore the energy distribution of soft X-ray (SXR) emissions from the quiescent Sun, active regions, and during solar flares, and to model the impact on Earth's ionosphere and thermosphere." The primary science instrument is the Amptek X123 X-ray spectrometer that has improved with each generation of the MinXSS experiment. This

third-generation MinXSS-3 has a higher energy resolution and larger effective area than its predecessors and is also known as the Dual-zone Aperture X-ray Solar Spectrometer (DAXSS). It was launched on the INSPIRESat-1 satellite on **2022 February 14**, and INSPIRESat-1 has successfully completed its 6 month prime mission. The INSPIRESat-1 is in a dawn–dusk, Sun-synchronous orbit and therefore has had 24 hr coverage of the Sun during most of its mission so far. The rise of Solar Cycle 25 has been observed by DAXSS. This paper introduces the INSPIRESat-1 DAXSS solar SXR observations, and we focus the science results here on a solar occultation experiment and multiple flares on **2022 April 24**. One key flare result is that the reduction of elemental abundances appears greatest during the flare impulsive phase, thus highlighting the important role of chromospheric evaporation during flares to inject warmer plasma into the coronal loops. Furthermore, these results are suggestive that the amount of chromospheric evaporation is related to flare temperature and intensity.

Solar-Cycle Variability Results from the Solar Radiation and Climate Experiment (SORCE) Mission

Thomas N. **Woods**, Jerald W. Harder, Greg Kopp & Martin Snow
Solar Physics volume 297, Article number: 43 (**2022**)
https://link.springer.com/content/pdf/10.1007/s11207-022-01980-z.pdf
The Solar Radiation and Climate Experiment (SORCE) was a NASA mission that operated from 2003 to 2020 to provide key climate-monitoring measurements of total solar irradiance (TSI) and solar spectral irradiance (SSI). This 17-year mission made TSI and SSI observations during the declining phase of Solar Cycle 23, during all of Solar Cycle 24, and at the very beginning of Solar Cycle 25. The SORCE solar-variability results include comparisons of the solar irradiance observed during Solar Cycles 23 and 24 and the solar-cycle minima levels in 2008 – 2009 and 2019 – 2020. The differences between these two minima are very small and are not significantly above the estimate of instrument stability over the 11-year period. There are differences in the SSI variability for Solar Cycles 23 and 24, notably for wavelengths longer than 250 nm. Consistency comparisons with SORCE variability on solar-rotation timescales and solar-irradiance model predictions suggest that the SORCE Solar Cycle 24 SSI results might be more accurate than the SORCE Solar Cycle 23 results. The SORCE solar-variability results have been useful for many Sun–climate studies and will continue to serve as a reference for comparisons with future missions studying solar variability.

A Self-consistent Model of the Solar Tachocline

T. S. **Wood**1 and N. H. Brummell2
2018 ApJ 853 97
We present a local but fully nonlinear model of the solar tachocline, using three-dimensional direct numerical simulations. The tachocline forms naturally as a statistically steady balance between Coriolis, pressure, buoyancy, and Lorentz forces beneath a turbulent convection zone. Uniform rotation is maintained in the radiation zone by a primordial magnetic field, which is confined by meridional flows in the tachocline and convection zone. Such balanced dynamics has previously been found in idealized laminar models, but never in fully self-consistent numerical simulations.

Evidence for Large-Scale Subsurface Convection in the Sun

M. F. **Woodard**
MNRAS **2016**
http://arxiv.org/pdf/1605.06192v1.pdf
A helioseismic statistical waveform analysis of subsurface flow was performed on two 720-day time series of SOHO/MDI Medium-l spherical-harmonic coefficients. The time series coincide with epochs of high and low solar activity. Time-dependent coupling-strength coefficients b(s,t;n,l) of modes of the same radial order n and degree l, but different azimuthal order m, were inferred from the waveform analysis. These coefficients are sensitive to flows and general aspherical structure. For odd values of s << l, the coefficient b(s,t;n,l) measures an average over depth of the amplitude of one spherical-harmonic (s,t) component of the toroidal flow velocity field. The depth-dependent weighting function defining the average velocity is the fractional kinetic energy density in radius of modes of the (n,l) multiplet. A mean-square (n,l)-dependent flow velocity was inferred from the b-coefficients for s in the range 5 through 35 for each n and l in the respective ranges 1 through 5 and 120 through 149 for the epochs of high and low activity. A further averaging, over l, yielded a root mean square flow velocity as a function of n for each epoch, which average increases from about 20 m/s at n=1 to 35 m/s at n=5. The inferred velocities are consistent with (though perhaps do not demand) a cellular pattern of flow extending over the vertical range of mode sensitivity, estimated to be about four percent of the solar radius below the photosphere.

The Solar Radiation and Climate Experiment (SORCE) Mission: Final Calibrations and Data Products

Editorial Postface

Thomas N. **Woods** & John W. Leibacher
Solar Physics volume 298, Article number: 25 (**2023**)
https://link.springer.com/content/pdf/10.1007/s11207-023-02125-6.pdf
The Solar Radiation and Climate Experiment (SORCE) was a NASA mission that operated from 2003 to 2020 to provide key climate-monitoring measurements of total solar irradiance (TSI) and solar spectral irradiance (SSI). This topical collection provides an overview of some of the key SORCE science results, an overview of mission operations and how anomalies impacted the science observations, a detailed description of the updated algorithms used in producing the final data products of TSI and SSI from the four SORCE instruments, and results from an underflight calibration-rocket experiment flown in June 2018. The 17-year-long SORCE mission has made many contributions to the climate records of TSI and SSI that date back to the 1970s, and, fortunately, similar observations from the Total and Spectral Solar Irradiance Sensor (TSIS-1) are able to continue these Sun-climate records after SORCE without a gap.

Solar Radiation and Climate Experiment (SORCE) X-Ray Photometer System (XPS): Final Data-Processing Algorithms

Thomas N. **Woods** & Joshua Elliott
Solar Physics volume 297, Article number: 64 (**2022**)
https://link.springer.com/content/pdf/10.1007/s11207-022-01997-4.pdf
The X-ray Photometer System (XPS) is one of four instruments onboard NASA's Solar Radiation and Climate Experiment (SORCE) mission. The SORCE spacecraft operated from 2003 to 2020 to provide key climate-monitoring measurements of total solar irradiance (TSI) and solar spectral irradiance (SSI). The XPS is a set of photometers to measure the solar X-ray ultraviolet (XUV) irradiance shortward of 34 nm and the bright hydrogen emission at 121.6 nm. Each photometer has a spectral bandpass of about 7 nm, and the XPS measurements have an accuracy of about 20%. The updates for the final data-processing algorithms for the XPS solar-irradiance data products are described. These processing updates include improvements for the instrumental corrections for background signal, visible-light signal, and degradation trending. Validation of these updates is primarily with measurements from a very similar XPS instrument onboard NASA's Thermosphere-Ionosphere-Mesosphere-Energetics-Dynamics (TIMED) mission. In addition, the XPS Level 4 spectral model has been improved with new reference spectra derived with recent XUV observations from NASA's Solar Dynamics Observatory (SDO) and Miniature X-ray Solar Spectrometer (MinXSS) cubesat.

Overview of the Solar Radiation and Climate Experiment (SORCE) Seventeen-Year Mission

Thomas N. **Woods**, Jerald W. Harder, Greg Kopp, Debra McCabe, Gary Rottman, Sean Ryan & Martin Snow
Solar Physics volume 296, Article number: 127 (**2021**)
https://link.springer.com/content/pdf/10.1007/s11207-021-01869-3.pdf
https://doi.org/10.1007/s11207-021-01869-3
The Solar Radiation and Climate Experiment (SORCE) was a NASA mission that operated from 2003 to 2020 to provide key climate-monitoring measurements of total solar irradiance (TSI) and solar spectral irradiance (SSI). Three important accomplishments of the SORCE mission are i) the continuation of the 42-year-long TSI climate data record, ii) the continuation of the ultraviolet SSI record, and iii) the initiation of the near-ultraviolet, visible, and near-infrared SSI records. All of the SORCE instruments functioned well over the 17-year mission, which far exceeded its five-year prime mission goal. The SORCE spacecraft, having mostly redundant subsystems, was also robust over the mission. The end of the SORCE mission was a planned passivation of the spacecraft following a successful two-year overlap with the NASA Total and Spectral Solar Irradiance Sensor (TSIS) mission, which continues the TSI and SSI climate records. There were a couple of instrument anomalies and a few spacecraft anomalies during SORCE's long mission, but operational changes and updates to flight software enabled SORCE to remain productive to the end of its mission. The most challenging of the anomalies was the degradation of the battery capacity that began to impact operations in 2009 and was the cause for the largest SORCE data gap (August 2013 – February 2014). An overview of the SORCE mission is provided with a couple of science highlights and a discussion of flight anomalies that impacted the solar observations. Companion articles about the SORCE instruments and their final science data-processing algorithms provide additional details about the instrument measurements over the duration of the mission.

New Solar Irradiance Measurements from the Miniature X-Ray Solar Spectrometer CubeSat

Thomas N. **Woods**, Amir Caspi, Phillip C. Chamberlin, Andrew Jones, Richard Kohnert, James Paul Mason, Christopher S. Moore, Scott Palo, Colden Rouleau, Stanley C. Solomon, Janet Machol, Rodney Viereck

ApJL **2016**
https://arxiv.org/pdf/1610.01936v1.pdf
The goal of the Miniature X-ray Solar Spectrometer (MinXSS) CubeSat is to explore the energy distribution of soft X-ray (SXR) emissions from the quiescent Sun, active regions, and during solar flares, and to model the impact on Earth's ionosphere and thermosphere. The energy emitted in the SXR range (0.1 to 10 keV) can vary by more than a factor of 100, yet we have limited spectral measurements in the SXRs to accurately quantify the spectral dependence of this variability. The MinXSS primary science instrument is an Amptek, Inc. X123 X-ray spectrometer that has an energy range of 0.5-30 keV with a nominal 0.15 keV energy resolution. Two flight models have been built. The first, MinXSS-1, has been making science observations since 2016 June 9, and has observed numerous flares, including 40 C-class and 7 M-class flares. These SXR spectral measurements have advantages over broadband SXR observations, such as providing the capability to derive multiple-temperature components and elemental abundances of coronal plasma, improved irradiance accuracy, and higher resolution spectral irradiance as input to planetary ionosphere simulations. MinXSS spectra obtained during the **M5.0 flare on 2016 July 23** highlight these advantages, and indicate how the elemental abundance changes from primarily coronal to more photospheric during the flare. MinXSS-1 observations are compared to the Geostationary Operational Environmental Satellite (GOES) X-Ray Sensor (XRS) measurements of SXR irradiance and estimated corona temperature. Additionally, a suggested improvement to the calibration of the GOES XRS data is presented.

Solar Models with dynamic screening and early mass loss tested by helioseismic, astrophysical, and planetary constraints

Suzannah R. **Wood**, Katie Mussack, Joyce A. Guzik
Solar Phys. 293:111 **2018**
https://arxiv.org/pdf/1807.03846.pdf
The faint young Sun paradox remains an open question. Presented here is one possible solution to this apparent inconsistency, a more massive early Sun. Based on conditions on early Earth and Mars, a luminosity constraint is set as a function of mass. We examine helioseismic constraints of these alternative mass-losing models. Additionally, we explore a dynamic electron screening correction in an effort to improve helioseismic agreement in the core of the an early mass-losing model.

Towards realistic estimates of solar global oscillation mode-coupling measurement noise

M F **Woodard**
MNRAS, Volume 505, Issue 3, August **2021**, Pages 3433–3441,
https://doi.org/10.1093/mnras/stab1519
Time series of the medium-l spherical-harmonic decomposition of SOHO/MDI Doppler images were used to investigate the noise of solar-oscillation mode-coupling measurements and to reveal the coupling signatures of global-scale Rossby-waves and magnetic activity. A theoretical model of mode-coupling noise was developed starting from the assumption that the Doppler oscillation signal obeys Gaussian statistics. The measured coupling noise was found to agree with the model noise at the level of 20 per cent. The noise of mode-coupling measurements obtained from MDI data turns out to be considerably larger than that of hypothetical, 'ideal' measurements, which could only be obtained from observations with more coverage of the Sun's surface than current instruments provide. The noise analysis was carried out for a simple suboptimal mode-coupling estimation procedure which is described in some detail. A more rigorous, maximum-likelihood, approach to mode-coupling measurement, which generalizes a method currently used to extract global oscillation mode information, is also described and its relationship to the simple mode-coupling analysis is discussed.

New Solar Irradiance Measurements from the Miniature X-Ray Solar Spectrometer Cubesat

Thomas N. **Woods**1, Amir Caspi2, Phillip C. Chamberlin3, Andrew Jones1, Richard Kohnert1, James Paul Mason1, Christopher S. Moore1, Scott Palo1, Colden Rouleau1, Stanley C. Solomon
2017 ApJ 835 122
https://arxiv.org/ftp/arxiv/papers/1610/1610.01936.pdf
The goal of the Miniature X-ray Solar Spectrometer (MinXSS) CubeSat is to explore the energy distribution of soft X-ray (SXR) emissions from the quiescent Sun, active regions, and during solar flares and to model the impact on Earth's ionosphere and thermosphere. The energy emitted in the SXR range (0.1–10 keV) can vary by more than a factor of 100, yet we have limited spectral measurements in the SXRs to accurately quantify the spectral dependence of this variability. The MinXSS primary science instrument is an Amptek, Inc. X123 X-ray spectrometer that has an energy range of 0.5–30 keV with a nominal 0.15 keV energy resolution. Two flight models have been built. These SXR spectral measurements have advantages over broadband SXR observations, such as providing the capability to derive multiple-temperature components and

elemental abundances of coronal plasma, improved irradiance accuracy, and higher resolution spectral irradiance as input to planetary ionosphere simulations. MinXSS spectra obtained during the M5.0 flare on 2016 July 23 highlight these advantages and indicate how the elemental abundance appears to change from primarily coronal to more photospheric during the flare. MinXSS-1 observations are compared to the Geostationary Operational Environmental Satellite (GOES) X-ray Sensor (XRS) measurements of SXR irradiance and estimated corona temperature. Additionally, a suggested improvement to the calibration of the GOES XRS data is presented.

A Different View of Solar Spectral Irradiance Variations: Modeling Total Energy over Six-Month Intervals

Thomas N. **Woods** , Martin Snow, Jerald Harder, Gary Chapman,
Solar Phys. Volume 290, Issue 10, pp 2649-2676 **2015** **Open Access**
A different approach to studying solar spectral irradiance (SSI) variations, without the need for long-term (multi-year) instrument degradation corrections, is examining the total energy of the irradiance variation during 6-month periods. This duration is selected because a solar active region typically appears suddenly and then takes 5 to 7 months to decay and disperse back into the quiet-Sun network. The solar outburst energy, which is defined as the irradiance integrated over the 6-month period and thus includes the energy from all phases of active region evolution, could be considered the primary cause for the irradiance variations. Because solar cycle variation is the consequence of multiple active region outbursts, understanding the energy spectral variation may provide a reasonable estimate of the variations for the 11-year solar activity cycle. The moderate-term (6-month) variations from the Solar Radiation and Climate Experiment (SORCE) instruments can be decomposed into positive (in-phase with solar cycle) and negative (out-of-phase) contributions by modeling the variations using the San Fernando Observatory (SFO) facular excess and sunspot deficit proxies, respectively. These excess and deficit variations are fit over 6-month intervals every 2 months over the mission, and these fitted variations are then integrated over time for the 6-month energy. The dominant component indicates which wavelengths are in-phase and which are out-of-phase with solar activity. The results from this study indicate out-of-phase variations for the 1400 – 1600 nm range, with all other wavelengths having in-phase variations.

Magnetic Influences on the Solar Wind (Ph.D. Dissertation)

Lauren N. **Woolsey**
Ph.D. Dissertation accepted by Harvard Graduate School of Arts and Sciences **2016**
http://arxiv.org/pdf/1605.04318v1.pdf
The steady, supersonic outflow from the Sun we call the solar wind was first posited in the 1950s and initial theories rightly linked the acceleration of the wind to the existence of the million-degree solar corona. Still today, the wind acceleration mechanisms and the coronal heating processes remain unsolved challenges in solar physics. In this work, I seek to answer a portion of the mystery by focusing on a particular acceleration process: Alfven waves launched by the motion of magnetic field footpoints in the photosphere. The entire corona is threaded with magnetic loops and flux tubes that open up into the heliosphere. I have sought a better understanding of the role these magnetic fields play in determining solar wind properties in open flux tubes. After an introduction of relevant material, I discuss my parameter study of magnetic field profiles and the statistical understanding we can draw from the resulting steady-state wind. In the chapter following, I describe how I extended this work to consider time dependence in the turbulent heating by Alfven waves in three dimensional simulations. The bursty nature of this heating led to a natural next step that expands my work to include not only the theoretical, but also a project to analyze observations of small network jets in the chromosphere and transition region, and the underlying photospheric magnetic field that forms thresholds in jet production. In summary, this work takes a broad look at the extent to which Alfven-wave-driven turbulent heating can explain measured solar wind properties and other observed phenomena. **See Introduction (Review)**

TIME-DEPENDENT TURBULENT HEATING OF OPEN FLUX TUBES IN THE CHROMOSPHERE, CORONA, AND SOLAR WIND

L. N. **Woolsey**1 and S. R. Cranmer
2015 ApJ 811 136
We investigate several key questions of plasma heating in open-field regions of the corona that connect to the solar wind. We present results for a model of Alfvén-wave-driven turbulence for three typical open magnetic field structures: a polar coronal hole, an open flux tube neighboring an equatorial streamer, and an open flux tube near a strong-field active region. We compare time-steady, one-dimensional turbulent heating models against fully time-dependent three-dimensional reduced-magnetohydrodynamic modeling of BRAID. We find that the time-steady results agree well with time-averaged results from BRAID. The time dependence allows us to investigate the variability of the magnetic fluctuations and of the heating in the corona. The high-frequency tail of the power spectrum of fluctuations forms a power law whose exponent varies with height, and we discuss the possible physical

explanation for this behavior. The variability in the heating rate is bursty and nanoflare-like in nature, and we analyze the amount of energy lost via dissipative heating in transient events throughout the simulation. The average energy in these events is 1021.91 erg, within the "picoflare" range, and many events reach classical "nanoflare" energies. We also estimated the multithermal distribution of temperatures that would result from the heating-rate variability, and found good agreement with observed widths of coronal differential emission measure distributions. The results of the modeling presented in this paper provide compelling evidence that turbulent heating in the solar atmosphere by Alfvén waves accelerates the solar wind in open flux tubes.

Partitioning of Magnetic Helicity in Reconnected Flux Tubes

Andrew N. **Wright**
2019 ApJ 878 102
sci-hub.se/10.3847/1538-4357/ab2120
The reconnection of two flux tubes with footpoints anchored to a plane, such as the photosphere, is considered. We focus on properties of the reconnected flux tubes, specifically their twist, which can be quantified using magnetic helicity. If the tubes are of equal flux (Φ) and are initially crossed we find the results are dependent upon the relative positioning of their footpoints: (i) nonequipartition of self-helicity is the typical situation; (ii) the total amount of self-helicity in the reconnected tubes lies between 0 and 2Φ2, corresponding to a total twist of between 0 and 2 turns. If the tubes are initially uncrossed the self-helicity of each reconnected tube depends upon footpoint arrangement. However, care needs to be taken when using these results as bringing the tubes together at the reconnection site can introduce twist or writhe, which will also need to be taken into account. In the case where the tubes are side by side and possess some overlap, reconnection may occur without distorting the tubes. For this situation the reconnected tubes will be crossed: (i) equipartition of self-helicity is never met, but can be approached in the limit of the footpoints being quasi-colinear; (ii) the overlying tube always has a self-helicity whose magnitude >Φ2/2 (it exceeds a half turn); the underling tube's self-helicity magnitude is always <Φ2/2 (less than a half turn). Our results have a broad application in developing models of reconnecting coronal magnetic fields, as well as in interpreting observations and simulations of these fields.

Rotational Characteristics of the Solar Transition Region Using SDO/AIA 304 Å Images

Qian-Rui **Wu**1,2,3, Sheng Zheng1,2, Shu-Guang Zeng1,2, Miao Wan4, Xiang-Yun Zeng1,2, Lin-Hua Deng4, and Yao Huang1,2
2023 ApJ 954 20
https://iopscience.iop.org/article/10.3847/1538-4357/ace623/pdf
To date, the rotational characteristics of the solar transition region remain unclear. In this work, by applying the flux modulation method to the images derived from the Solar Dynamics Observatory/Atmospheric Imaging Assembly between 2011 and 2022 at 304 Å wavelength, we have studied the rotation of the solar transition region, and the results obtained are as follows. The solar transition region rotates differentially, while, from the perspective of the entire time interval, the rotation coefficients A and B are 14.39 (±0.08) and −1.61 (±0.15), respectively, and we find no prominent asymmetry in the average rotation rate of the northern and southern hemispheres. The solar transition region rotates fastest during the solar cycle maximum, and the average rotation rate follows the overall trend of solar activity. Both the equatorial rotation rate (represented by coefficient A) and the latitudinal gradient (represented by coefficient B) of the solar transition region are smaller than that of the solar chromosphere and the corona, indicating the solar transition region rotates more slowly and more rigidly than the other two layers, and we speculate that the solar chromosphere and corona seem to restrain the rotation of the solar transition region at the same

Highly Energetic Electrons Accelerated in Strong Solar Flares as a Preferred Driver of Sunquakes

H. **Wu**, Y. Dai, M. D. Ding
ApJL **943** L6 **2023**
https://arxiv.org/pdf/2301.02865.pdf
https://iopscience.iop.org/article/10.3847/2041-8213/acb0d1/pdf
Sunquakes are enhanced seismic waves excited in some energetic solar flares. Up to now, their origin has still been controversial. In this Letter, we select and study 20 strong flares in Solar Cycle 24, whose impulse phase is fully captured by the \emph{Reuven Ramaty High Energy Solar Spectroscopic Imager} (\emph{RHESSI}). For 11 out of 12 sunquake-active flares in our sample, the hard X-ray (HXR) emission shows a good temporal and spatial correlation with the white-light (WL) enhancement and the sunquake. Spectral analysis also reveals a harder photon spectrum that extends to several hundred keV, implying a considerable population of flare-accelerated nonthermal electrons at high energies. Quantitatively, the total energy of electrons above 300 keV in sunquake-active flares is systematically different from that in sunquake-quiet flares, while the difference is marginal for electrons above 50 keV. All these facts support highly energetic electrons as a preferred driver of the sunquakes. Such an electron-driven scenario can be reasonably accommodated in the framework of a recently proposed selection rule for

sunquake generation. For the remaining one event, the sunquake epicenter is cospatial with a magnetic imprint, i.e., a permanent change of magnetic field on the photosphere. Quantitative calculation shows that the flare-induced downward Lorentz force can do enough work to power the sunquake, acting as a viable sunquake driver for this specific event. **9 Aug 2011, 24 Sep 2011, 2012 October 23, 27 Oct 2014,**
Table 1. List of the Flares under study and the Sunquake Information 2011-2017

Predicting Sunspot Numbers for Solar Cycles 25 and 26

S.-S. **Wu**, G. Qin
ApJ **2021**
https://arxiv.org/pdf/2102.06001.pdf
The prediction of solar activity is important for advanced technologies and space activities. The peak sunspot number (SSN), which can represent the solar activity, has declined continuously in the past four solar cycles (21−24), and the Sun would experience a Dalton-like minimum, or even the Maunder-like minimum, if the declining trend continues in the following several cycles, so that the predictions of solar activity for cycles 25 and 26 are crucial. In Qin & Wu, 2018, ApJ, we established an SSN prediction model denoted as two-parameter modified logistic prediction (TMLP) model, which can predict the variation of SSNs in a solar cycle if the start time of the cycle has been determined. In this work, we obtain a new model denoted as TMLP-extension (TMLP-E). If the start time of a cycle n is already known, TMLP-E can predict the variation of SSNs in the cycle n+1. Cycle 25 is believed to start in December 2019, so that the predictions of cycles 25 and 26 can be made with our models. It is found that the predicted solar maximum, ascent time, and cycle length are 115.1, 4.84 yr, and 11.06 yr, respectively, for cycle 25, and 107.3, 4.80 yr, and 10.97 yr, respectively, for cycle 26. The solar activities of cycles 25 and 26 are predicted to be at the same level as that of cycle 24, but will not decrease further. We therefore suggest that the cycles 24−26 are at a minimum of Gleissberg cycle.

Chromospheric UV Bursts and Turbulent-driven Magnetic Reconnection

Pin **Wu**
2019 ApJ 885 158
https://doi.org/10.3847/1538-4357/ab4a06
We use Interface Region Imaging Spectrograph (IRIS) spacecraft data to study a group of Chromospheric ultraviolet bursts (UVBs) associated with an active region. We classify the UVBs into two types: smaller ones that can only be measured once by the scanning slit, and larger UVBs that are measured twice by the slit. The UVBs' optically thin Si iv 1402.77 Å line profiles are studied intensively. By fitting the smaller UVBs' lines with 1–2 Gaussians, we obtain a variety of line-of-sight flow measurements that hint various 3D orientations of small-scale magnetic reconnections, each associated with a UVB. The larger UVBs are, however, unique in a way that they each have two sets of measurements at two slit locations. This makes it possible to unambiguously detect two oppositely directed heated flows jetting out of a single UVB, a signature of magnetic reconnection operating at the heart of the UVB. Here, we report on the first of such an observation. Additionally, all the optically thin Si iv 1402.77 Å line profiles from those UVBs consistently demonstrate excessive broadening, an order of magnitude larger than would be expected from thermal broadening, suggesting that those small-scale reconnections could be driven by large scale (macroscale) turbulence in the active region.

Solar Cycle Variation of the Heliospheric Plasma Sheet Thickness

Chin-Chun **Wu**, Kan Liou, Ronald P. Lepping
Solar Physics July **2019**, 294:90
https://link.springer.com/content/pdf/10.1007%2Fs11207-019-1464-0.pdf
Past independent studies of the heliospheric plasma sheet (HPS) have shown that the thickness is highly variable, ranging from ≈3.8×105≈3.8×105 to 8.9×1068.9×106 km. Here we conduct a survey of the previous results and find a solar cycle dependence – where the HPS tends to be wider during solar-minimum years and narrower during solar-maximum years. The HPS is thicker near solar minimum than near solar maximum by a factor of 1.6 (in Solar Cycle 23) and 8 (in Solar Cycle 24). We also found that the average HPS thickness in 2007 (near the minimum of Solar Cycle 23/24) was almost ten times larger than that in 1995 (near minimum of Solar Cycle 22/23), and it was associated with a weak polar magnetic field in 2007. Based on the solar-surface-field measurements, we found that the average solar magnetic-field strength [|B||B|] at 2.5 solar radii [R⊙] was ≈40≈40% larger in 1995 than in 2007 (0.22 gauss versus 0.16 gauss). We also found a larger (≈27≈27%) magnetic pressure-gradient force in 1995 than in 2007. Because this magnetic gradient force points toward the Equator in the corona (which is probably also true farther out), a wider HPS is expected to occur in 2007 than in 1995, at least close to the Sun. This result supports the so-called heliospheric plasma-sheet inflation hypothesis, i.e. the HPS is wider if the Sun's polar field is weaker and narrower if the Sun's polar field is stronger.

Chromospheric UV bursts and turbulent driven magnetic reconnection

Pin **Wu**

ApJ **2019**

https://arxiv.org/pdf/1910.00355.pdf

We use Interface Region Imaging Spectrograph (IRIS) spacecraft data to study a group of Chromospheric ultraviolet bursts (UVBs) associated with an active region. Solar total and spectral irradiance reconstruction over the last 9000 years

C.-J. **Wu**, N. A. Krivova, S. K. Solanki, I. G. Usoskin

A&A 620, A120 **2018**

https://arxiv.org/pdf/1811.03464.pdf

Changes in solar irradiance and in its spectral distribution are among the main natural drivers of the climate on Earth. However, irradiance measurements are only available for less than four decades, while assessment of solar influence on Earth requires much longer records. The aim of this work is to provide the most up-to-date physics-based reconstruction of the solar total and spectral irradiance (TSI/SSI) over the last nine millennia. The concentrations of the cosmogenic isotopes 14C and 10Be in natural archives have been converted to decadally averaged sunspot numbers through a chain of physics-based models. TSI and SSI are reconstructed with an updated SATIRE model. Reconstructions are carried out for each isotope record separately, as well as for their composite. We present the first ever SSI reconstruction over the last 9000 years from the individual 14C and 10Be records as well as from their newest composite. The reconstruction employs physics-based models to describe the involved processes at each step of the procedure. Irradiance reconstructions based on two different cosmogenic isotope records, those of 14C and 10Be, agree well with each other in their long-term trends despite their different geochemical paths in the atmosphere of Earth. Over the last 9000 years, the reconstructed secular variability in TSI is of the order of 0.11%, or 1.5 W/m2. After the Maunder minimum, the reconstruction from the cosmogenic isotopes is consistent with that from the direct sunspot number observation. Furthermore, over the nineteenth century, the agreement of irradiance reconstructions using isotope records with the reconstruction from the sunspot number by Chatzistergos et al. (2017) is better than that with the reconstruction from the WDC-SILSO series (Clette et al. 2014), with a lower chi-square-value.

Solar activity over nine millennia: A consistent multi-proxy reconstruction

Chi Ju **Wu**, I. G. Usoskin, N. Krivova, G. A. Kovaltsov, M. Baroni, E. Bard, S. K. Solanki

A&A 615, A93 **2018**

https://arxiv.org/pdf/1804.01302.pdf

https://www.aanda.org/articles/aa/pdf/2018/07/aa31892-17.pdf

Solar activity in the past millennia can only be reconstructed from cosmogenic radionuclide records in terrestrial archives. However, because of the diversity of the proxy archives, it is difficult to build a homogeneous reconstruction. Here we provide a new consistent multiproxy reconstruction of the solar activity over the last 9000 years, using available long-span datasets of 10Be and 14C in terrestrial archives. A new method, based on a Bayesian approach, was applied for the first time to solar activity reconstruction. A Monte Carlo search for the most probable value of the modulation potential was performed to match data from different datasets for a given time. We used six 10Be series from Greenland and Antarctica, and the global 14C production series. The 10Be series were resampled to match wiggles related to the grand minima in the 14C reference dataset. The GRIP and the EDML 10Be series diverge from each other during the second half of the Holocene, while the 14C series lies between them. A likely reason for this is the insufficiently precise beryllium transport and deposition model for Greenland. A slow 6-millennia variability with lows at ca. 5500 BC and 1500 AD of solar activity is found. Two components of solar activity can be statistically distinguished: the main 'normal' component and a component corresponding to grand minima. A possible existence of a component representing grand maxima is indicated, but it cannot be separated from the main component in a statistically significant manner. A new consistent reconstruction of solar activity over the last nine millennia is presented with the most probable values of decadal sunspot numbers and their realistic

uncertainties. Independent components of solar activity corresponding to the main moderate activity and the grand-minimum state are identified; they may be related to different operation modes of the dynamo.

Instrument Calibration of the Interface Region Imaging Spectrograph (IRIS) Mission

J.-P. **Wülser**, S. Jaeggli, B. De Pontieu, T. Tarbell, P. Boerner, S. Freeland et al.
Solar Physics November **2018**, 293:149
https://link.springer.com/article/10.1007/s11207-018-1364-8
The Interface Region Imaging Spectrograph (IRIS) is a NASA small explorer mission that provides high-resolution spectra and images of the Sun in the 133 – 141 nm and 278 – 283 nm wavelength bands. The IRIS data are archived in calibrated form and made available to the public within seven days of observing. The calibrations applied to the data include dark correction, scattered light and background correction, flat fielding, geometric distortion correction, and wavelength calibration. In addition, the IRIS team has calibrated the IRIS absolute throughput as a function of wavelength and has been tracking throughput changes over the course of the mission. As a resource for the IRIS data user, this article describes the details of these calibrations as they have evolved over the first few years of the mission. References to online documentation provide access to additional information and future updates.

Coronal rain in magnetic bipolar weak fields

Chun **Xia**, Rony Keppens, Xia Fang
A&A 603, A42 **2017**
https://arxiv.org/pdf/1706.01804.pdf
We intend to investigate the underlying physics for the coronal rain phenomenon in a representative bipolar magnetic field, including the formation and the dynamics of coronal rain blobs. With the MPI-AMRVAC code, we performed three dimensional radiative magnetohydrodynamic (MHD) simulation with strong heating localized on footpoints of magnetic loops after a relaxation to quiet solar atmosphere. Progressive cooling and in-situ condensation starts at the loop top due to radiative thermal instability. The first large-scale condensation on the loop top suffers Rayleigh-Taylor instability and becomes fragmented into smaller blobs. The blobs fall vertically dragging magnetic loops until they reach low beta regions and start to fall along the loops from loop top to loop footpoints. A statistic study of the coronal rain blobs finds that small blobs with masses of less than 10^10 g dominate the population. When blobs fall to lower regions along the magnetic loops, they are stretched and develop a non-uniform velocity pattern with an anti-parallel shearing pattern seen to develop along the central axis of the blobs. Synthetic images of simulated coronal rain with Solar Dynamics Observatory Atmospheric Imaging Assembly well resemble real observations presenting dark falling clumps in hot channels and bright rain blobs in a cool channel. We also find density inhomogeneities during a coronal rain "shower", which reflects the observed multi-stranded nature of coronal rain.

Study on the Temporal Evolution of the Radial Differential Rotation of Solar Corona Using Radio Emissions

N. B. **Xiang**, X. H. Zhao, L. H. Deng, F. Y. Li, Y. J. Wang, X. W. Tan
ApJ **2024**
https://arxiv.org/pdf/2411.18105
The daily measurements of the disc-integrated solar radio flux, observed by the Radio Solar Telescope Network (RSTN), at 245, 410, 610, 1415, 2695, 4995, and 8800 MHz during the time interval of 1989 January 1 to 2019 December 17, are used to investigate the temporal evolution of radial differential rotation of solar corona using the methods of Ensemble Empirical Mode Decomposition and wavelet analysis. Overall, the results reveal that over the 30-year period, the rotation rates for the observed solar radio flux within the frequency range of 245\textendash8800 MHz show an increase with frequency. This verifies the existence of the radial differential rotation of the solar corona over long timescales of nearly 3 solar cycles. Based on the radio emission mechanism, to some extent, the results can also serve as an indicator of how the rotation of the solar upper atmosphere varies with altitude within a specific range. From the temporal variation of rotation cycle lengths of radio flux, the coronal rotation at different altitudes from the low corona to approximately 1.3 R⊙ exhibits complex temporal variations with the progression of the solar cycle. However, in this altitude range, over the past 30 years from 1989 to 2019, the coronal rotation consistently becomes gradually slower as the altitude increases. Finally, the EEMD method can extract rotation cycle signals from these highly randomized radio emissions, and so it can be used to investigate the rotation periods for the radio emissions at higher or lower frequencies.

Systematic investigation of mid-term periodicity of the solar full-disk magnetic fields

Nan-Bin **Xiang**
RAA **2019** Vol. 19 No. 9, 131(12pp)
http://www.raa-journal.org/raa/index.php/raa/article/view/4374/4857

The Magnetic Plage Strength Index (MPSI) and the Mount Wilson Sunspot Index (MWSI), which have been measured at Mount Wilson Observatory (MWO) since the 1970s and which indicate weak and strong magnetic field activity on the solar full disk, respectively, are used to systematically investigate midterm periodicities in the solar full-disk magnetic fields. Multitudinous mid-term periodicities are detected in MPSI and MWSI on timescales of 0.3 to 4.5 yr, and these periodicities are found to fluctuate around several typical periodicities within a small amplitude in different solar cycles or phases. The periodicity of 3.44 yr is found in MPSI, and the periodicities of 3.85 and 3.00 yr are detected in MWSI. Our analysis indicates that they reflect the true oscillating signals of solar magnetic field activity. The typical periodicities are 2.8, 2.3 and 1.8 yr in MPSI and MWSI, and possible mechanisms for these periodicities are discussed. A 1.3 yr periodicity is only detected in MPSI, and should be related to meridional flows on the solar surface. The typical annual periodicity of MPSI and MWSI is 1.07 yr, which is not derived from the annual variation of Earth's heliolatitude. Several periodicities shorter than 1 yr found in MPSI and MWSI are considered to be Rieger-type periodicities.

Resonant Mode Conversion of Alfvén Waves to Kinetic Alfvén Waves in an Inhomogeneous Plasma

L. **Xiang**1,2, L. Chen1, and D. J. Wu1
2019 ApJ 881 61
sci-hub.se/10.3847/1538-4357/ab2bf1
Kinetic Alfvén waves (KAWs) are dispersive Alfvén waves (AWs) with a perpendicular wavelength comparable to the ion (ion–acoustic) gyroradius or the electron inertial length and can play an important role in wave energy dissipation and particle energization. In this paper, we investigate the resonant mode conversion of AWs into KAWs for the case of an arbitrary angle α between the density gradient of the ambient plasma and the ambient magnetic field in an inhomogeneous two-temperature magnetoplasma. The results show that the mode conversion sensitively depends on the angle α, the density inhomogeneous gradient kri , and the parallel wavenumber kzri , as well as the ion to electron temperature ratio T T i e. In particular, the excited KAWs are stronger when α is closer to °90° and are hardly excited for 0 < . Moreover, the maximal strength of the excited KAW increases with° a 40 the increase of kzri , but decreases with the increase of kri . Also, the maximal strength of the excited KAW has a °larger value at larger T T i e for 80 90 < . These results are helpful for our comprehensive understanding of° a the resonant mode conversion of AWs into KAWs in solar magnetic atmospheres when AWs originating from the photosphere propagate along solar magnetic fields into the corona.

Photospheric Swirls in a Quiet-Sun Region

Quan **Xie**, Jiajia Liu, Chris J. Nelson, Robert Erdélyi, Yuming Wang
ApJ **2024**
https://arxiv.org/pdf/2412.03816
Swirl-shaped flow structures have been observed throughout the solar atmosphere, in both emission and absorption, at different altitudes and locations, and are believed to be associated with magnetic structures. However, the distribution patterns of such swirls, especially their spatial positions, remain unclear. Using the Automated Swirl Detection Algorithm (ASDA), we identified swirls from the high-resolution photospheric observations, centered on Fe I 630.25 nm, of a quiet region near the Sun's central meridian by the Swedish 1-m Solar Telescope. Through a detailed study of the locations of the detected small-scale swirls with an average radius of ∼300 km, we found that most of them are located in lanes between mesogranules (which have an average diameter of ∼5.4 Mm) instead of the commonly believed intergranular lanes. The squared rotation, expansion/contraction, vector speeds, and proxy kinetic energy are all found to follow Gaussian distributions. Their rotation speed, expansion/contraction speed, and circulation are positively correlated with their radius. These results suggest that photospheric swirls at different scales and locations across the observational 56.5" × 57.5" field-of-view (FOV) could share the same triggering mechanism at preferred spatial and energy scales. A comparison with previous work suggests that the number of photospheric swirls is positively correlated with the number of local magnetic concentrations, stressing the close relation between swirls and local magnetic concentrations:the number of swirls should positively correlate with the number and strength of local magnetic concentrations. **2012 June 21, 2019 July 07**

The data center for the Spectrometer and Telescope for Imaging X-rays (STIX) on board Solar Orbiter **https://datacenter.stix.i4ds.net/stix**

Hualin **Xiao**1, Shane Maloney2, Säm Krucker1, Ewan Dickson3, Paolo Massa4, Erica Lastufka1, Andrea Francesco Battaglia1,5, László Etesi1, Nicky Hochmuth6, Frédéric Schuller7, Daniel F. Ryan1, Olivier Limousin8, Hannah Collier1,5, Alexander Warmuth7 and Michele Piana9,10
A&A 673, A142 (**2023**)
https://www.aanda.org/articles/aa/pdf/2023/05/aa46031-23.pdf

Context. The Spectrometer and Telescope for Imaging X-rays (STIX) on board Solar Orbiter observes solar X-ray emission in the range of 4–150 keV and produces spectra and images of solar flares over a wide range of flare magnitudes. During nominal operation, STIX continuously generates data. A constant data flow requires fully automated data-processing pipelines to process and analyze the data, and a data platform to manage, visualize, and distribute the data products to the scientific community.
Aims. The STIX Data Center has been built to fulfill these needs. In this paper, we outline its main components to help the community better understand the tools and data it provides.
Methods. The STIX Data Center is operated at the University of Applied Sciences and Arts Northwestern Switzerland (FHNW) and consists of automated processing pipelines and a data platform. The pipelines process STIX telemetry data, perform common analysis tasks, and generate data products at different processing levels. They have been designed to operate fully automatically with minimal human intervention. The data platform provides web-based user interfaces and application programmable interfaces for searching and downloading STIX data products.
Results. The STIX Data Center has been operating successfully for more than two years. The platform facilitates instrument operations and provides vital support to STIX data users. 7 Oct 2022, 26 Jan 2023

North–South Asymmetry of the Rotation of the Solar Magnetic Field

Jinglan **Xie**1,2,3,4, Xiangjun Shi1,3,4, and Zhining Qu
2018 ApJ 855 84
http://sci-hub.tw/http://iopscience.iop.org/0004-637X/855/2/84/
Using the rotation rates of the solar magnetic field during solar cycles 21 to 23 obtained by Chu et al. by analyzing the synoptic magnetic maps produced by the NSO/Kitt Peak and SOHO/MDI during the years 1975 to 2008, the temporal variation of the equatorial rotation rate (A) and the latitude gradient of rotation (B) in the northern and southern hemispheres are studied separately. The results indicate that the rotation is more differential (about 4.3%) in the southern hemisphere in the considered time frame. It is found that the north–south asymmetry of A and the asymmetry of B show increasing trends in the considered time frame, while the north–south asymmetry of the solar activity shows a decreasing trend. There exists a significant negative correlation (at 95% confidence level) between the asymmetry of B and the asymmetry of the solar activity, and this may be due to stronger magnetic activity in a certain hemisphere that may suppress the differential rotation to some extent. The periodicities in the variation of A and B are also studied, and periods of about 5.0 and 10.5 yr (5.5 and 10.4 yr) can be found for the variation of the northern (southern) hemisphere B. Moreover, the north–south asymmetry of A and the asymmetry of B have similar periods of about 2.6–2.7 and 5.2–5.3 yr. Further, cross-correlation analysis indicates that there exists a phase difference (about eight months) between the northern and southern hemisphere B, and this means that the northern hemisphere B generally leads by about eight months.

Temporal Variation of Solar Coronal Rotation

J. L. **Xie**1,2,3,4, X. J. Shi1,3,4, and J. Zhang
2017 ApJ 841 42
http://sci-hub.cc/10.3847/1538-4357/aa6d7d
In this paper, by applying the wavelet transformation analysis to the data of the daily 10.7 cm radio flux covering the period from 1947 February 14 to 2014 August 31, a significant period of about 27 days can be found, indicating the existence of rotational modulation in the temporal variation of the daily 10.7 cm radio flux. Then, the solar coronal rotation periods are obtained based on the result of the wavelet transformation analysis, and the temporal variation of the coronal rotation is revisited. We find that there exist significant periods of about 2.1, 3.0, 4.5, 6.6, 8.6, and 10.3 yr in the temporal variation of the coronal rotation. A possible period of 22.0 yr can also be found, but its statistical significance is below the 95% confidence level. The coronal rotation seems to show a weak decreasing trend during the considered time. The dependence of the coronal rotation on solar cycle phase is analyzed. The rotation periods are found to be varying with the solar cycle phase, and they are relatively longer around the minimum year of the solar cycle. The result based on the cross-correlation analysis between the rotation periods and the daily 10.7 cm radio flux indicates that there exists a phase difference of about 5.5 yr between them.

Forecasting solar cycle 25 using comprehensive precursor combination and multiple regression technique

Yating **Xiong**, Jianyong Lu, Kai Zhao, Meng Sun, Yang Gao
MNRAS, Volume 505, Issue 1, **2021**, Pages 1046–1052,
https://doi.org/10.1093/mnras/stab1159
In this paper, we propose a new model to predict the complete sunspot cycle based on the comprehensive precursor information (peak, skewness, maximum geomagnetic index aa of the previous cycle, and start value of predicted

cycle). The monthly average sunspot original data are processed by Gaussian smoothing and the new model is validated by the observed sunspots of cycle 24. Compared with the traditional 13-month moving average, the Gaussian filter has less missing information and is better to describe the overall trend of the raw data. Through the permutation and combination of multiple parameters in precursor methods of solar cycle forecasting, the multiple regression technique is used to successfully achieve the peak prediction. The regression coefficient (R) of the empirical model established in this paper can reach 0.95. By adding a new parameter to the original HWR function, we provide a complete solar cycle profile showing unimodal structure. It shows that the peak value of cycle 25 will come in March 2024, with a peak of 140.2.

Data-Driven Forecasting of Sunspot Cycles: Pros and Cons of a Hybrid Approach.

Xu, Q., Jain, R. & Xing, W.
Sol Phys 299, 25 (**2024**).
https://doi.org/10.1007/s11207-024-02270-6
https://link.springer.com/content/pdf/10.1007/s11207-024-02270-6.pdf
Understanding the number of sunspots is crucial for comprehending the Sun's magnetic-activity cycle and its influence on space weather and the Earth. Recent advancements in machine learning have significantly improved the accuracy of time-series predictions, revealing a compelling approach for sunspot forecasts. Our work takes the pioneering work by proposing a hybrid forecasting approach that combines the Seasonal Autoregressive Integrated Moving Average (SARIMA) with machine-learning algorithms like Random Forest and Support Vector Machine, delivering high prediction accuracy. Despite its high accuracy, we highlight the need for caution in deploying machine-learning-based methods for sunspot-number prediction, demonstrated through a detailed case study with only three extra time stamps leading to a dramatic change. More specifically, when making a forecast of monthly averaged sunspot numbers from 2023–2043 based on data from 1749–2023, we found that the observations in June, July, and August 2023 have a significant impact on the forecast, particularly in the long term. Given the multiseasonal and nonstationary nature of the sunspot time series, we conclude that this kind of phenomenon cannot be simply captured by a pure data-driven model, which can be highly sensitive in the forecast in the long term, and requires a more comprehensive approach, possibly with a model that includes physics.

Magnetic field evolution around a fast-moving pore emerging from the quiet Sun⋆

Zhe **Xu**1,2,⋆⋆, Haisheng Ji1, Junchao Hong2, Kaifan Ji2 and Jiayan Yang2
A&A 660, A55 (**2022**)
https://www.aanda.org/articles/aa/pdf/2022/04/aa43021-21.pdf
Context. Solar pores are intense concentrations of magnetic fields on the solar surface and plasma flows have always played a key role in spurring the evolution of the pores.
Aims. In this study, we present the evolution of the magnetic field and plasma velocity around a fast-moving pore. The target pore expands into the quiet Sun area with a sufficiently fast speed after its emergence, while the background magnetic fields around the pore are simple. These characteristics provide us with an excellent opportunity to study the interaction between plasma motions and ambient magnetic fields.
Methods. We analyzed the Helioseismic and Magnetic Imager (HMI) vector magnetograms with a pixel size of 0.5″ and a temporal cadence of 12 min across a duration of 11 h. We also adopted he HMI dopplergrams present the line-of-sight velocities. The horizontal flow fields were obtained using the Differential Affine Velocity Estimator for Vector Magnetograms method.
Results. Pure horizontal magnetic fields are generated in the moving frontwards when the pore is subject to fast movement. The generated magnetic fields occur outside the emerging site and thus can be ruled out as the emerging flux from the interior. Instead, they are highly correlated with the broader downflows and expanding horizontal plasma motions in front of the pore. A magnetic gap can be observed between the magnetic fields inside and outside the pore. The temporal evolution of the generated magnetic fields is related to the speed of the pore, which is also distinguished from the original fields within the pore.
Conclusions. The observations suggest that the plasma flows driven by the fast proper motion of the pore compress and stretch the local magnetic field to a horizontal non-radial direction, ultimately leading to the magnetic field amplification in the front part of the moving pore. **2012 February 6**

Asymmetric Distribution of the Solar Photospheric Magnetic Field Values

Jing-Chen **Xu**, Ke-Jun Li, Peng-Xin Gao
ApJ **919** 102 **2021**
https://arxiv.org/pdf/2107.03548.pdf
https://doi.org/10.3847/1538-4357/ac106e
Understanding the characteristics of the solar magnetic field is essential for interpreting solar activities and dynamo. In this research, we investigated the asymmetric distribution of the solar photospheric magnetic field values, using synoptic charts constructed from space-borne high-resolution magnetograms. It is demonstrated that the Lorentzian function describes the distribution of magnetic field values in the synoptic charts much better than the Gaussian

function, and this should reflect the gradual decay process from strong to weak magnetic fields. The asymmetry values are calculated under several circumstances, and the results generally show two periodicities related to the variation of the solar B0 angle and the solar cycle, respectively. We argue that it is the small-scale magnetic fields, the inclination of the solar axis, the emergence and evolution of magnetic flux, and the polar fields that are responsible for the features of asymmetry values. We further determined the polar field reversal time of solar cycles 23 and 24 with the flip of asymmetry values. Specifically, for cycle 24, we assert that the polar polarities of both hemispheres reversed at the same time - in March 2014; as to cycle 23, the reversal time of the S-hemisphere is March 2001, while the determination of the N-hemisphere is hampered by missing data.

Migration of Solar Polar Crown Filaments in the Past 100 Years

Yan **Xu**1,2, Dipankar Banerjee3,4,5, Subhamoy Chatterjee6, Werner Pötzi7, Ziran Wang8, Xindi Ruan8, Ju Jing1,2, and Haimin Wang1,2
2021 ApJ 909 86
https://doi.org/10.3847/1538-4357/abdc1e
Polar crown filaments (PCFs) are formed above the polarity inversion line, which separates unipolar polar fields and the nearest dispersed fields. They are important features in studying solar polar fields and their cyclical variations. Due to the relatively weak field strength and projection effects, measuring polar magnetic fields is more difficult than obtaining the field strengths concentrated in active regions at lower latitudes. "Rush-to-the-pole" of PCFs represent the progress of unipolar polar fields from the previous solar cycle being canceled by the dispersed fields generated in the current cycle. Such progress is a good indicator of the polarity reversal in the polar areas and a precursor for the solar maximum. In this study, PCFs are identified from a 100 yr archive, covering cycles 16–24. This archive consists of full-disk Hα images obtained from the Kodaikanal Solar Observatory of the Indian Institute of Astrophysics, Kanzelhöhe Solar Observatory, and Big Bear Solar Observatory. The poleward migration speeds are measured and show an obvious asymmetry in the northern and southern hemispheres. In addition, our results show that the PCFs usually reach their highest latitudes first in the northern hemisphere, except cycle 17. Similarly, previous studies show that the magnetic field reversed first at the north pole in six out of nine cycles. We also compare the temporal variations of PCF migration and the latitude gradient factor of the differential rotation, which shows a trend in the southern hemisphere. Moreover, the migration speed of PCFs does not seem to be well correlated with the maximum sunspot numbers.

On the Rotation of the Solar Chromosphere

Jing-Chen **Xu**1,2,3, Peng-Xin Gao1,2,3, and Xiang-Jun Shi1,2,3
2020 ApJ 902 64
https://doi.org/10.3847/1538-4357/abb5b7
https://arxiv.org/pdf/2010.10851
Rotation is a significant characteristic of the Sun and other stars, and it plays an important role in understanding their dynamo actions and magnetic activities. In this study, the rotation of the solar chromospheric activity is investigated from a global point of view with an over 40 yr Mg ii index. We determined the time-varying rotational period lengths (RPLs) with the synchrosqueezed wavelet transform, which provides high temporal and frequency resolution; furthermore, we compared the RPLs with the photospheric and coronal RPLs obtained from the sunspot numbers and the 10.7 cm radio flux data. The significance of the RPLs is taken into consideration. We found that the RPLs of the chromosphere exhibit a downward trend, as do those of the photosphere and corona; in addition, their RPLs at the recent four solar maxima also show a declining trend. This suggests that the rotation of the solar atmosphere has been accelerating during the recent four solar cycles, which is inferred to be caused by the declining strength of solar activity. The variations of the solar atmospheric RPLs show periodicities of multiple harmonics of the solar cycle period, and it is modulated by the solar activity cycle.

Localized Amplification of Magnetic Field in the Solar Photosphere Associated with a Rapid Moving Pore

Zhe **Xu**1,2,3, Haisheng Ji1,3, Kaifan Ji2,3, Yi Bi2,3, Bo Yang2,3, Junchao Hong2,3, and Jiayan Yang2,3

https://doi.org/10.3847/2041-8213/abb096
https://iopscience.iop.org/article/10.3847/2041-8213/abb096/pdf
In the Sun, the flows of hot plasma drive a dynamo that generates a global magnetic field as well as smaller-scale local fields. The existence of a magnetic field in turn affects the motion of plasma so that complex dynamic characteristics can be observed. In this Letter, we give an analysis on the localized amplification of magnetic fields in front of a moving pore. Moving with the pore, the formation of semicircular penumbra-like structures and enhancement of horizontal fields can be observed simultaneously. The increasing horizontal magnetic fields in a penumbra-like area probably did not come from the pore, since the penumbra-like structures were not connected to the pore and a magnetic gap existed. The possibility of flux emergence can also be safely excluded. We further report that horizontal magnetic fields in the front of a moving pore are amplified in accordance with the MHD

induction equation after necessary yet reasonable simplification. All characteristics show that the flows driven by the moving pore can lead to the amplification of the magnetic fields around its front. The observations are from the Helioseismic and Magnetic Imager on board the Solar Dynamics Observatory. **2016 May 15**

Solar Image Deconvolution by Generative Adversarial Network

Long **Xu**, Wenqing Sun, Yihua Yan, Weiqiang Zhang
Research in Astron. Astrophys. **2020**
https://arxiv.org/pdf/2001.03850.pdf
With Aperture synthesis (AS) technique, a number of small antennas can assemble to form a large telescope which spatial resolution is determined by the distance of two farthest antennas instead of the diameter of a single-dish antenna. Different from direct imaging system, an AS telescope captures the Fourier coefficients of a spatial object, and then implement inverse Fourier transform to reconstruct the spatial image. Due to the limited number of antennas, the Fourier coefficients are extremely sparse in practice, resulting in a very blurry image. To remove/reduce blur, "CLEAN" deconvolution was widely used in the literature. However, it was initially designed for point source. For extended source, like the sun, its efficiency is unsatisfied. In this study, a deep neural network, referring to Generative Adversarial Network (GAN), is proposed for solar image deconvolution. The experimental results demonstrate that the proposed model is markedly better than traditional CLEAN on solar images.

Collective Study of Polar Crown Filaments in the Past Four Solar Cycles

Yan **Xu**, Werner Potzi, Hewei Zhang, Nengyi Huang, Ju Jing, and Haimin Wang
2018 ApJL 862 L23
https://arxiv.org/pdf/1807.11844.pdf
http://sci-hub.tw/10.3847/2041-8213/aad40d
Polar Crown Filaments (PCFs) form above the magnetic polarity inversion line, which separates the unipolar polar fields and the nearest dispersed fields from trailing part of active regions with opposite polarity. The statistical properties of PCFs are correlated with the solar cycle. Therefore, study of PCFs plays an important role in understanding the variation of solar cycle, especially the prolonged cycle 23 and the current "abnormal" solar cycle 24. In this study, we investigate PCFs using full disk Hα data from 1973 to early 2018, recorded by Kanzelhöhe Solar Observatory (KSO) and Big Bear Solar Observatory (BBSO), in digital form from 1997 to 2018 and in 35 mm film (digitized) from 1973 to 1996. PCFs are identified manually because their segmented shape and close-to-limb location were not handled well by automatical detections in several previous studies. Our results show that the PCFs start to move poleward at the beginning of each solar cycle. When the PCFs approach to the maximum latitude, the polar field strength reduces to zero followed by a reversal. The migration rates are about 0.4 to 0.7 degree per Carrington rotation, with clear N-S asymmetric pattern. In cycles 21 and 23, the PCFs in the northern hemisphere migrate faster than those in the southern hemisphere. However, in the "abnormal" cycle 24, the southern PCFs migrate faster, which is consistent with other observations of magnetic fields and radio emission. In addition, there are more days in cycle 23 and 24 without PCFs than in the previous cycles. **2013-March-23**

Modulations of the Surface Magnetic Field on the Intra-cycle Variability of Total Solar Irradiance

J. C. **Xu**, D. F. Kong, F. Y. Li
Astrophysics and Space Science 363:98 **2018**
https://arxiv.org/pdf/1804.06079.pdf
Solar photospheric magnetic field plays a dominant role in the variability of total solar irradiance (TSI). The modulation of magnetic flux at six specific ranges on TSI is characterized for the first time. The daily flux values of magnetic field at four ranges are extracted from MDI/{\sl SOHO}, together with daily flux of active regions (MFar) and quiet regions (MFqr); the first four ranges (MF1−4) are: 1.5--2.9, 2.9--32.0, 32.0--42.7, and 42.7--380.1 (×1018 Mx per element), respectively. Cross-correlograms show that MF4, MFqr, and MFar are positively correlated with TSI, while MF2 is negatively correlated with TSI; the correlations between MF1, MF3 and TSI are insignificant. The bootstrapping tests confirm that the impact of MF4 on TSI is more significant than that of MFar and MFqr, and MFar leads TSI by one rotational period. By extracting the rotational variations in the MFs and TSI, the modulations of the former on the latter at the solar rotational timescale are clearly illustrated and compared during solar maximum and minimum times, respectively. Comparison of the relative amplitudes of the long-term variation show that TSI is in good agreement with the variation of MF4 and MFar; besides, MF2 is in antiphase with TSI, and it lags the latter by about 1.5 years.

Phase Relations between the Sunspot Numbers and Total Solar Irradiance

J. C. **Xu**1,2,3,4, J. L. Xie1,3,4, and Z. N. Qu
2017 ApJ 851 141
http://iopscience.iop.org.sci-hub.tw/0004-637X/851/2/141/

Understanding the effect of sunspot activities on the variations in the total solar irradiance (TSI) is essential for the interpretation of the variability of TSI as well as its reconstruction. Phase relations between the sunspot numbers (SN) and two TSI composite data are investigated. It is found that TSI and SN are positively correlated, and the former lags the latter by about 29 days, which is approximately a solar rotation period; analyses of the data sets in the four individual cycles show that in cycles 21, 23, and 24, TSI lags SN by 28.9–30.3 days, while in cycle 22, the lag is only 21.8–22.3 days. The abnormality in cycle 22 is probably caused by its stronger magnetic field in sunspots compared with its adjacent cycles. The nonlinearity between TSI and SN is confirmed and explained with the different behavior and effect of spots, faculae, and magnetic network. Based on the cross-wavelet transform and wavelet coherence analysis, a common periodicity between TSI and SN at the timescale of the solar cycle is clearly revealed; at timescales longer than about four years, high values of coherence above the 95% confidence level together with a strong phase synchronization feature are exhibited. At timescales shorter than three rotational periods, the relation between TSI and SN indicates low correlations and a noisy behavior with strong phase mixing due to the lifetime of spots and faculae; moreover, if the short-term effect of spots and faculae is smoothed out, then their coherence reaches high values in partial areas at periods from three rotations to about four years.

THE ROTATION OF THE SOLAR PHOTOSPHERIC MAGNETIC FIELD

J. C. **Xu**1,2,3,4 and P. X. Gao

2016 ApJ 833 144

The rotational characteristics of the solar photospheric magnetic field at four flux ranges are investigated together with the total flux of active regions (MFar) and quiet regions (MFqr). The first four ranges (MF1–4) are (1.5–2.9) × 1018, (2.9–32.0) × 1018, (3.20–4.27) × 1019, and (4.27–38.01) × 1019, respectively (the unit is Mx per element). Daily values of the flux data are extracted from magnetograms of the Michelson Doppler Imager on board the Solar and Heliospheric Observatory. Lomb–Scargle periodograms show that only MF2, MF4, MFqr, and MFar exhibit rotational periods. The periods of the first three types of flux are very similar, i.e., 26.20, 26.23, and 26.24 days, respectively, while that of MFar is longer, 26.66 days. This indicates that active regions rotate more slowly than quiet regions on average, and strong magnetic fields tend to repress the surface rotation. Sinusoidal function fittings and cross-correlation analyses reveal that MFar leads MF2 and MF4 by 5 and 1 days, respectively. This is speculated to be related with the decaying of active regions. MF2 and MFar are negatively correlated, while both MF4 and MFqr are positively correlated with MFar. At the timescale of the solar activity cycle, MFar leads (negatively) MF2 by around one year (350 days), and leads MF4 by about 3 rotation periods (82 days). The relation between MF2 and MFar may be explained by the possibility that the former mainly comes from a higher latitude, or emerges from the subsurface shear layer. We conjecture that MF4 may partly come from the magnetic flux of active regions; this verifies previous results that were obtained with indirect solar magnetic indices.

On the Origin of Differences in Helicity Parameters Derived from Data of Two Solar Magnetographs

Haiqing **Xu**, Hongqi Zhang, K. Kuzanyan, T. Sakurai

Solar Phys. Volume 291, Issue 8, pp 2253–2267 **2016**

We analyzed how sensitivity and accuracy in solar magnetic field measurements may affect the values of mean current helicity density hchc and twist parameter αavαav by comparing these values obtained from two magnetographs (SMFT at Beijing and SFT at Mitaka, Tokyo). When we computed the helicity parameters from the SFT data, we replaced the values of the longitudinal field component, transverse field strength, and transverse field azimuth angle with those from the SMFT data and examined the differences. The results show that the correlation coefficient and the fraction of the data that agree in signs of hchc or αavαav increase when an SFT parameter is substituted by the corresponding SMFT parameter because one source of discrepancy is removed. The increase in correlation coefficient is largest when the azimuthal angles and transverse field strengths are set identical in the two instruments; the correlation coefficient of hchc (αavαav) increases from 0.74 (0.56) to 0.86 (0.78), respectively, indicating that the differences in the transverse field strength and its azimuthal angle are the largest source of discrepancy in the values of hchc or αavαav. We found a nonlinear relationship in the components of the magnetic field between the two instruments for some data samples; we conclude that this is due to the discrepancy in the calibration procedure between the two instruments. This nonlinearity can be another source of difference in determining helical parameters between the two instruments.

Current helicity and magnetic field anisotropy in solar active regions

H. **Xu**, R. Stepanov, K. Kuzanyan, D. Sokoloff, H. Zhang, Y. Gao

MNRAS **2015**

http://arxiv.org/pdf/1509.02652v1.pdf

The electric current helicity density $\chi=\langle\epsilon ijkbi\partial bk\partial xj\rangle$ contains six terms, where bi are components of the magnetic field. Due to the observational limitations, only four of the above six terms can be inferred from solar photospheric vector magnetograms. By comparing the results for simulation we distinguished the statistical difference of above six terms for isotropic and anisotropic cases. We estimated the relative degree of anisotropy for three typical active

regions and found that it is of order 0.8 which means the assumption of local isotropy for the observable current helicity density terms is generally not satisfied for solar active regions. Upon studies of the statistical properties of the anisotropy of magnetic field of solar active regions with latitudes and with evolution in the solar cycle, we conclude that the consistency of that assumption of local homogeneity and isotropy requires further analysis in the light of our findings.

Angular Distribution of Solar Wind Magnetic Field Vector at 1 Au

F. **Xu**1,2, G. Li2, L. Zhao2, Y. Zhang1,2, O. Khabarova2,3, B. Miao4, and J. le Roux
2015 ApJ 801 58.

We study the angular distribution of the solar wind magnetic field vector at 1 AU and its solar cycle dependence usingACE observations. A total of twelve 27.27 day (the duration of a solar rotation) intervals during the solar maximum, the solar minimum, as well as the ascending and descending phases of solar cycle 23 are examined. For all selected intervals, we obtain the angular distribution function $f_\tau(\alpha)$, where α is the angle between the instantaneous solar wind magnetic field vector and the average background magnetic field vector, and τ is the period length for the averaging. Our results show that in all periods $f_\tau(\alpha)$has two populations, one at small angles and one at large angles. We suggest that the second population is due to the presence of current sheets in the solar wind. The solar-cycle dependence of $f_\tau(\alpha)$ and a τ-scaling property of the second population of $f_\tau(\alpha)$are discussed. The τ scaling shows a clear dependence on the solar wind type. The implication of $f_\tau(\alpha)$ for particle acceleration at interplanetary shocks driven by coronal mass ejections, such as those in solar energetic particle events, is also discussed.

Simulations of stray light from the surface scattering of the Solar Corona Imager primary mirror

Jianchao **Xue**, Marco Romoli, Federico Landini, Cristian Baccani, Hui Li, Yunqi Wang, Bo Chen
Proceedings of SPIE **2020**
https://arxiv.org/pdf/2012.07367.pdf

The Solar Corona Imager is an internally occulted coronagraph on board the ASO-S mission, which has the advantage of imaging the inner corona in H I {Lyman-\textalpha} (Ly-alpha) and white-light (WL) wavebands. However, scattering of solar disk light by the primary mirror (M1) becomes the main source of stray light. To study the methods of stray light suppression, three scattering models are used to model M1 scattering in Zemax OpticStudio. The ratio of coronal emission to predicted stray light decrease along field of view in both channels. The stray light in Ly-alpha channel is generally lower than coronal emission, but the stray light in WL channel tends to be one order of magnitude higher than coronal signal at 2.5 Rsun. Optimized parameter combinations that suppress the stray light to required level are obtained, which put some limitations on the M1 manufacture. Besides, K-correlation model is recommended to simulate surface scattering.

Inference of electric currents in the solar photosphere

A. Pastor **Yabar**, J.M. Borrero, C. Quintero Noda, B. Ruiz Cobo
A&A 656, L20 **2021**
https://arxiv.org/pdf/2112.04356.pdf
https://www.aanda.org/articles/aa/pdf/2021/12/aa42149-21.pdf
https://doi.org/10.1051/0004-6361/202142149

We aim at demonstrating the capabilities of a newly developed method for determining electric currents in the solar photosphere. We employ three-dimensional radiative magneto-hydrodynamic (MHD) simulations to produce synthetic Stokes profiles in several spectral lines with a spatial resolution similar to what the newly operational 4-meter Daniel K. Inouye Solar Telescope (DKIST) solar telescope should achieve. We apply a newly developed inversion method of the polarized radiative transfer equation with magneto-hydrostatic (MHS) constraints to infer the magnetic field vector in the three-dimensional Cartesian domain, B(x,y,z), from the synthetic Stokes profiles. We then apply Ampere's law to determine the electric currents, j, from the inferred magnetic field, B(x,y,z), and compare the results with the electric currents present in the original MHD simulation. We show that the method employed here is able to attain reasonable reliability (close to 50 % of the cases are within a factor of two, and this increases to 60 %-70 % for pixels with B≥300 G) in the inference of electric currents for low atmospheric heights (optical depths at 500 nm $\tau_5 \in [1, 0.1]$) regardless of whether a small or large number of spectral lines are inverted. Above these photospheric layers, the method's accuracy strongly deteriorates as magnetic fields become weaker and as the MHS approximation becomes less accurate. We also find that the inferred electric currents have a floor value that is related to low-magnetized plasma, where the uncertainty in the magnetic field inference prevents a sufficiently accurate determination of the spatial derivatives. We present a method that allows the inference of the three components of the electric current vector at deep atmospheric layers (photospheric layers) from spectropolarimetric observations.

Photospheric magnetic topology of a north polar region

A. Pastor **Yabar** (1), M. J. Martínez González (2,3), M. Collados

A&A 635, A210 **2020**

https://arxiv.org/pdf/2003.04267.pdf

Aims. We aim to characterise the magnetism of a large fraction of the north polar region close to a maximum of activity, when the polar regions are reversing their dominant polarity.
Methods. We make use of full spectropolarimetric data from the CRisp Imaging Spectro-Polarimeter installed at the Swedish Solar Telescope. The data consist of a photospheric spectral line, which is used to infer the various physical parameters of different quiet Sun regions by means of the solution of the radiative transfer equation. We focus our analysis on the properties found for the north polar region and their comparison to the same analysis applied to data taken at disc centre and low-latitude quiet Sun regions for reference. We also analyse the spatial distribution of magnetic structures throughout the north polar region.
Results. We find that the physical properties of the polar region (line-of-sight velocity, magnetic flux, magnetic inclination and magnetic azimuth) are compatible with those found for the quiet Sun at disc centre and are similar to the ones found at low latitudes close to the limb. Specifically, the polar region magnetism presents no specific features. The structures for which the transformation from a line-of-sight to a local reference frame was possible harbour large magnetic fluxes (>1017 Mx) and are in polarity imbalance with a dominant positive polarity, the largest ones (>1019 Mx) being located below 73◦ latitude.

Wave transformations near a coronal magnetic null-point

Nitin **Yadav**, Rony Keppens

A&A 681, A43 (**2024**)

https://arxiv.org/pdf/2310.17573.pdf

We investigate the viability of MHD waves, in particular acoustic p-modes, in causing strong current accumulation at the null points. We begin with a three-dimensional numerical setup incorporating a gravitationally stratifed solar atmosphere and an axially symmetric magnetic feld including a coronal magnetic null point. To excite waves, we employ wave drivers mimicking global p-modes. We found that most of the vertical velocity transmits through the Alfvén acoustic equipartition layer maintaining acoustic nature while a small fraction generates fast waves via the mode conversion process. The fast waves undergo almost total refection at the transition region due to sharp gradients in density and Alfvén speed. There are only weak signatures of Alfvén wave generation near the transition region due to fast-to-Alfvén mode conversion. Since the slow waves propagate with the local sound speed, they are not much afected by the density gradients at the transition region and undergo secondary mode conversion and transmission at the Alfvén-acoustic equipartition layer surrounding the null point, leading to fast wave focusing at the null point. These fast waves have associated perturbations in current density, showing oscillatory signatures compatible with the second harmonic of the driving frequency which could result in resistive heating and enhanced intensity in the presence of fnite resistivity. We conclude that MHD waves could be a potential source for oscillatory current dissipation around the magnetic null point. We conjecture that besides oscillatory magnetic reconnection, global p-modes could lead to the formation of various quasiperiodic energetic events.

Solar Atmospheric Heating Due to Small-scale Events in an Emerging Flux Region

Rahul **Yadav**, Maria D. Kazachenko, Andrey N. Afanasyev, Jaime de la Cruz Rodríguez, Jorrit Leenaarts

ApJ **958** 54 **2023**

https://arxiv.org/pdf/2309.06452.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/acfd2b/pdf

We investigate the thermal, kinematic and magnetic structure of small-scale heating events in an emerging flux region (EFR). We use high-resolution multi-line observations (including Ca II 8542~Å, Ca II K, and Fe I 6301~Å line pair) of an EFR located close to the disk center from the CRISP and CHROMIS instruments at the Swedish 1-m Solar Telescope. We perform non-LTE inversions of multiple spectral lines to infer the temperature, velocity, and magnetic field structure of the heating events. Additionally, we use the data-driven Coronal Global Evolutionary Model to simulate the evolution of the 3D magnetic field configuration above the events and understand their dynamics. Furthermore, we analyze the differential emission measure to gain insights into the heating of the coronal plasma in the EFR. Our analysis reveals the presence of numerous small-scale heating events in the EFR, primarily located at polarity inversion lines of bipolar structures. These events not only heat the lower atmosphere but also significantly heat the corona. The data-driven simulations, along with the observed enhancement of currents and Poynting flux, suggest that magnetic reconnection in the lower atmosphere is likely responsible for the observed heating at these sites. **September 19, 2016**

Three-dimensional MHD wave propagation near a coronal null point: a new wave mode decomposition approach

N. **Yadav**, Rony Keppens, B. Popescu Braileanu

A&A **2022**
https://arxiv.org/pdf/2201.09704.pdf
We present a new MHD wave decomposition method that overcomes the limitations of existing wave identification methods. Our method allows to investigate the energy fluxes in different MHD modes at different locations of the solar atmosphere as waves generated by vortex flows travel through the solar atmosphere and pass near the magnetic null. We simulate wave dynamics through a coronal null configuration and apply a rotational wave driver at our bottom photospheric boundary. To identify the wave energy fluxes associated with different MHD wave modes, we employ a wave-decomposition method that is able to uniquely distinguish different MHD modes. Our proposed method utilizes the geometry of an individual magnetic field-line in 3D space to separate out velocity perturbations associated with the three fundamental MHD waves. Our method for wave identification is consistent with previous flux-surface-based methods and gives expected results in terms of wave energy fluxes at various locations of the null configuration. We show that ubiquitous vortex flows excite MHD waves that contribute significantly to the Poynting flux in the solar corona. Alfvén wave energy flux accumulates on the fan surface and fast wave energy flux accumulates near the null point. There is a strong current density buildup at the spine and fan surface.The proposed method has advantages over previously utilized wave decomposition methods, since it may be employed in realistic simulations or magnetic extrapolations, as well as in real solar observations, whenever the 3D fieldline shape is known. The enhancement in energy flux associated with magneto-acoustic waves near nulls may have important implications in the formation of jets and impulsive plasma flows.

Slow magneto-acoustic waves in simulations of a solar plage region carry enough energy to heat the chromosphere

Nitin **Yadav**, Robert H. Cameron, Sami K. Solanki
A&A 652, A43 **2021**
https://arxiv.org/pdf/2105.02932.pdf
https://www.aanda.org/articles/aa/pdf/2021/08/aa39908-20.pdf
https://doi.org/10.1051/0004-6361/202039908
We study the properties of slow magneto-acoustic waves that are naturally excited due to turbulent convection and investigate their role in the energy balance of a plage region using three dimensional (3D) radiation-MHD simulations. We calculate the horizontally averaged (over the whole domain) frequency power spectra for both longitudinal and vertical (i.e. the component perpendicular to the surface) components of velocity. To compare our results with the observations we degrade the simulation data with Gaussian kernels having FWHM of 100 km and 200 km, and calculate horizontally averaged power spectra for the vertical component of velocity. The power spectra of the longitudinal component of velocity, averaged over field lines in the core of a kG magnetic flux concentration, reveal that the dominant period of oscillations shifts from around 6.5 minutes in the photosphere to around 4 minutes in the chromosphere. At the same time, the velocity power spectra, averaged horizontally over the whole domain, show that low frequency waves (approximately 6.5 minute period) may reach well into the chromosphere. Importantly, waves with frequencies above 5 mHz propagating along different field lines are found to be out of phase with each other even within a single magnetic concentration. The horizontally averaged power spectra of the vertical component of velocity at various effective resolutions show that the observed acoustic wave energy fluxes are underestimated, by a factor of three even if determined from observations carried out at a high spatial resolution of 200 km. Our results show that longitudinal waves carry (just) sufficient energy to heat the chromosphere in solar plage. We conjecture that current observations (with spatial resolution around 200 km) underestimate the energy flux by roughly a factor of three, or more if the observations have lower spatial resolution.

Vortex Flow Properties in Simulations of Solar Plage Region: Evidence for their role in chromospheric heating

Nitin **Yadav**, Robert H. Cameron, Sami K. Solanki
A&A 645, A3 **2021**
https://arxiv.org/pdf/2010.14971.pdf
Context. Vortex flows exist across a broad range of spatial and temporal scales in the solar atmosphere. Small-scale vortices are thought to play an important role in energy transport in the solar atmosphere. However, their physical properties remain poorly understood due to the limited spatial resolution of the observations.
Aims. We explore and analyze the physical properties of small-scale vortices inside magnetic flux tubes using numerical simulations, and investigate whether they contribute to heating the chromosphere in a plage region.
Methods. Using the three-dimensional radiative magnetohydrodynamic simulation code MURaM, we perform numerical simulations of a unipolar solar plage region. To detect and isolate vortices we use the swirling strength criterion and select the locations where the fluid is rotating with an angular velocity greater than a certain threshold. We concentrate on small-scale vortices as they are the strongest and carry most of the energy. We explore the spatial profiles of physical quantities such as density and horizontal velocity inside these vortices. Moreover, to learn their general characteristics, a statistical investigation is performed.

Results. Magnetic flux tubes have a complex filamentary substructure harboring an abundance of small-scale vortices. At the interfaces between vortices strong current sheets are formed that may dissipate and heat the solar chromosphere. Statistically, vortices have higher densities and higher temperatures than the average values at the same geometrical height in the chromosphere.
Conclusions. We conclude that small-scale vortices are ubiquitous in solar plage regions; they are denser and hotter structures that contribute to chromospheric heating, possibly by dissipation of the current sheets formed at their interfaces.

Simulations Show that Vortex Flows Could Heat the Chromosphere in Solar Plage

Nitin **Yadav**1, R. H. Cameron1, and S. K. Solanki1
2020 ApJL 894 L17
https://doi.org/10.3847/2041-8213/ab8dc5
The relationship between vortex flows at different spatial scales and their contribution to the energy balance in the chromosphere is not yet fully understood. We perform three-dimensional (3D) radiation-magnetohydrodynamic simulations of a unipolar solar plage region at a spatial resolution of 10 km using the MURaM code. We use the swirling-strength criterion that mainly detects the smallest vortices present in the simulation data. We additionally degrade our simulation data to smooth out the smaller vortices, so that also the vortices at larger spatial scales can be detected. Vortex flows at various spatial scales are found in our simulation data for different effective spatial resolutions. We conclude that the observed large vortices are likely clusters of much smaller ones that are not yet resolved by observations. We show that the vertical Poynting flux decreases rapidly with reduced effective spatial resolutions and is predominantly carried by the horizontal plasma motions rather than vertical flows. Since the small-scale horizontal motions or the smaller vortices carry most of the energy, the energy transported by vortices deduced from low-resolution data is grossly underestimated. In full-resolution simulation data, the Poynting flux contribution due to vortices is more than adequate to compensate for the radiative losses in plage, indicating their importance for chromospheric heating.

Three-dimensional magnetic field structure of a flux emerging region in the solar atmosphere

Rahul **Yadav**, J. de la Cruz Rodríguez, C. J. Díaz Baso, Avijeet Prasad, Tine Libbrecht, Carolina Robustini, A. Asensio Ramos
A&A **2019**
https://arxiv.org/pdf/1910.13279.pdf
We analyze high-resolution spectropolarimetric observations of a flux emerging region (FER) in order to understand its magnetic and kinematic structure. Our spectropolarimetric observations in the He I 1083.0 nm spectral region of a FER are recorded with GRIS at the 1.5 m aperture GREGOR telescope. A Milne-Eddington based inversion code was employed to extract the photospheric information of the Si I spectral line, whereas the He I triplet line was analyzed with the Hazel inversion code, which takes into account the joint action of the Hanle and the Zeeman effect. The spectropolarimetric analysis of Si I line displays a complex magnetic structure near the vicinity of FER. Moreover, we find supersonic downflows of 40 km/sec appears near the footpoints of loops connecting two pores of opposite polarity, whereas a strong upflows of 22 km/sec appears near the apex of the loops. Furthermore, non-force-free field extrapolations were performed separately at two layers in order to understand the magnetic field topology of the FER. We determine, using extrapolations from the photosphere and the observed chromospheric magnetic field, that the average formation height of the He triplet line is 2 Mm from the solar surface. The reconstructed loops using photospheric extrapolations along an arch filament system have a maximum height of 10.5 Mm from the solar surface with a foot-points separation of 19 Mm, whereas the loops reconstructed using chromospheric extrapolations are around 8.4 Mm high from the solar surface with a foot-point separation of 16 Mm at the chromospheric height. The magnetic topology in the FER suggests the presence of small-scale loops beneath the large loops. Under suitable conditions, due to magnetic reconnection, these loops can trigger various heating events in the vicinity of the FER. **3 June, 2015**

SPIN: An Inversion Code for the Photospheric Spectral Line

Rahul **Yadav**, Shibu K. Mathew, Alok Ranjan Tiwary
Solar Physics August **2017**, 292:105
Inversion codes are the most useful tools to infer the physical properties of the solar atmosphere from the interpretation of Stokes profiles. In this paper, we present the details of a new Stokes Profile INversion code (SPIN) developed specifically to invert the spectro-polarimetric data of the Multi-Application Solar Telescope (MAST) at Udaipur Solar Observatory. The SPIN code has adopted Milne–Eddington approximations to solve the polarized radiative transfer equation (RTE) and for the purpose of fitting a modified Levenberg–Marquardt algorithm has been employed. We describe the details and utilization of the SPIN code to invert the spectro-polarimetric data. We also present the details of tests performed to validate the inversion code by comparing the results from the other widely

used inversion codes (VFISV and SIR). The inverted results of the SPIN code after its application to Hinode/SP data have been compared with the inverted results from other inversion codes.

Statistical properties of the most powerful solar and heliospheric disturbances

O.S. **Yakovchouk**[a], , I.S. Veselovsky[a, b], and K. Mursula

Advances in Space Research

Volume 43, Issue 4, 16 February **2009**, Pages 634-640

We present and discuss here the first version of a data base of extreme solar and heliospheric events. The data base contains now 87 extreme events mostly since 1940. An event is classified as extreme if one of the three critical parameters passed a lower limit. The critical parameters were the X-ray flux (parameter *R*), solar proton flux (parameter *S*) and geomagnetic disturbance level (parameter *G*). We find that the five strongest extreme events based on four variables (X-rays SEP, Dst, Ap) are completely separate except for the October 2003 event which is one the five most extreme events according to SEP, Dst and Ap. This underlines the special character of the October 2003 event, making it unique within 35 years. We also find that the events based on *R* and *G* are rather separate, indicating that the location of even extreme flares on the solar disk is important for geomagnetic effects. We also find that $S = 3$ events are not extreme in the same sense as $R > 3$ and $G > 3$ events, while $S = 5$ events are missing so far. This suggests that it might be useful to rescale the classification of SEP fluxes.

Effects of Cowling Resistivity in the Weakly-Ionized Chromosphere

Mehmet Sarp **Yalim**, Avijeet Prasad, Nikolai Pogorelov, Gary Zank, Qiang Hu

ApJL **899** L4 **2020**

https://arxiv.org/pdf/2007.12275.pdf

https://doi.org/10.3847/2041-8213/aba69a

The physics of the solar chromosphere is complex from both theoretical and modeling perspectives. The plasma temperature from the photosphere to corona increases from ~5,000 K to ~1 million K over a distance of only ~10,000 km from the chromosphere and the transition region. Certain regions of the solar atmosphere have sufficiently low temperature and ionization rates to be considered as weakly-ionized. In particular, this is true at the lower chromosphere. As a result, the Cowling resistivity is orders of magnitude greater than the Coulomb resistivity. Ohm's law therefore includes anisotropic dissipation. To evaluate the Cowling resistivity, we need to know the external magnetic field strength and to estimate the neutral fraction as a function of the bulk plasma density and temperature. In this study, we determine the magnetic field topology using the non-force-free field (NFFF) extrapolation technique based on SDO/HMI SHARP vector magnetogram data, and the stratified density and temperature profiles from the Maltby-M umbral core model for sunspots. We investigate the variation and effects of Cowling resistivity on heating and magnetic reconnection in the chromosphere as the flare-producing active region (AR) 11166 evolves. In particular, we analyze a C2.0 flare emerging from AR11166 and find a normalized reconnection rate of 0.051. **2011- 03-07-10**

A data-driven MHD model of the weakly-ionized chromosphere

Mehmet Sarp **Yalim**, Avijeet Prasad, Nikolai Pogorelov, Gary Zank, Qiang Hu

Journal of Physics Conference Series - Proceedings of the 19th Annual International Astrophysics **2020**

https://arxiv.org/pdf/2007.12361.pdf

The physics of the solar chromosphere is complex from both theoretical and modeling perspectives. The plasma temperature from the photosphere to corona increases from ~5,000 K to ~1 million K over a distance of only ~10,000 km from the chromosphere and the transition region. Certain regions of the solar atmosphere have sufficiently low temperature and ionization rates to be considered as weakly-ionized. In particular, this is true at the lower chromosphere. In this paper, we present an overview of our data-driven magnetohydrodynamics model for the weakly-ionized chromosphere and show a benchmark result. It utilizes the Cowling resistivity which is orders of magnitude greater than the Coulomb resistivity. Ohm's law therefore includes anisotropic dissipation. We investigate the effects of the Cowling resistivity on heating and magnetic reconnection in the chromosphere as the flare-producing active region (AR) 11166 evolves. In particular, we analyze a C2.0 flare emerging from AR11166 and find a normalized reconnection rate of 0.12. **2011- 03-07-10**

Forecasting Solar Cycle 25 with a Principled Bayesian Two-stage Statistical Model

Youwei **Yan**1, David C. Stenning1, Vinay L. Kashyap2, and Yaming Yu3

2021 Res. Notes AAS 5 192

https://iopscience.iop.org/article/10.3847/2515-5172/ac1ea0

https://doi.org/10.3847/2515-5172/ac1ea0

We update the Bayesian analysis of sunspot numbers (SSNs) developed by Yu et al. prior to the peak of Solar Cycle 24 to account for the recalibration of the SSN index. We show that the model yields an accurate hindcast of Cycle

24 with the revised SSN, and use the data acquired since then to predict the strength and peak of Cycle 25. We predict the behavior of Cycle 25 to be moderate to weak, with a peak SSN of 120±27 to occur c. 2025 July (±7 months).

Research progress based on observations of the New Vacuum Solar Telescope Review

Xiaoli **Yan**, Zhong Liu, Jun Zhang, Zhi Xu
SCIENCE CHINA Technological Sciences **2019**
https://arxiv.org/pdf/1910.09127.pdf

The purpose of this paper is to introduce the main scientific results made by the one-meter New Vacuum Solar Telescope (NVST), which was put into commission on 2010. NVST is one of the large aperture solar telescopes in the world, located on the shore of Fuxian lake of Yunnan province in China, aiming at serving solar physicists by providing them with high resolution photospheric and chromospheric observational data. Based on the data from NVST and complementary observations from space (e.g., Hinode, SDO and IRIS, etc), dozens of scientific papers have been published with a wide range of topics concentrating mainly on dynamics and activities of fine-scale magnetic structures and their roles in the eruptions of active-region filaments and flares. The achievements include dynamic characteristics of photospheric bright points, umbral dots, penumbral waves, and sunspot/light bridge oscillation, observational evidence of small-scale magnetic reconnection, and fine-scale dynamic structure of prominences. All these new results will shed light on the better understanding of solar eruptive activities. Data release, observation proposals, and future research subjects are introduced and discussed.
Bright points. Umbral dot, penumbral wave. Sunspot light bridge. Formation, fine-scale structures, and eruption mechanism of solar filaments. Fine structure of solar prominences. Filament formation. Magnetic structures of active-region filaments. Filament eruption. Small-scale magnetic reconnection in the solar eruptions. Release of twist in a filament by magnetic reconnection. Interchange magnetic reconnection between a filament and nearby open fields. Magnetic reconnection between a twisted arch filament system and coronal loops. Magnetic reconnection between two active-region filaments. Oscillatory magnetic reconnection. Small-scale eruptive activities. Mini-filaments and jets. Formation and trigger mechanism of solar flares

SELF-ABSORPTION IN THE SOLAR TRANSITION REGION

Limei **Yan**1,2, Hardi Peter2, Jiansen He1, Hui Tian3, Lidong Xia4, Linghua Wang1, Chuanyi Tu1, Lei Zhang1, Feng Chen2, and Krzysztof Barczynski2
2015 ApJ 811 48

Transient brightenings in the transition region of the Sun have been studied for decades and are usually related to magnetic reconnection. Recently, absorption features due to chromospheric lines have been identified in transition region emission lines raising the question of the thermal stratification during such reconnection events. We analyze data from the Interface Region Imaging Spectrograph in an emerging active region. Here the spectral profiles show clear self-absorption features in the transition region lines of Si iv. While some indications existed that opacity effects might play some role in strong transition region lines, self-absorption has not been observed before. We show why previous instruments could not observe such self-absorption features, and discuss some implications of this observation for the corresponding structure of reconnection events in the atmosphere. Based on this we speculate that a range of phenomena, such as explosive events, blinkers or Ellerman bombs, are just different aspects of the same reconnection event occurring at different heights in the atmosphere.

Combined Surface Flux Transport and Helioseismic Far-side Active Region Model (FARM)

Dan **Yang**, Stephan G. Heinemann, Robert H. Cameron, Laurent Gizon
Solar Phys. **2024**
https://arxiv.org/pdf/2411.18701

Maps of the magnetic field at the Sun's surface are commonly used as boundary conditions in space-weather modeling. However, continuous observations are only available from the Sun's Earth-facing side. One commonly used approach to mitigate the lack of far-side information is to apply a surface flux transport (SFT) model to model the evolution of the magnetic field as the Sun rotates. Helioseismology can image active regions on the far side using acoustic oscillations, and hence has the potential to improve the modeled surface magnetic field. In this study, we propose a novel approach for estimating magnetic fields of active regions on the Sun's far side based on seismic measurements, and then include them into a SFT model. To calibrate seismic signal to magnetic field, we apply our SFT model to line-of-sight magnetograms from SDO/HMI to obtain reference maps of global magnetic fields. The resulting maps are compared with seismic maps on the Sun's far side computed using helioseismic holography. The spatial structure of the magnetic field within an active region is reflected in the spatial structure of seismic phase shifts. We assign polarities to the unipolar magnetic-field concentrations based on Hale's law and require approximate flux balance between the two polarities. From 2010 to 2024, we modeled 859 active regions, with an average total unsigned flux of 7.84·1021 Mx and an average area of 4.48·1010 km2. Approximately 4.2% of the active regions were found to have an anti-Hale configuration, which we manually corrected. Comparisons between modeled open-field areas and EUV observations reveal a substantial improvement in agreement when far-side active

regions are included. This proof of concept study demonstrates the potential of the ``combined surface flux transport and helioseismic Far-side Active Region Model" (FARM) to improve space-weather modeling. **19 May – 16 June 2010, 25 Mar- 5 Apr 2013, 17 Apr 2013, 3-15 Oct 2013**

Combined Surface Flux Transport and Helioseismic Far-Side Active Region Model (FARM).

https://link.springer.com/content/pdf/10.1007/s11207-024-02405-9.pdf
Maps of the magnetic field at the Sun's surface are commonly used as boundary conditions in space-weather modeling. However, continuous observations are only available from the Earth-facing part of the Sun's surface. One commonly used approach to mitigate the lack of far-side information is to apply a surface flux transport (SFT) model to model the evolution of the magnetic field as the Sun rotates. Helioseismology can image active regions on the far side using acoustic oscillations and hence has the potential to improve the modeled surface magnetic field. In this study, we propose a novel approach for estimating magnetic fields of active regions on the Sun's far side based on seismic measurements and then include them into an SFT model. To calibrate the conversion from helioseismic signal to magnetic field, we apply our SFT model to line-of-sight magnetograms from Helioseismic and Magnetic Imager (HMI) on board the Solar Dynamics Observatory (SDO) to obtain reference maps of global magnetic fields (including the far side). The resulting magnetic maps are compared with helioseismic phase maps on the Sun's far side computed using helioseismic holography. The spatial structure of the magnetic field within an active region is reflected in the spatial structure of the helioseismic phase shifts. We assign polarities to the unipolar magnetic-field concentrations based upon Hale's law and require approximate flux balance between the two polarities. From 2010 to 2024, we modeled 859 active regions, with an average total unsigned flux of 7.84·1021 Mx and an average area of 4.48·1010 km2. Approximately 4.2% of the active regions were found to have an anti-Hale configuration, which we manually corrected. Including these far-side active regions resulted in an average increase of 1.2% (up to 25.3%) in the total unsigned magnetogram flux. Comparisons between modeled open-field areas and EUV observations reveal a substantial improvement in agreement when far-side active regions are included. This proof of concept study demonstrates the potential of the "combined surface flux transport and helioseismic Far-side Active Region Model" (FARM) to improve space-weather modeling.

Meridional Flow in the Solar Polar Caps Revealed by Magnetic Field Observation and Simulation

Shuhong **Yang**1,2,7, Jie Jiang3, Zifan Wang1,2,7, Yijun Hou1,2,7, Chunlan Jin1,2,7, Qiao Song4,6, Yukun Luo3, Ting Li1,2,7, Jun Zhang5, Yuzong Zhang1,2,7Show full author list

https://iopscience.iop.org/article/10.3847/1538-4357/ad61e2/pdf
As a large-scale motion on the Sun, the meridional flow plays an important role in determining magnetic structure and strength and solar cycle. However, the meridional flow near the solar poles is still unclear. The Hinode observations show that the magnetic flux density in polar caps decreases from the lower latitudes to the poles. Using a surface flux transport model, we simulate the global radial magnetic field to explore the physical process leading to the observed polar magnetic distribution pattern. For the first time, the high-resolution observations of the polar magnetic fields observed by Hinode are used to directly constrain the simulation. Our simulation reproduces the observed properties of the polar magnetic fields, suggesting the existence of a counter-cell meridional flow in the solar polar caps with a maximum amplitude of about 3 m s−1.

Long-term variation of the solar polar magnetic fields at different latitudes

Shuhong **Yang**1,2,7 , Jie Jiang3 , Zifan Wang1,2,7 , Yijun Hou1,2,7 , Chunlan Jin1,2,7 +++
Research in Astron. Astrophys. **2024** Vol. 24 No. 7, 075015
https://arxiv.org/pdf/2408.15168
The polar magnetic fields of the Sun play an important role in governing solar activity and powering fast solar wind. However, because our view of the Sun is limited in the ecliptic plane, the polar regions remain largely uncharted. Using the high spatial resolution and polarimetric precision vector magnetograms observed by Hinode from 2012 to 2021, we investigate the long-term variation of the magnetic fields in polar caps at different latitudes. The Hinode magnetic measurements show that the polarity reversal processes in the north and south polar caps are non-simultaneous. The variation of the averaged radial magnetic flux density reveals that, in each polar cap, the polarity reversal is completed successively from the 70° latitude to the pole, reflecting a poleward magnetic flux migration therein. These results clarify the polar magnetic polarity reversal process at different latitudes.

Complexity of emerging magnetic flux during lifetime of solar ephemeral regions

Hanlin **Yang**, Chunlan Jin, Zifan Wang, Jingxiu Wang

ApJ **2024**

https://arxiv.org/pdf/2403.18979.pdf

As a relatively active region, ephemeral region (ER) exhibits highly complex pattern of magnetic flux emergence. We aim to study detailed secondary flux emergences (SFEs) which we define as bipoles that they appear close to ERs and finally coalesce with ERs after a period. We study the SFEs during the whole process from emergence to decay of 5 ERs observed by the Helioseismic and Magnetic Imager (HMI) aboard Solar Dynamics Observatory (SDO) . The maximum unsigned magnetic flux for each ER is around 1020 Mx. Each ER has tens of SFEs with an average emerging magnetic flux of approximately 5×1018 Mx. The frequency of normalized magnetic flux for all the SFEs follows a power law distribution with an index of -2.08 . The majority of SFEs occur between the positive and negative polarities of ER , and their growth time is concentrated within one hour. The magnetic axis of SFE is found to exhibit a random distribution in the 5 ERs. We suggest that the relationship between SFEs and ERs can be understood by regarding the photospheric magnetic field observations as cross-sections of an emerging magnetic structure. Tracking the ERs' evolution, we propose that these SFEs in ERs may be sequent emergences from the bundle of flux tube of ERs, and that SFEs are partially emerged Ω-loops.

Direct assessment of SDO/HMI helioseismology of active regions on the Sun's far side using SO/PHI magnetograms

D. **Yang**, L. Gizon, H. Barucq, J. Hirzberger, D. Orozco Suárez, +++

A&A 674, A183 **2023**

https://arxiv.org/pdf/2305.01594.pdf

https://www.aanda.org/articles/aa/pdf/2023/06/aa46030-23.pdf

Earth-side observations of solar p modes can be used to image and monitor magnetic activity on the Sun's far side. Here we use magnetograms of the far side obtained by the Polarimetric and Helioseismic Imager (PHI) onboard Solar Orbiter (SO) to directly assess -- for the first time -- the validity of far-side helioseismic holography. We wish to co-locate the positions of active regions in helioseismic images and magnetograms, and to calibrate the helioseismic measurements in terms of magnetic field strength. We identify three magnetograms on 18 November 2020, 3 October 2021, and 3 February 2022 displaying a total of six active regions on the far side. The first two dates are from SO's cruise phase, the third from the beginning of the nominal operation phase. We compute contemporaneous seismic phase maps for these three dates using helioseismic holography applied to time series of Dopplergrams from the Helioseismic and Magnetic Imager (HMI) on the Solar Dynamics Observatory (SDO). Among the six active regions seen in SO/PHI magnetograms, five active regions are identified on the seismic maps at almost the same positions as on the magnetograms. One region is too weak to be detected above the seismic noise. To calibrate the seismic maps, we fit a linear relationship between the seismic phase shifts and the unsigned line-of-sight magnetic field averaged over the active region areas extracted from the SO/PHI magnetograms. SO/PHI provides the strongest evidence so far that helioseismic imaging provides reliable information about active regions on the far side, including their positions, areas, and mean unsigned magnetic field.

Solar Orbiter nugget #9 2023 https://www.cosmos.esa.int/web/solar-orbiter/science-nuggets/far-side-helioseismology-using-sophi

Imaging individual active regions on the Sun's far side with improved helioseismic holography

Dan **Yang**, Laurent Gizon, Hélène Barucq

A&A **2022**

https://arxiv.org/pdf/2211.07219.pdf

Helioseismic holography is a useful method to detect active regions on the Sun's far side and improve space weather forecasts. We aim to improve helioseismic holography by using a clear formulation of the problem, an accurate forward solver in the frequency domain, and a better understanding of the noise properties. Building on the work of Lindsey et al., we define the forward- and backward-propagated wave fields (ingression and egression) in terms of a Green's function. This Green's function is computed using an accurate forward solver in the frequency domain. We analyse overlapping segments of 31 hr of SDO/HMI dopplergrams, with a cadence of 24 hr. Phase shifts between the ingression and the egression are measured and averaged to detect active regions on the far side. The phase maps are compared with direct EUV intensity maps from STEREO/EUVI. We confirm that medium-size active regions can be detected on the far side with high confidence. Their evolution (and possible emergence) can be monitored on a daily time scale. Seismic maps averaged over 3 days provide an active region detection rate as high as 75% and a false discovery rate only as low as 7%, for active regions with areas above one thousandth of an hemisphere. For a large part, these improvements can be attributed to the use of a complete Green's function (all skips) and to the use

of all observations on the front side (full pupil). Improved helioseismic holography enables the study of the evolution of medium-size active regions on the Sun's far side.

Rotating Solar Models in Agreement with Helioseismic Results and Updated Neutrino Fluxes

Wuming **Yang**

ApJ **939** 61 **2022**

https://arxiv.org/pdf/2209.13483

https://iopscience.iop.org/article/10.3847/1538-4357/ac94cd/pdf

Standard solar models (SSMs) constructed in accordance with old solar abundances are in reasonable agreement with seismically inferred results, but SSMs with new low-metal abundances disagree with the seismically inferred results. The constraints of neutrino fluxes on solar models exist in parallel with those of helioseismic results. The solar neutrino fluxes were updated by Borexino Collaboration. We constructed rotating solar models with new low-metal abundances where the effects of enhanced diffusion and convection overshoot were included. A rotating model using OPAL opacities and the Caffau abundance scale has better sound-speed and density profiles than the SSM with the old solar abundances and reproduces the observed p-mode frequency ratios r02 and r13. The depth and helium abundance of the convection zone of the model agree with the seismically inferred ones at the level of 1σ. The updated neutrino fluxes are also reproduced by the model at the level of 1σ. The effects of rotation and enhanced diffusion not only improve the model's sound-speed and density profiles but bring the neutrino fluxes predicted by the model into agreement with the detected ones. Moreover, the calculations show that OP may underestimate opacities for the regions of the Sun with $T \gtrsim 5\times106$ K by around 1.5%, while OPAL may underestimate opacities for the regions of the Sun with 2×106 K $\lesssim T \lesssim 5\times106$ K by about 1−2%.

Relative Magnetic Helicity Based on a Periodic Potential Field

Kai E. **Yang**, Michael S. Wheatland, Stuart A. Gilchrist

ApJ **894** 151 **2020**

https://arxiv.org/pdf/2004.08590.pdf

https://doi.org/10.3847/1538-4357/ab8810

Magnetic helicity is conserved under ideal magnetohydrodynamics (MHD) and quasi-conserved even under a resistive process. The standard definition for magnetic helicity cannot be applied directly to an open magnetic field in a volume, because it is gauge-dependent. Instead, the relative magnetic helicity is widely used. We find that the energy of a potential magnetic field in a rectangular domain with periodic lateral boundary conditions is less than that of the field with a fixed normal component on all six boundaries. To make use of this lower energy potential field in the analysis of relative magnetic helicity, we introducing a new definition for magnetic helicity for the magnetic field, which involves the periodic potential field. We apply this definition to a sequence of analytic solutions and a numerical simulation. The results show that our new gauge-invariant helicity is very close to the current-carrying part of the relative magnetic helicity of the original magnetic field. We find also that the ratio between the current-carrying helicity and the relative magnetic helicity for the original and our defined relative helicity show different behavior. It seems that the new helicity is more sensitive to the component of the field due to the electric current in the volume, which is the source for instabilities and solar eruptive phenomena.

The origin and effect of hemispheric helicity imbalance in solar dynamo

S. **Yang**, V.V. Pipin, D.D. Sokoloff, K.M. Kuzanyan, H. Zhang

J. Plasma Phys. **2020**

https://arxiv.org/pdf/1912.11285.pdf

In this paper we study the effects of hemispheric imbalance of magnetic helicity density on breaking the equatorial reflection symmetry of the dynamo generated large-scale magnetic field. Our study employs the axisymmetric dynamo model which takes into account the nonlinear effect of magnetic helicity conservation. We find that the evolution of the net magnetic helicity density, in other words, the magnetic helicity imbalance, on the surface follows the evolution of the parity of the large-scale magnetic field. Random fluctuations of the α-effect and the helicity fluxes can inverse the causal relationship, i.e., the magnetic helicity imbalance or the imbalance of magnetic helicity fluxes can drive the magnetic parity breaking. We also found that evolution of the net magnetic helicity of the small-scale fields follows the evolution of the net magnetic helicity of the large-scale fields with some time lag. We interpret this as an effect of the difference of the magnetic helicity fluxes out of the Sun from the large and small scales.

Light Bridge Brightening and Plasma Ejection Driven by a Magnetic Flux Emergence Event

Xu **Yang**1,2, Vasyl Yurchyshyn2, Kwangsu Ahn2, Matt Penn3, and Wenda Cao

2019 ApJ 886 64

sci-hub.se/10.3847/1538-4357/ab4a7d
Observations with the Goode Solar Telescope (GST) are presented here showing that the emergence of 1.91 × 1018 Mx of new magnetic flux occurred at the edge of a filamentary light bridge (LB). This emergence was accompanied by brightness enhancement of a photospheric overturning convection cell (OCC) at the endpoints of the emerging magnetic structure. We present an analysis of the origin and the dynamics of this event using high-resolution GST Fe i 1564.85 nm vector magnetic field data, TiO photospheric, and Hα chromospheric images. The emerged structure was 1.5 × 0.3 Mm in size at the peak of development and lasted for 17 minutes. Doppler observations showed presence of systematic upflows before the appearance of the magnetic field signal and downflows during the decay phase. Changes in the orientation of the associated transverse fields, determined from the differential angle, suggest the emergence of a twisted magnetic structure. A fan-shaped jet was observed to be spatially and temporally correlated with the endpoint of the OCC intruding into the LB. Our data suggest that the emerging fields may have reconnected with the magnetic fields in the vicinity of the LB, which could lead to the formation of the jet. Our observation is the first report of flux emergence within a granular LB with evidence in the evolution of vector magnetic field, as well as photosphere convection motions, and supports the idea that the impulsive jets above the LB are caused by magnetic reconnection. **2016 February 9**

Chromospheric cannonballs on the Sun

Shuhong **Yang**, Jun Zhang, Xiaohong Li, Zhong Liu, Yongyuan Xiang
ApJL **880** L24 **2019**
https://arxiv.org/pdf/1906.10850.pdf
https://iopscience.iop.org/article/10.3847/2041-8213/ab2fe2/pdf
In the highly dynamic chromosphere, there exist many kinds of small-scale activities, such as spicules, surges, and Ellerman bombs. Here, we report the discovery of a new phenomenon in the chromosphere observed with the New Vacuum Solar Telescope at the Fuxian Solar Observatory. In the high tempo-spatial resolution Hα images, some dark or bright structures are found to fly along the curved trajectory, looking like cannonballs. Their average size, mass, and velocity are about 1.5 × 109 km3, 1.5 × 108 kg, and 56 km s−1, respectively. In the simultaneous (extreme-)ultraviolet images obtained by the Solar Dynamics Observatory, these cannonballs appear as brighter features compared to the surrounding area, implying that there exists some kind of heating during this process. The photospheric magnetograms show the magnetic flux emergence and interaction with the pre-existing fields. These observations reveal that the cannonballs are chromospheric material blobs launched due to the magnetic reconnection between emerging magnetic flux and the pre-existing loops. **2017 August 06, 2017 October 28, 2018 May 11**

Rotating Solar Models with Low Metal Abundances as Good as Those with High Metal Abundances

Wuming **Yang**
ApJ **873** 18 **2019**
https://arxiv.org/pdf/1901.11290.pdf
Standard solar models (SSM) constructed in accord with low metal abundances disagree with the seismically inferred results. We constructed rotating solar models with low metal abundances that included enhanced settling and convection overshoot. In one of our rotating models, \textbf{AGSSr2a}, the convection overshoot allowed us to recover the radius of the base of convection zone (CZ) at a level of 1σ. The rotational mixing almost completely counteracts the enhanced settling for the surface helium abundance, but only partially for the surface heavy-element abundance. At the level of 1σ, the combination of rotation and enhanced settling brings the surface helium abundance into agreement with the seismically inferred value of 0.2485±0.0035, and makes the model have better sound-speed and density profiles than SSM constructed in accordance with high metal abundances. The radius of the base of the CZ and the surface helium abundance of \textbf{AGSSr2a} are 0.713 R⊙ and 0.2472, respectively; the absolute values of the relative differences in sound speed and density between it and the Sun are less than 0.0025 and 0.015, respectively. Moreover, predicted neutrino fluxes of our model are comparable with the predictions of previous research works.

Observational Evidence of Magnetic Reconnection Associated with Magnetic Flux Cancellation

Bo **Yang**1,2,3, Jiayan Yang1,2, Yi Bi1,2, Junchao Hong1,2, Haidong Li1,2, Zhe Xu1,2,4, and Hechao Chen
2018 ApJ 861 135 DOI 10.3847/1538-4357/aac37f
Using high spatial and temporal data from the Solar Dynamics Observatory (SDO) and the Interface Region Imaging Spectrograph (IRIS), several observational signatures of magnetic reconnection in the course of magnetic flux cancellation are presented, including two loop–loop interaction processes, multiple plasma blob ejections, and a sheet-like structure that appeared above the flux cancellation sites with a Y-shaped and an inverted Y-shaped end. The IRIS 1400 Å observations show that the plasma blobs were ejected from the tip of the Y-shaped ends of the

sheet-like structure. Obvious photospheric magnetic flux cancellation occurred after the first loop–loop interaction and continued until the end of the observation. Complemented by the nonlinear force-free field extrapolation, we found that two sets of magnetic field lines, which revealed an X-shaped configuration, aligned well with the interacted coronal loops. Moreover, a magnetic null point was found to be situated at about 0.9 Mm height, which was right above the flux cancellation sites and located between the two sets of magnetic field lines. These results suggest that the flux cancellation might be a result of the submergence of magnetic field lines following a magnetic reconnection that occurs in the lower atmosphere of the Sun, and the ejected plasma blobs should be plasmoids created in the sheet-like structure due to the tearing-mode instability. This observation reveals a detailed magnetic field structure and a dynamic process above the flux cancellation sites and will help us to understand magnetic reconnection in the lower atmosphere of the Sun.

Observationally quantified reconnection providing a viable mechanism for active region coronal heating

Kai E. **Yang**, Dana W. Longcope, M. D. Ding & Yang Guo
Nature Communications volume 9, Article number: 692 (**2018**)
https://www.nature.com/articles/s41467-018-03056-8.pdf
The heating of the Sun's corona has been explained by several different mechanisms including wave dissipation and magnetic reconnection. While both have been shown capable of supplying the requisite power, neither has been used in a quantitative model of observations fed by measured inputs. Here we show that impulsive reconnection is capable of producing an active region corona agreeing both qualitatively and quantitatively with extreme-ultraviolet observations. We calculate the heating power proportional to the velocity difference between magnetic footpoints and the photospheric plasma, called the non-ideal velocity. The length scale of flux elements reconnected in the corona is found to be around 160 km. The differential emission measure of the model corona agrees with that derived using multi-wavelength images. Synthesized extreme-ultraviolet images resemble observations both in their loop-dominated appearance and their intensity histograms. This work provides compelling evidence that impulsive reconnection events are a viable mechanism for heating the corona. **11 Feb 2012**

Automated Segmentation of High-Resolution Photospheric Images of Active Regions

Meng **Yang**, Yu Tian, Changhui Rao
Solar Physics February **2018**, 293:15
https://link.springer.com/content/pdf/10.1007%2Fs11207-017-1236-7.pdf
Due to the development of ground-based, large-aperture solar telescopes with adaptive optics (AO) resulting in increasing resolving ability, more accurate sunspot identifications and characterizations are required. In this article, we have developed a set of automated segmentation methods for high-resolution solar photospheric images. Firstly, a local-intensity-clustering level-set method is applied to roughly separate solar granulation and sunspots. Then reinitialization-free level-set evolution is adopted to adjust the boundaries of the photospheric patch; an adaptive intensity threshold is used to discriminate between umbra and penumbra; light bridges are selected according to their regional properties from candidates produced by morphological operations. The proposed method is applied to the solar high-resolution TiO 705.7-nm images taken by the 151-element AO system and Ground-Layer Adaptive Optics prototype system at the 1-m New Vacuum Solar Telescope of the Yunnan Observatory. Experimental results show that the method achieves satisfactory robustness and efficiency with low computational cost on high-resolution images. The method could also be applied to full-disk images, and the calculated sunspot areas correlate well with the data given by the National Oceanic and Atmospheric Administration (NOAA). **2015-07-08, 12 Jan. 2016, 07 Oct. 2016**

Ghost Images in Helioseismic Holography? Toy Models in a Uniform Medium

Dan **Yang**
Solar Physics 293:17 **2018**
https://arxiv.org/pdf/1801.01759.pdf
https://link.springer.com/content/pdf/10.1007%2Fs11207-018-1246-0.pdf
Helioseismic holography is a powerful technique used to probe the solar interior based on estimations of the 3D wavefield. Porter--Bojarski holography, which is a well-established method used in acoustics to recover sources and scatterers in 3D, is also an estimation of the wavefield, and hence it has the potential to be applied to helioseismology. Here we present a proof of concept study, where we compare helioseismic holography and Porter--Bojarski holography under the assumption that the waves propagate in a homogeneous medium. We consider the problem of locating a point source of wave excitation inside a sphere. Under these assumptions, we find that the two imaging methods have the same capability of locating the source, with the exception that helioseismic holography suffers from "ghost images" (i.e., artificial peaks away from the source location). We conclude that Porter--Bojarski holography may improve the current method used in helioseismology.

Formation of Cool and Warm Jets by Magnetic Flux Emerging from the Solar Chromosphere to Transition Region

Liping **Yang**1,2,3, Hardi Peter4, Jiansen He2,3, Chuanyi Tu2, Linghua Wang2, Lei Zhang1, and Limei Yan2

2018 ApJ 852 16

In the solar atmosphere, jets are ubiquitous at various spatial-temporal scales. They are important for understanding the energy and mass transports in the solar atmosphere. According to recent observational studies, the high-speed network jets are likely to be intermittent but continual sources of mass and energy for the solar wind. Here, we conduct a 2D magnetohydrodynamics simulation to investigate the mechanism of these network jets. A combination of magnetic flux emergence and horizontal advection is used to drive the magnetic reconnection in the transition region between a strong magnetic loop and a background open flux. The simulation results show that not only a fast warm jet, much similar to the network jets, is found, but also an adjacent slow cool jet, mostly like classical spicules, is launched. Differing from the fast warm jet driven by magnetic reconnection, the slow cool jet is mainly accelerated by gradients of both thermal pressure and magnetic pressure near the outer border of the mass-concentrated region compressed by the emerging loop. These results provide a different perspective on our understanding of the formation of both the slow cool jets from the solar chromosphere and the fast warm jets from the solar transition region.

Evolution of Relative Magnetic Helicity: New Boundary Conditions for the Vector Potential

Shangbin **Yang**, Joerg Buechner, Jan Skala, Hongqi Zhang

A&A **2017**

https://arxiv.org/pdf/1712.09219.pdf

We recently proposed a method to calculate the relative magnetic helicity in a finite volume for a given magnetic field which however required the flux to be balanced separately on all the sides of the considered volume. In order to allow finite magnetic fluxes through the boundaries, a Coulomb gauge is constructed that allows for global magnetic flux balance. We tested and verified our method in a theoretical fore-free magnetic field model. We apply the new method to the former calculation data and found a difference of less than 1.2\%. We also applied our method to the magnetic field above active region NOAA 11429 obtained by a new photospheric-data-driven MHD model code GOEMHD3. We analyzed the magnetic helicity evolution in the solar corona using our new method. It was found that the normalized magnetic helicityis equal to -0.038 when fast magnetic reconnection is triggered. This value is comparable to the previous value (-0.029) in the MHD simulations when magnetic reconnection happened and the observed normalized magnetic helicity (-0.036) from the eruption of newly emerging active regions. We found that only 8\% of the accumulated magnetic helicity is dissipated after it is injected through the bottom boundary. This is in accordance with the Woltjer conjecture. Only 2\% of magnetic helicity injected from the bottom boundary escapes through the corona. This is consistent with the observation of magnetic clouds, which could take away magnetic helicity into the interplanetary space, in the case considered here, several halo CMEs and two X-class solar flares origin from this active region. **March 07. 2012**

SCATTERING MATRIX FOR THE INTERACTION BETWEEN SOLAR ACOUSTIC WAVES AND SUNSPOTS. I. MEASUREMENTS

Ming-Hsu **Yang**1, Dean-Yi Chou1, and Hui Zhao

2017 ApJ 835 102

Assessing the interaction between solar acoustic waves and sunspots is a scattering problem. The scattering matrix elements are the most commonly used measured quantities to describe scattering problems. We use the wavefunctions of scattered waves of NOAAs 11084 and 11092 measured in the previous study to compute the scattering matrix elements, with plane waves as the basis. The measured scattered wavefunction is from the incident wave of radial order n to the wave of another radial order n', for $n = 0$–5. For a time-independent sunspot, there is no mode mixing between different frequencies. An incident mode is scattered into various modes with different wavenumbers but the same frequency. Working in the frequency domain, we have the individual incident plane-wave mode, which is scattered into various plane-wave modes with the same frequency. This allows us to compute the scattering matrix element between two plane-wave modes for each frequency. Each scattering matrix element is a complex number, representing the transition from the incident mode to another mode. The amplitudes of diagonal elements are larger than those of the off-diagonal elements. The amplitude and phase of the off-diagonal elements are detectable only for $n - 1 \leqslant n' \leqslant n + 1$ and $-3\Delta k \leqslant \delta k_x \leqslant 3\Delta k$, where δk_x is the change in the transverse component of the wavenumber and $\Delta k = 0.035$ rad Mm^{-1}.

Enhancement of a sunspot light wall with external disturbances

Shuhong **Yang**, Jun Zhang, Robert Erdélyi

ApJL 833 L18 **2016**
https://arxiv.org/pdf/1611.10032v1.pdf
Based on the \emph{Interface Region Imaging Spectrograph} observations, we study the response of a solar sunspot light wall to external disturbances. A flare occurrence near the light wall caused material to erupt from the lower solar atmosphere into the corona. Some material falls back to the solar surface, and hits the light bridge (i.e., the base of the light wall), then sudden brightenings appear at the wall base followed by the rise of wall top, leading to an increase of the wall height. Once the brightness of the wall base fades, the height of the light wall begins to decrease. Five hours later, another nearby flare takes place, a bright channel is formed that extends from the flare towards the light bridge. Although no obvious material flow along the bright channel is found, some ejected material is conjectured to reach the light bridge. Subsequently, the wall base brightens and the wall height begins to increase again. Once more, when the brightness of the wall base decays, the wall top fluctuates to lower heights. We suggest, based on the observed cases, that the interaction of falling material and ejected flare material with the light wall results in the brightenings of wall base and causes the height of the light wall to increase. Our results reveal that the light wall can be not only powered by the linkage of \emph{p}-mode from below the photosphere, but may also be enhanced by external disturbances, such as falling material.

FINE-SCALE PHOTOSPHERIC CONNECTIONS OF ELLERMAN BOMBS

Heesu **Yang**1, Jongchul Chae1, Eun-Kyung Lim2, Donguk Song1, Kyuhyoun Cho1, Hannah Kwak1, Vasyl B Yurchyshyn3, and Yeon-Han Kim2
2016 ApJ 829 100
We investigate the photospheric and magnetic field structures associated with Ellerman bombs (EBs) using the 1.6 m New Solar Telescope at Big Bear Solar Observatory. The nine observed EBs were accompanied by elongated granule-like features (EGFs) that showed transverse motions prior to the EBs with an average speed of about 3.8 km s−1. Each EGF consisted of a sub-arcsecond bright core encircled by a dark lane around its moving front. The bright core appeared in the TiO broadband filter images and in the far wings of the Hα and Ca ii 8542 Å lines. In four EBs, the bi-directional expanding motion of the EGFs was identified in the TiO images. In those cases, the EGFs were found to be accompanied by an emerging flux (EF). In four other EBs, the EGF developed at the edge of a penumbra and traveled in the sunspot's radial direction. The EGFs in these cases were identified as a moving magnetic feature (MMF). Our results show a clear connection among the magnetic elements, photospheric features, and EBs. This result suggests that the EBs result from magnetic reconnection forced by EFs or MMFs that are frequently manifested by EGFs.

Magnetic-reconnection Generated Shock Waves as a Driver of Solar Surges

Heesu **Yang**1, Jongchul Chae1, Eun-Kyung Lim2, Kyoung-sun Lee3, Hyungmin Park1, Dong-uk Song1, and Kyuhyoun Cho
2014 ApJ 790 L4
We found that a surge consists of multiple shock features. In our high-spatiotemporal spectroscopic observation of the surge, each shock is identified with the sudden appearance of an absorption feature at the blue wings of the Ca II 8542 Å line and Hα line that gradually shifts to the red wings. The shock features overlap with one another with the time interval of 110 s, which is much shorter than the duration of each shock feature, 300-400 s. This finding suggests that the multiple shocks might not have originated from a train of sinusoidal waves generated by oscillations and flows in the photosphere. As we found the signature of the magnetic flux cancelations at the base of the surge, we conclude that the multiple shock waves in charge of the surge were generated by the magnetic reconnection that occurred in the low atmosphere in association with the flux cancelation.

Simulation of the Unusual Solar Minimum with 3D SIP-CESE MHD Model by Comparison with Multi-Satellite Observations

Liping **Yang**, Xueshang Feng, Changqing Xiang, Shaohua Zhang and S. T. Wu
Solar Physics, Volume 271, Numbers 1-2, 91-110, **2011**
The observations both near the Sun and in the heliosphere during the activity minimum between solar cycles 23 and 24 exhibit different phenomena from those typical of the previous solar minima. In this paper, we have chosen Carrington rotation 2070 in 2008 to investigate the properties of the background solar wind by using the three-dimensional (3D) Solar–InterPlanetary Conservation Element/Solution Element Magnetohydrodynamic (MHD) model. We also study the effects of polar magnetic fields on the characteristics of the solar corona and the solar wind by conducting simulations with an axisymmetric polar flux added to the observed magnetic field. The numerical results are compared with the observations from multiple satellites, such as the Solar and Heliospheric Observatory (SOHO), Ulysses, Solar Terrestrial Relations Observatory (STEREO), Wind and the Advanced Composition Explorer (ACE). The comparison demonstrates that the first simulation with the observed magnetic

fields reproduces some observed peculiarities near the Sun, such as relatively small polar coronal holes, the presence of mid- and low-latitude holes, a tilted and warped current sheet, and the broad multiple streamers. The numerical results also capture the inconsistency between the locus of the minimum wind speed and the location of the heliospheric current sheet, and predict slightly slower and cooler polar streams with a relatively smaller latitudinal width, broad low-latitude intermediate-speed streams, and globally weak magnetic field and low density in the heliosphere. The second simulation with strengthened polar fields indicates that the weak polar fields in the current minimum play a crucial role in determining the states of the corona and the solar wind.

Investigations of Sizes and Dynamical Motions of Solar Photospheric Granules by a Novel Granular Segmenting Algorithm

Liu **Yanxiao**1, Jiang Chaowei1, Yuan Ding1, Zuo Pingbing1, Wang Yi1, and Cao Wenda2,3
2021 ApJ 923 133
https://doi.org/10.3847/1538-4357/ac2dfd
Granules observed in the solar photosphere are believed to be convective and turbulent, but the physical picture of the granular dynamical process remains unclear. Here we performed an investigation of granular dynamical motions of full length scales based on data obtained by the 1 m New Vacuum Solar Telescope and the 1.6 m Goode Solar Telescope. We developed a new granule segmenting method, which can detect both small faint and large bright granules. A large number of granules were detected, and two critical sizes, 265 and 1420 km, were found to separate the granules into three length ranges. The granules with sizes above 1420 km follow Gaussian distribution, and demonstrate flat in flatness function, which shows that they are non-intermittent and thus are dominated by convective motions. Small granules with sizes between 265 and 1420 km are fitted by a combination of power-law function and Gauss function, and exhibit nonlinearity in flatness function, which reveals that they are in the mixing motions of convection and turbulence. Mini granules with sizes below 265 km follow the power-law distribution and demonstrate linearity in flatness function, indicating that they are intermittent and strongly turbulent. These results suggest that a cascade process occurs: large granules break down due to convective instability, which transports energy into small ones; then turbulence is induced and grows, which competes with convection and further causes the small granules to continuously split. Eventually, the motions in even smaller scales enter in a turbulence-dominated regime.

Surface Flux Transport

Anthony R. **Yeates**, Mark C.M. Cheung, Jie Jiang, Kristof Petrovay, Yi-Ming Wang
Space Science Reviews **2023**
https://arxiv.org/pdf/2303.01209
We review the surface flux transport model for the evolution of magnetic flux patterns on the Sun's surface. Our underlying motivation is to understand the model's prediction of the polar field (or axial dipole) strength at the end of the solar cycle. The main focus is on the "classical" model: namely, steady axisymmetric profiles for differential rotation and meridional flow, and uniform supergranular diffusion. Nevertheless, the review concentrates on recent advances, notably in understanding the roles of transport parameters and - in particular - the source term. We also discuss the physical justification for the surface flux transport model, along with efforts to incorporate radial diffusion, and conclude by summarizing the main directions where researchers have moved beyond the classical model.

Widespread Occurrence of High-Velocity Upflows in Solar Active Regions

S. L. **Yardley**, D. H. Brooks, D. Baker
A&A 650, L10 **2021**
https://arxiv.org/pdf/2106.01396.pdf
https://www.aanda.org/articles/aa/pdf/2021/06/aa41131-21.pdf
https://doi.org/10.1051/0004-6361/202141131
We performed a systematic study of 12 active regions (ARs) with a broad range of areas, magnetic flux and associated solar activity in order to determine whether there are upflows present at the AR boundaries and if these upflows exist, whether there is a high speed asymmetric blue wing component present in the upflows. To identify the presence and locations of the AR upflows we derive relative Doppler velocity maps by fitting a Gaussian function to {\it Hinode}/EIS Fe XII 192.394\,Å line profiles. To determine whether there is a high speed asymmetric component present in the AR upflows we fit a double Gaussian function to the Fe XII 192.394\,Å mean spectrum that is computed in a region of interest situated in the AR upflows. Upflows are observed at both the east and west boundaries of all ARs in our sample with average upflow velocities ranging between -5 to -26~km s−1. A blue wing asymmetry is present in every line profile. The intensity ratio between the minor high speed asymmetric Gaussian component compared to the main component is relatively small for the majority of regions however, in a minority of cases (8/30) the ratios are large and range between 20 to 56~\%. These results suggest that upflows and the high speed asymmetric blue wing component are a common feature of all ARs. **31 Jan 2011, 15 Apr 2011**
Table 1. The NOAA ARs and EIS data used in this study (2010-2011)

Latitude Quenching Nonlinearity in the Solar Dynamo

Anthony R. **Yeates**, Luca Bertello, Alexander A. Pevtsov, Alexei A. Pevtsov
ApJ **2024**
https://arxiv.org/pdf/2412.02312
We compare two candidate nonlinearities for regulating the solar cycle within the Babcock-Leighton paradigm: tilt quenching (whereby the tilt of active regions is reduced in stronger cycles) and latitude quenching (whereby flux emerges at higher latitudes in stronger solar cycles). Digitized historical observations are used to build a database of individual magnetic plage regions from 1923 to 1985. The regions are selected by thresholding in Ca II K synoptic maps, with polarities constrained using Mount Wilson Observatory sunspot measurements. The resulting data show weak evidence for tilt quenching, but much stronger evidence for latitude-quenching. Further, we use proxy observations of the polar field from faculae to construct a best-fit surface flux transport model driven by our database of emerging regions. A better fit is obtained when the sunspot measurements are used, compared to a reference model where all polarities are filled using Hale's Law. The optimization suggests clearly that the "dynamo effectivity range" of the Sun during this period should be less than 10 degrees; this is also consistent with latitude quenching being dominant over tilt quenching.

The Sun's Non-Potential Corona over Solar Cycle 24

Anthony R. **Yeates**
Solar Phys. **299**, 83 **2024**
https://arxiv.org/pdf/2405.14322
https://link.springer.com/content/pdf/10.1007/s11207-024-02328-5.pdf
The global magnetic field in the solar corona is known to contain free magnetic energy and magnetic helicity above that of a current-free (potential) state. But the strength of this non-potentiality and its evolution over the solar cycle remain uncertain. Here we model the corona over Solar Cycle 24 using a simplified magneto-frictional model that retains the magnetohydrodynamic induction equation but assumes relaxation towards force-free equilibrium, driven by solar surface motions and flux emergence. The model is relatively conservative compared to some others in the literature, with free energy approximately 20-25% of the potential field energy. We find that unsigned helicity is about a factor 10 higher at Maximum than Minimum, while free magnetic energy shows an even greater increase. The cycle averages of these two quantities are linearly correlated, extending a result found previously for active regions. Also, we propose a practical measure of eruptivity for these simulations, and show that this increases concurrently with the sunspot number, in accordance with observed coronal mass ejection rates. Whilst shearing by surface motions generates 50% or more of the free energy and helicity in the corona, we show that active regions must emerge with their own internal helicity otherwise the eruptivity is substantially reduced and follows the wrong pattern over time. **2010-09-01, 2010-09-28, 2013-12-29, 2014-12-15, 2019-03-03**

Surface Flux Transport on the Sun

Anthony R. **Yeates**, Mark C. M. Cheung, Jie Jiang, Kristof Petrovay & Yi-Ming Wang
Space Science Reviews volume 219, Article number: 31 (**2023**)
https://link.springer.com/content/pdf/10.1007/s11214-023-00978-8.pdf
We review the surface flux transport model for the evolution of magnetic flux patterns on the Sun's surface. Our underlying motivation is to understand the model's prediction of the polar field (or axial dipole) strength at the end of the solar cycle. The main focus is on the "classical" model: namely, steady axisymmetric profiles for differential rotation and meridional flow, and uniform supergranular diffusion. Nevertheless, the review concentrates on recent advances, notably in understanding the roles of transport parameters and – in particular – the source term. How Good Is the Bipolar Approximation of Active Regions for Surface Flux Transport?

Anthony R. **Yeates**
Solar Physics volume 295, Article number: 119 (**2020**)
https://link.springer.com/content/pdf/10.1007/s11207-020-01688-y.pdf
We investigate how representing active regions with bipolar magnetic regions (BMRs) affects the end-of-cycle polar field predicted by the surface flux transport model. Our study is based on a new database of BMRs derived from the SDO/HMI active region patch data between 2010 and 2020. An automated code is developed for fitting each active region patch with a BMR, matching both the magnetic flux and axial dipole moment of the region and removing repeat observations of the same region. By comparing the predicted evolution of each of the 1090 BMRs with the predicted evolution of their original active region patches, we show that the bipolar approximation leads to a 24% overestimate of the net axial dipole moment, given the same flow parameters. This is caused by neglecting the more

complex multipolar and/or asymmetric magnetic structures of many of the real active regions, and may explain why previous flux transport models had to reduce BMR tilt angles to obtain realistic polar fields. Our BMR database and the Python code to extract it are freely available. **30 September 2017**

Sparse Reconstruction of Electric Fields from Radial Magnetic Data

Anthony R. **Yeates**

2017 ApJ 836 131

Accurate estimates of the horizontal electric field on the Sun's visible surface are important not only for estimating the Poynting flux of magnetic energy into the corona but also for driving time-dependent magnetohydrodynamic models of the corona. In this paper, a method is developed for estimating the horizontal electric field from a sequence of radial-component magnetic field maps. This problem of inverting Faraday's law has no unique solution. Unfortunately, the simplest solution (a divergence-free electric field) is not realistically localized in regions of nonzero magnetic field, as would be expected from Ohm's law. Our new method generates instead a localized solution, using a basis pursuit algorithm to find a sparse solution for the electric field. The method is shown to perform well on test cases where the input magnetic maps are flux balanced in both Cartesian and spherical geometries. However, we show that if the input maps have a significant imbalance of flux—usually arising from data assimilation—then it is not possible to find a localized, realistic, electric field solution. This is the main obstacle to driving coronal models from time sequences of solar surface magnetic maps.

The global distribution of magnetic helicity in the solar corona⋆

A. R. **Yeates**1 and G. Hornig

A&A 594, A98 (**2016**)

By defining an appropriate field line helicity, we apply the powerful concept of magnetic helicity to the problem of global magnetic field evolution in the Sun’s corona. As an ideal-magnetohydrodynamic invariant, the field line helicity is a meaningful measure of how magnetic helicity is distributed within the coronal volume. It may be interpreted, for each magnetic field line, as a magnetic flux linking with that field line. Using magneto-frictional simulations, we investigate how field line helicity evolves in the non-potential corona as a result of shearing by large-scale motions on the solar surface. On open magnetic field lines, the helicity injected by the Sun is largely output to the solar wind, provided that the coronal relaxation is sufficiently fast. But on closed magnetic field lines, helicity is able to build up. We find that the field line helicity is non-uniformly distributed, and is highly concentrated in twisted magnetic flux ropes. Eruption of these flux ropes is shown to lead to sudden bursts of helicity output, in contrast to the steady flux along the open magnetic field lines.

Can a single active region change the course of the solar cycle?

Anthony **Yeates**, Deb Baker, Lidia van Driel-Gesztelyi

UKSP Nugget #63, Nov **2015**

http://www.uksolphys.org/uksp-nugget/63-can-a-single-active-region-change-the-course-of-the-solar-cycle/

Active regions with extreme tilt could limit the predictability of solar activity.

In summary, the evidence is pointing to a limit for how early we can make cycle predictions. We may simply have to wait for most of the active regions to emerge in a given cycle, before we can be sure that no more rogue regions will emerge and change the outcome. It is rather reminiscent of the perils of long-range weather forecasting; perhaps the butterfly diagram and the butterfly effect have more in common than you might think.

Source of a Prominent Poleward Surge During Solar Cycle 24

A.R. **Yeates**, D. Baker, L. van Driel-Gesztelyi

Solar Physics Volume 290, Issue 11, pp 3189-3201 **2015**

http://arxiv.org/pdf/1502.04854v1.pdf

As an observational case study, we consider the origin of a prominent poleward surge of leading polarity, visible in the magnetic butterfly diagram during Solar Cycle 24. A new technique is developed for assimilating individual regions of strong magnetic flux into a surface flux transport model. By isolating the contribution of each of these regions, the model shows the surge to originate primarily in a single high-latitude activity group consisting of a bipolar active region present in Carrington Rotations 2104-05 (November 2010-January 2011) and a multipolar active region in Rotations 2107-08 (February-April 2011). This group had a strong axial dipole moment opposed to Joy's law. On the other hand, the modelling suggests that the transient influence of this group on the butterfly diagram will not be matched by a large long-term contribution to the polar field, because of its location at high latitude. This is in accordance with previous flux transport models.

Asymmetric Latitudinal Gradients of Galactic Cosmic Rays at Low and High Cutoff Rigidities in Two Negative Solar Magnetic Cycles: Solar Cycles 21/22 and 23/24

T. **Yeeram**

Solar Physics September **2019**, 294:132
sci-hub.se/10.1007/s11207-019-1521-8
The south–north asymmetry of the Galactic cosmic-ray (GCR) density [nn] denoted as δnS-N/nδnS-N/n with respect to the heliospheric current sheet (HCS), observed by neutron monitors at low (≈ 1 GV) and high (≈ 13 and ≈ 17 GV) cutoff rigidities [PcPc], is investigated in two negative solar magnetic polarities when the dominant polar field is toward the northern hemisphere of the Sun. Using a new simple correction method for secular changes due to solar activity for the δnS-N/nδnS-N/n reveals that it is inversely rigidity dependent. Annual values of the corrected δnS-N/nδnS-N/n are close to zero in both solar magnetic cycles and exhibit substantial deviations due to their temporal 27-day variations. After corrections for Earth's excursions in helio-latitude for the north–south (NS) differences of HCS tilt angle [αα] as ΔαEN-SΔαN-SE, the number of 27.3-day Carrington rotations that possess correspondences between the corrected δnS-N/nδnS-N/n and ΔαEN-SΔαN-SE in both solar cycles (SCs) is significantly increased. Correlations of the two parameters are considerably increased in both SCs, particularly for SC 21/22. The asymmetric or unidirectional latitudinal gradients [G⊥G⊥] derived from the consistencies between corrected δnS-N/nδnS-N/n and ΔαEN-SΔαN-SE for the low and high PcPc in the SC 21/22 are 1.38% AU−1 and 0.69% AU−1, respectively, which are a few times larger than of SC 23/24. This suggests that asymmetric cosmic-ray modulation by the asymmetric HCS is more pronounced in SC 21/22 than in SC 23/24. Although the corrections also provide results that are fairly consistent with the drift model for the symmetric or bidirectional latitudinal gradient [GzGz], the effects of the SN asymmetric modulation of the GCR density are important as well. It is found that G⊥G⊥, GzGz, and SN asymmetric GCR modulation by NS asymmetric solar-wind speed are also inversely dependent on rigidity. The interplay between SN asymmetric modulation of the GCR density by the asymmetries in HCS and solar-wind speed, together with the effects of diffusion, are discussed for both of the negative solar magnetic cycles.

Reconstruction of total solar irradiance variability as simultaneously apparent from Solar Orbiter and Solar Dynamics Observatory

Solar irradiance variability has been monitored almost exclusively from the Earth's perspective. {We present a method to combine the unprecedented observations of the photospheric magnetic field and continuum intensity from outside the Sun-Earth line, which is being recorded by the Polarimetric and Helioseismic Imager on board the Solar Orbiter mission (SO/PHI), with solar observations recorded from the Earth's perspective to examine the solar irradiance variability from both perspectives simultaneously.} Taking SO/PHI magnetograms and continuum intensity images from the cruise phase of the Solar Orbiter mission and concurrent observations from the Helioseismic and Magnetic Imager onboard the Solar Dynamics Observatory (SDO/HMI) as input into the SATIRE-S model, we successfully reconstructed the total solar irradiance variability as apparent from both perspectives. In later stages of the SO mission, the orbital plane will tilt in such a way as to bring the spacecraft away from the ecliptic to heliographic latitudes of up to 33◦. The current study sets the template for the reconstruction of solar irradiance variability as seen from outside the ecliptic from data that SO/PHI is expected to collect from such positions. {Such a reconstruction will be beneficial to factoring inclination into how the brightness variations of the Sun compare to those of other cool stars, whose rotation axes are randomly inclined.

Intensity contrast of solar network and faculae -- II. Implications for solar irradiance modelling

K. L. **Yeo**, N. A. Krivova
A&A **2021**
https://arxiv.org/pdf/2102.09530.pdf
We aim to gain insight into the effect of network and faculae on solar irradiance from their apparent intensity. Taking full-disc observations from the Solar Dynamics Observatory, we examined the intensity contrast of network and faculae in the continuum and core of the Fe I 6173 Å line and 1700 Å, including the variation with magnetic flux density, distance from disc centre, nearby magnetic fields, and time. The brightness of network and faculae is believed to be suppressed by nearby magnetic fields from its effect on convection. The difference in intensity contrast between the quiet-Sun network and active region faculae, noted by various studies, arises because active regions are more magnetically crowded and is not due to any fundamental physical differences between network and faculae. These results highlight that solar irradiance models need to include the effect of nearby magnetic fields on network and faculae brightness. We found evidence that suggests that departures from local thermal equilibrium (LTE) might have limited effect on intensity contrast. This could explain why solar irradiance models that are based on the intensity contrast of solar surface magnetic features calculated assuming LTE reproduce the observed spectral variability even where the LTE assumption breaks down. Certain models of solar irradiance employ chromospheric indices as direct indications of the effect of network and faculae on solar irradiance. Based on past studies of the Ca

II K line and on the intensity contrast measurements derived here, we show that the fluctuations in chromospheric emission from network and faculae are a reasonable estimate of the emission fluctuations in the middle photosphere, but not of those in the lower photosphere. The data set, which extends from 2010 to 2018, indicates that intensity contrast was stable to about 3% in this period.

The Dimmest State of the Sun

K. L. **Yeo**, S. K. Solanki, N. A. Krivova, M. Rempel, L. S. Anusha, A. I. Shapiro, R. V. Tagirov, V. Witzke

Geophysical Research Letters, 47, e2020GL090243 (**2020**)

https://arxiv.org/pdf/2102.09487.pdf

How the solar electromagnetic energy entering the Earth's atmosphere varied since pre-industrial times is an important consideration in the climate change debate. Detrimental to this debate, estimates of the change in total solar irradiance (TSI) since the Maunder minimum, an extended period of weak solar activity preceding the industrial revolution, differ markedly, ranging from a drop of 0.75 Wm-2 to a rise of 6.3 Wm-2. Consequently, the exact contribution by solar forcing to the rise in global temperatures over the past centuries remains inconclusive. Adopting a novel approach based on state-of-the-art solar imagery and numerical simulations, we establish the TSI level of the Sun when it is in its least-active state to be 2.0 +/- 0.7 Wm-2 below the 2019 level. This means TSI could not have risen since the Maunder minimum by more than this amount, thus restricting the possible role of solar forcing in global warming.

How faculae and network relate to sunspots, and the implications for solar and stellar brightness variations

K. L. **Yeo**, S. K. Solanki, N. A. Krivova

A&A 639, A139 **2020**

https://arxiv.org/pdf/2006.14274.pdf

https://www.aanda.org/articles/aa/pdf/2020/07/aa37739-20.pdf

How global faculae and network coverage relates to that of sunspots is relevant to the brightness variations of the Sun and Sun-like stars. We extend earlier studies that found the facular-to-sunspot-area ratio diminishes with total sunspot coverage. Chromospheric indices and the total magnetic flux enclosed in network and faculae, referred to here as 'facular indices', are modulated by the amount of facular and network present. We probed the relationship between various facular and sunspot indices through an empirical model that takes into account how active regions evolve. This model was incorporated into a total solar irradiance (TSI) model. The model presented here replicates most of the observed variability in the facular indices, and is better at doing so than earlier models. Contrary to recent studies, we found the relationship between the facular and sunspot indices to be stable over the past four decades. The model indicates that, like the facular-to-sunspot-area ratio, the ratio of the variation in chromospheric emission and total network and facular magnetic flux to sunspot area decreases with the latter. The TSI model indicates the ratio of the TSI excess from faculae and network to the deficit from sunspots also declines with sunspot area, with the consequence being that TSI rises with sunspot area more slowly than if the two quantities were linearly proportional to one another. The extrapolation of the TSI model to higher activity levels indicates that in the activity range where Sun-like stars are observed to switch from growing brighter with increasing activity to becoming dimmer instead, the activity-dependence of TSI exhibits a similar transition as sunspot darkening starts to rise more rapidly with activity than facular brightening. This bolsters the interpretation of this behavior of Sun-like stars as the transition from a faculae-dominated to a spot-dominated regime.

A&A 624, A135 (**2019**)

sci-hub.se/10.1051/0004-6361/201935123

Aims. We aim to gain insight into the effect of network and faculae on solar irradiance from their apparent intensity.
Methods. Taking full-disc observations from the Solar Dynamics Observatory, we examined the intensity contrast of network and faculae in the continuum and core of the Fe I 6173 Å line and 1700 Å, including the variation with magnetic flux density, distance from disc centre, nearby magnetic fields, and time.
Results. The brightness of network and faculae is believed to be suppressed by nearby magnetic fields from its effect on convection. We note that the degree of magnetically crowding of an area also affects the magnetic flux tube sizes and the depth at which magnetic concentrations are embedded in intergranular lanes, such that intensity contrast can be enhanced in magnetically crowded areas at certain flux densities and distances from disc centre. The difference in intensity contrast between the quiet-Sun network and active region faculae, noted by various studies, arises because active regions are more magnetically crowded and is not due to any fundamental physical differences between network and faculae. These results highlight that solar irradiance models need to include the effect of nearby

magnetic fields on network and faculae brightness. We found evidence that suggests that departures from local thermal equilibrium (LTE) might have limited effect on intensity contrast. This could explain why solar irradiance models that are based on the intensity contrast of solar surface magnetic features calculated assuming LTE reproduce the observed spectral variability even where the LTE assumption breaks down. Certain models of solar irradiance employ chromospheric indices as direct indications of the effect of network and faculae on solar irradiance. Based on past studies of the Ca II K line and on the intensity contrast measurements derived here, we show that the fluctuations in chromospheric emission from network and faculae are a reasonable estimate of the emission fluctuations in the middle photosphere, but not of those in the lower photosphere. This is due to the different physical mechanisms that underlie the magnetic intensity enhancement in the various atmospheric regimes, and represents a fundamental limitation of these solar irradiance models. Any time variation in the radiant properties of network and faculae is, of course, relevant to their effect on solar irradiance. The data set, which extends from 2010 to 2018, indicates that their intensity contrast was stable to about 3% in this period.
Conclusions. This study offers new insights into the radiant behaviour of network and faculae, with practical implications for solar irradiance modelling.

Solar Irradiance Variability is Caused by the Magnetic Activity on the Solar Surface

K. L. **Yeo**, S. K. Solanki, C. M. Norris, B. Beeck, Y. C. Unruh, N. A. Krivova
PHYSICAL REVIEW LETTERS **2017**

Supplementary Materials; this https URL
The variation in the radiative output of the Sun, described in terms of solar irradiance, is important to climatology. A common assumption is that solar irradiance variability is driven by its surface magnetism. Verifying this assumption has, however, been hampered by the fact that models of solar irradiance variability based on solar surface magnetism have to be calibrated to observed variability. Making use of realistic three-dimensional magnetohydrodynamic simulations of the solar atmosphere and state-of-the-art solar magnetograms from the Solar Dynamics Observatory, we present a model of total solar irradiance (TSI) that does not require any such calibration. In doing so, the modeled irradiance variability is entirely independent of the observational record. (The absolute level is calibrated to the TSI record from the Total Irradiance Monitor.) The model replicates 95% of the observed variability between April 2010 and July 2016, leaving little scope for alternative drivers of solar irradiance variability at least over the time scales examined (days to years). **December 16, 2012**

EMPIRE: A robust empirical reconstruction of solar irradiance variability

K. L. **Yeo**, N. A. Krivova, S. K. Solanki
JGR Volume 122, Issue 4 April 2017 Pages 3888–3914 **2017**
https://arxiv.org/pdf/1704.07652.pdf
We present a new empirical model of total and spectral solar irradiance (TSI and SSI) variability entitled EMPirical Irradiance REconstruction (EMPIRE). As with existing empirical models, TSI and SSI variability is given by the linear combination of solar activity indices. In empirical models, UV SSI variability is usually determined by fitting the rotational variability in activity indices to that in measurements. Such models have to date relied on ordinary least squares regression, which ignores the uncertainty in the activity indices. In an advance from earlier efforts, the uncertainty in the activity indices is accounted for in EMPIRE by the application of an error-in-variables regression scheme, making the resultant UV SSI variability more robust. The result is consistent with observations and unprecedentedly, with that from other modelling approaches, resolving the long-standing controversy between existing empirical models and other types of models. We demonstrate that earlier empirical models, by neglecting the uncertainty in activity indices, underestimate UV SSI variability. The reconstruction of TSI and visible and IR SSI from EMPIRE is also shown to be consistent with observations. The EMPIRE reconstruction is of utility to climate studies as a more robust alternative to earlier empirical reconstructions.

UV solar irradiance in observations and the NRLSSI and SATIRE-S models

K. L. **Yeo**, W. T. Ball, N. A. Krivova, S. K. Solanki, Y. C. Unruh, J. Morrill
J. Geophys. Res. (Space Phys.) v. 120 (**2015**)
http://arxiv.org/pdf/1507.01224v1.pdf
Total solar irradiance and UV spectral solar irradiance have been monitored since 1978 through a succession of space missions. This is accompanied by the development of models aimed at replicating solar irradiance by relating the variability to solar magnetic activity. The NRLSSI and SATIRE-S models provide the most comprehensive reconstructions of total and spectral solar irradiance over the period of satellite observation currently available. There is persistent controversy between the various measurements and models in terms of the wavelength dependence of the variation over the solar cycle, with repercussions on our understanding of the influence of UV solar irradiance variability on the stratosphere. We review the measurement and modelling of UV solar irradiance variability over the period of satellite observation. The SATIRE-S reconstruction is consistent with spectral solar irradiance observations where they are reliable. It is also supported by an independent, empirical reconstruction of

UV spectral solar irradiance based on UARS/SUSIM measurements from an earlier study. The weaker solar cycle variability produced by NRLSSI between 300 and 400 nm is not evident in any available record. We show that although the method employed to construct NRLSSI is principally sound, reconstructed solar cycle variability is detrimentally affected by the uncertainty in the SSI observations it draws upon in the derivation. Based on our findings, we recommend, when choosing between the two models, the use of SATIRE-S for climate studies.

Solar Cycle Variation in Solar Irradiance **Review**

K. L. **Yeo**, N. A. Krivova, S. K. Solanki

Space Science Reviews December **2014**, Volume 186, Issue 1-4, pp 137-167

The correlation between solar irradiance and the 11-year solar activity cycle is evident in the body of measurements made from space, which extend over the past four decades. Models relating variation in solar irradiance to photospheric magnetism have made significant progress in explaining most of the apparent trends in these observations. There are, however, persistent discrepancies between different measurements and models in terms of the absolute radiometry, secular variation and the spectral dependence of the solar cycle variability. We present an overview of solar irradiance measurements and models, and discuss the key challenges in reconciling the divergence between the two.

Analysis and modeling of solar irradiance variations

K. L. **Yeo**

Doctoral thesis, **2014**

http://arxiv.org/pdf/1412.3935v1.pdf

A prominent manifestation of the solar dynamo is the 11-year activity cycle, evident in indicators of solar activity, including solar irradiance. Although a relationship between solar activity and the brightness of the Sun had long been suspected, it was only directly observed after regular satellite measurements became available with the launch of Nimbus-7 in 1978. The measurement of solar irradiance from space is accompanied by the development of models aimed at describing the apparent variability by the intensity excess/deficit effected by magnetic structures in the photosphere. The more sophisticated models, termed semi-empirical, rely on the intensity spectra of photospheric magnetic structures generated with radiative transfer codes from semi-empirical model atmospheres. An established example of such models is SATIRE-S (Spectral And Total Irradiance REconstruction for the Satellite era). One key limitation of current semi-empirical models is the fact that the radiant properties of network and faculae are not adequately represented due to the use of plane-parallel model atmospheres (as opposed to three-dimensional model atmospheres). This thesis is the compilation of four publications, detailing the results of investigations aimed at setting the groundwork necessary for the eventual introduction of three-dimensional atmospheres into SATIRE-S and a review of the current state of the measurement and modelling of solar irradiance. Also presented is an update of the SATIRE-S model. We generated a daily reconstruction of total and spectral solar irradiance, covering 1974 to the present, that is more reliable and, in most cases, extended than similar reconstructions from contemporary models.

Reconstruction of total and spectral solar irradiance from 1974 to 2013 based on KPVT, SoHO/MDI and SDO/HMI observations

K. L. **Yeo**, N. A. Krivova, S. K. Solanki, K. H. Glassmeier

A&A, 570, A85 **2014**

http://arxiv.org/pdf/1408.1229v1.pdf

Total and spectral solar irradiance are key parameters in the assessment of solar influence on changes in the Earth's climate. We present a reconstruction of daily solar irradiance obtained using the SATIRE-S model spanning 1974 to 2013 based on full-disc observations from the KPVT, SoHO/MDI and SDO/HMI. SATIRE-S ascribes variation in solar irradiance on timescales greater than a day to photospheric magnetism. The solar spectrum is reconstructed from the apparent surface coverage of bright magnetic features and sunspots in the daily data using the modelled intensity spectra of these magnetic structures. We cross-calibrated the various data sets, harmonizing the model input so as to yield a single consistent time series as the output. The model replicates 92% of the variability in the PMOD TSI composite including the secular decline between the 1996 and 2008 solar cycle minima. The model also reproduces most of the variability in observed Lyman-alpha irradiance and the Mg II index. The UV solar irradiance measurements from the UARS and SORCE missions are mutually consistent up to about 180 nm before they start to exhibit discrepant rotational and cyclical variability, indicative of unresolved instrumental effects. As a result, the agreement between model and measurement starts to deteriorate above this wavelength. As with earlier similar investigations, the reconstruction cannot reproduce the overall trends in SORCE/SIM SSI. We argue, from the lack of clear solar cycle modulation in the SIM record and the inconsistency between the total flux recorded by the instrument and TSI, that unaccounted instrumental trends are present. The reconstruction is consistent with observations from multiple sources, demonstrating its validity. It also provides further evidence that photospheric magnetism is the prime driver of variation in solar irradiance on timescales greater than a day.

Solar cycle variation in solar irradiance **Review**

K. L. **Yeo**, N. A. Krivova, S. K. Solanki
Space Sci. Rev., (**2014**)
http://arxiv.org/pdf/1407.4249v1.pdf
The correlation between solar irradiance and the 11-year solar activity cycle is evident in the body of measurements made from space, which extend over the past four decades. Models relating variation in solar irradiance to photospheric magnetism have made significant progress in explaining most of the apparent trends in these observations. There are, however, persistent discrepancies between different measurements and models in terms of the absolute radiometry, secular variation and the spectral dependence of the solar cycle variability. 2023
https://arxiv.org/ftp/arxiv/papers/2304/2304.14707.pdf
Solar activity and solar wind parameters decreased significantly in solar cycles (SCs) 23-24. In this paper, we analyze solar wind measurements at the rising phase of SC 25 and compare them with similar data from the previous cycles. For this purpose, we simultaneously selected the OMNI database data for 1976-2022, both by phases of the 11-year solar cycle and by large-scale solar wind types (in accordance with IKI's catalog, see this http URL), and calculated the mean values of the parameters for the selected datasets. The obtained results testify in favor of the hypothesis that the continuation of this cycle will be similar to the previous cycle 24, i.e. SC 25 will be weaker than SCs 21 and 22.

Drop of solar wind at the end of the 20th century

Yuri I. **Yermolaev**, Irina G. Lodkina, Alexander A. Khokhlachev, Michael Yu. Yermolaev, Maria O. Riazantseva, Liudmila S. Rakhmanova, Natalia L. Borodkova, Olga V. Sapunova, Anastasiia V. Moskaleva
2021
https://arxiv.org/ftp/arxiv/papers/2105/2105.10955.pdf
Variations in the solar wind (SW) parameters with scales of several years are an important characteristic of solar activity and the basis for a long-term space weather forecast. We examine the behavior of interplanetary parameters over 21-24 solar cycles (SCs) on the basis of OMNI database (this https URL). Since changes in parameters can be associated both with changes in the number of different large-scale types of SW, and with variations in the values of these parameters at different phases of the solar cycle and during the transition from one cycle to another, we select the entire study period in accordance with the Catalog of large-scale SW types for 1976-2019 (See the site this http URL, [Yermolaev et al., 2009]), which covers the period from 21 to 24 SCs, and in accordance with the phases of the cycles, and averaging the parameters at selected intervals. In addition to a sharp drop in the number of ICMEs (and associated Sheath types), there is a noticeable drop in the value (by 20-40%) of plasma parameters and magnetic field in different types of solar wind at the end of the 20th century and a continuation of the fall or persistence at a low level in the 23-24 cycles. Such a drop in the solar wind is apparently associated with a decrease in solar activity and manifests itself in a noticeable decrease in space weather factors.

ALMA Observations of the Solar Chromosphere on the Polar Limb

Takaaki **Yokoyama**, Masumi Shimojo, Takenori J. Okamoto, Haruhisa Iijima
ApJ **2018**
https://arxiv.org/pdf/1807.01411.pdf
We report the results of the Atacama Large Millimeter/sub-millimeter Array (ALMA) observations of the solar chromosphere on the southern polar limb. Coordinated observations with the Interface Region Imaging Spectrograph (IRIS) are also conducted. ALMA provided unprecedented high spatial resolution in the millimeter band (≈ 2.0 arcsec) at 100 GHz frequency with a moderate cadence (20 s). The results are as follows: (1) The ALMA 100 GHz images show saw-tooth patterns on the limb, and a comparison with SDO/AIA 171\AA\ images shows a good correspondence of the limbs with each other. (2) The ALMA 100 GHz movie shows a dynamic thorn-like structure elongating from the saw-tooth patterns on the limb, with lengths reaching at least 8 arcsec, thus suggesting jet-like activity in the ALMA microwave range. These **ALMA jets** are in good correspondence with

IRIS jet clusters. (3) A blob ejection event is observed. By comparing with the IRIS Mg II slit-jaw images, the trajectory of the blob is located along the spicular patterns. **2017 April 29**

Which Component of Solar Magnetic Field Drives the Evolution of Interplanetary Magnetic Field over Solar Cycle?

Minami **Yoshida**, Toshifumi Shimizu, Shin Toriumi

ApJ **950** 156 **2023**

https://arxiv.org/pdf/2304.13347.pdf

https://iopscience.iop.org/article/10.3847/1538-4357/acd053/pdf

The solar magnetic structure changes over the solar cycle. It has a dipole structure during solar minimum, where the open flux extends mainly from the polar regions into the interplanetary space. During maximum, a complex structure is formed with low-latitude active regions and weakened polar fields, resulting in spread open field regions. However, the components of the solar magnetic field that is responsible for long-term variations in the interplanetary magnetic field (IMF) are not clear, and the IMF strength estimated based on the solar magnetic field is known to be underestimated by a factor of 3 to 4 against the actual in-situ observations (the open flux problem). To this end, we decomposed the coronal magnetic field into the components of the spherical harmonic function of degree and order (ℓ,m) using the potential field source surface model with synoptic maps from SDO/HMI for 2010 to 2021. As a result, we found that the IMF rapidly increased in December 2014 (seven months after the solar maximum), which coincided with the increase in the equatorial dipole, (ℓ,m)=(1,±1), corresponding to the diffusion of active regions toward the poles and in the longitudinal direction. The IMF gradually decreased until December 2019 (solar minimum) and its variation corresponded to that of the non-dipole component $\ell \geq 2$. Our results suggest that the understanding of the open flux problem may be improved by focusing on the equatorial dipole and the non-dipole component and that the influence of the polar magnetic field is less significant.

High-frequency Wave Propagation Along a Spicule Observed by CLASP

Masaki **Yoshida**, Yoshinori Suematsu, Ryohko Ishikawa, Takenori J. Okamoto, Masahito Kubo, Ryouhei Kano, Noriyuki Narukage, Takamasa Bando, Amy R. Winebarger, Ken Kobayashi, Javier Trujillo Bueno, and Frédéric Auchère

2019 ApJ 887 2

https://doi.org/10.3847/1538-4357/ab4ce7

The Chromospheric Lyman-Alpha Spectro-Polarimeter (CLASP) sounding rocket experiment, launched in 2015 September, observed the hydrogen Lyα line (121.6 nm) in an unprecedented high temporal cadence of 0.3 s. CLASP performed sit-and-stare observations of the quiet Sun near the limb for 5 minutes with a slit perpendicular to the limb and successfully captured an off-limb spicule evolving along the slit. The Lyα line is well suited for investigating how spicules affect the corona because it is sensitive to higher temperatures than other chromospheric lines, owing to its large optical thickness. We found high-frequency oscillations of the Doppler velocity with periods of 20–50 s and low-frequency oscillation of periods of ~240 s on the spicule. From a wavelet analysis of the time sequence data of the Doppler velocity, in the early phase of the spicule evolution, we found that waves with a period of ~30 s and a velocity amplitude of 2–3 km s−1 propagated upward along the spicule with a phase velocity of ~470 km s−1. In contrast, in the later phase, possible downward and standing waves with smaller velocity amplitudes were also observed. The high-frequency waves observed in the early phase of the spicule evolution would be related with the dynamics and the formation of the spicules. Our analysis enabled us to identify the upward, downward, and standing waves along the spicule and to obtain the velocity amplitude of each wave directly from the Doppler velocity for the first time. We evaluated the energy flux by the upward-propagating waves along the spicule, and discussed the impact to the coronal heating.

Difference between even- and odd-numbered cycles in the predictability of solar activity and prediction of the amplitude of cycle 25

A. **Yoshida**

Ann. Geophys., 32, 1035-1042, **2014**

http://www.ann-geophys.net/32/1035/2014/angeo-32-1035-2014.html

It was shown previously that the sunspot number (SSN) at a point 3 years before the minimum is well correlated with the maximum SSN of the succeeding cycle, and a better correlation is obtained when the maximum SSN is replaced by the average SSN over a cycle for which the average SSN is calculated by dividing cycles at a point 3 years before the minimum (Yoshida and Yamagishi, 2010; Yoshida and Sayre, 2012). Following these findings, we demonstrate in this paper that the correlation between the SSN 3 years before the minimum and the amplitude of the coming cycle differs significantly between even-numbered and odd-numbered cycles: the correlation is much better for even-numbered cycles. Further, it is shown that the amplitude of even-numbered cycles is strongly correlated with that of the succeeding odd-numbered cycles, while the correlation between amplitudes of odd-numbered cycles

and those of succeeding even-numbered cycles is very poor. Using the excellent correlations, we estimate the maximum SSN of the current cycle 24 at 81.3 and predict the maximum SSN of cycle 25 to be 115.4 ± 11.9. It is of note, however, that a peak of the SSN has been observed in February 2012 and the peak value 66.9 is considerably smaller than the estimated maximum SSN of cycle 24. We conjecture that the second higher peak of the SSN may appear.

Calibration of Hinode/XRT for Coalignment

Yoshimura, K., McKenzie, David E.
Solar Phys. Volume 290, Issue 8, pp 2355-2372 **2015**
http://ylstone.physics.montana.edu/yosimura/hinode/coalignment/KY_coal_paper_20150706.pdf
We present coalignment calibration procedures for the X-ray Telescope (XRT) onboard the Hinode satellite in this paper. We performed not only an XRT stand-alone calibration, but also cross-calibration using data from the Helioseismic and Magnetic Imager (HMI) and the Atmospheric Imaging Assembly (AIA) onboard the Solar Dynamics Observatory (SDO). Several new methods described herein may also be useful for the coalignment calibration of other instruments. We have developed a database of coalignment coefficients and software to access it, so that all XRT images can be easily and accurately overlaid onto the images from other instruments, especially AIA and HMI. **17-18 Jan 2011,** 28 January 2011. **19 Aug 2011**

Applications of Atomic Data to Studies of the Sun

Peter R. **Young**
European Physical Journal D **2024**
https://arxiv.org/pdf/2409.09166
The Sun is a standard reference object for Astrophysics and also a fascinating subject of study in its own right. X-ray and extreme ultraviolet movies of the Sun's atmosphere show an extraordinary diversity of plasma phenomena, from barely visible bursts and jets to coronal mass ejections that impact a large portion of the solar surface. The processes that produce these phenomena, heat the corona and power the solar wind remain actively studied and accurate atomic data are essential for interpreting observations and making model predictions. For the Sun's interior intense effort is focused on resolving the "solar problem," (a discrepancy between solar interior models and helioseismology measurements) and atomic data are central to both element abundance measurements and interior physics such as opacity and nuclear reaction rates. In this article, topics within solar interior and solar atmosphere physics are discussed and the role of atomic data described. Areas of active research are highlighted and specific atomic data needs are identified.

Properties of EUV Imaging Spectrometer (EIS) Slot Observations

Peter R. **Young** & Ignacio Ugarte-Urra
Solar Physics volume 297, Article number: 87 (**2022**)
https://link.springer.com/content/pdf/10.1007/s11207-022-02014-4.pdf
The Extreme ultraviolet Imaging Spectrometer (EIS) on board the Hinode spacecraft has been operating since 2006, returning high-resolution data in the 170 – 212 and 246 – 292 Å wavelength regions. EIS has four slit options, with the narrow 1″ and 2″ slits used for spectroscopy and the wide 40″ and 266″ slits used for monochromatic imaging. In this article several properties of the 40″ slit (or slot) are measured using the Fe XII 195.12 Å line, which is formed at 1.5 MK. The projected width of the slot on the detector shows a small variation along the slit with an average value of 40.949″. The slot image is tilted on the detector and a quadratic formula is provided to describe the tilt. The tilt corresponds to four pixels on the detector and the slot centroid is offset mostly to the right (longer wavelengths) of the 1″ slit by up to four pixels. Measurement of the intensity decrease at the edge of the slot leads to an estimate of the spatial resolution of the images in the xx-direction. The resolution varies quadratically along the slot, with a minimum value of 2.9″ close to the detector center. Intensities measured from the slot images are found to be on average 14% higher than those measured from the 1″ slit at the same spatial location. Background subtraction is necessary to derive accurate intensities in quiet-Sun and coronal-hole regions. Prescriptions for deriving accurate slot intensities for different types of slot datasets are presented.

An Analysis of Spikes in Atmospheric Imaging Assembly (AIA) Data

Peter R. **Young**, Nicholeen M. Viall, Michael S. Kirk, Emily I. Mason & Lakshmi Pradeep Chitta
Solar Physics volume 296, Article number: 181 (**2021**
https://link.springer.com/content/pdf/10.1007/s11207-021-01929-8.pdf
https://doi.org/10.1007/s11207-021-01929-8
https://arxiv.org/pdf/2108.02624.pdf
The Atmospheric Imaging Assembly (AIA) on the Solar Dynamics Observatory (SDO) returns high-resolution images of the solar atmosphere in seven extreme ultraviolet wavelength channels. The images are processed on the ground to remove intensity spikes arising from energetic particles hitting the instrument, and the despiked images are provided to the community. In this work a three-hour series of images from the 171 A channel obtained on **2017**

February 28 was studied to investigate how often the despiking algorithm gave false positives caused by compact brightenings in the solar atmosphere. The latter were identified through spikes appearing in the same detector pixel for three consecutive frames, and 1096 examples were found from the 900 image frames. These "three-spikes" were assigned to 126 dynamic solar features, and it is estimated that the three-spike method identifies 25% of the total number of features affected by despiking. For any 10 minute sequence of AIA 171 A images there are therefore around 28 solar features that have their intensity modified by despiking. The features are found in active regions, quiet Sun and coronal holes and, in relation to solar surface area, there is a greater proportion within coronal holes. In 96% of the cases, the despiked structure is a compact brightening of size 2 arcsec or less and the remaining 4% have narrow, elongated structures. In all cases, the events are not rendered invisible by the AIA processing pipeline, but the total intensity over the event's lifetimes can be reduced by up to 67%. Scientists are recommended to always restore the original intensities to AIA data when studying short-lived or rapidly-evolving features that exhibit fine-scale structure.

Future Prospects for Solar EUV and Soft X-ray Spectroscopy Missions **Review**

Peter R. **Young**

Frontiers issue on Solar Instrumentation April **2021**

https://arxiv.org/pdf/2102.02943.pdf

https://www.frontiersin.org/articles/10.3389/fspas.2021.662790/full

https://doi.org/10.3389/fspas.2021.662790

Future prospects for solar spectroscopy missions operating in the extreme ultraviolet (EUV) and soft X-ray (SXR) wavelength ranges, 1.2-1600 A, are discussed. NASA is the major funder of Solar Physics missions, and brief summaries of the opportunities for mission development under NASA are given. The methods of observing the Sun in the two wavelength ranges are summarized with a particular focus on imaging spectroscopy techniques. The major spectral features in the EUV and SXR regions are identified, and then the upcoming instruments and concepts are summarized. The instruments range from large spectrometers on dedicated missions, to tiny, low-cost CubeSats launched through rideshare opportunities.

Solar Ultraviolet Bursts **Review**

Peter R. **Young**, Hui Tian, Hardi Peter, Robert J. Rutten, Chris J. Nelson, Zhenghua Huang, ...

Space Science Reviews December **2018**, 214:120

https://link.springer.com/content/pdf/10.1007%2Fs11214-018-0551-0.pdf

The term “ultraviolet (UV) burst” is introduced to describe small, intense, transient brightenings in ultraviolet images of solar active regions. We inventorize their properties and provide a definition based on image sequences in transition-region lines. Coronal signatures are rare, and most bursts are associated with small-scale, canceling opposite-polarity fields in the photosphere that occur in emerging flux regions, moving magnetic features in sunspot moats, and sunspot light bridges. We also compare UV bursts with similar transition-region phenomena found previously in solar ultraviolet spectrometry and with similar phenomena at optical wavelengths, in particular Ellerman bombs. Akin to the latter, UV bursts are probably small-scale magnetic reconnection events occurring in the low atmosphere, at photospheric and/or chromospheric heights. Their intense emission in lines with optically thin formation gives unique diagnostic opportunities for studying the physics of magnetic reconnection in the low solar atmosphere. This paper is a review report from an International Space Science Institute team that met in 2016–2017. **Sep 24, 2013, October 22-23, 2013, 2013 December 6, 13 Feb 2014, 4 March 2014, 2014 June 15, 24 Oct 2014, 26 Oct 2016**

A Si IV/O IV electron density diagnostic for the analysis of IRIS solar spectra

P.R. **Young**, F.P. Keenan, R.O. Milligan, H. Peter

ApJ **857** 5 **2018**

https://arxiv.org/pdf/1803.01721.pdf

Solar spectra of ultraviolet bursts and flare ribbons from the Interface Region Imaging Spectrograph (IRIS) have suggested high electron densities of >1012 cm−3 at transition region temperatures of 0.1 MK, based on large intensity ratios of Si IV λ1402.77 to O IV λ1401.16. In this work a rare observation of the weak O IV λ1343.51 line is reported from an X-class flare that peaked at 21:41 UT on **2014 October 24**. This line is used to develop a theoretical prediction of the Si IV λ1402.77 to O IV λ1401.16 ratio as a function of density that is recommended to be used in the high density regime. The method makes use of new pressure-dependent ionization fractions that take account of the suppression of dielectronic recombination at high densities. It is applied to two sequences of flare kernel observations from the October 24 flare. The first shows densities that vary between 3×1012 to 3×1013 cm−3 over a seven minute period, while the second location shows stable density values of around 2×1012 cm−3 over a three minute period.

Element Abundance Ratios in the Quiet Sun Transition Region

P. R. **Young**

2018 ApJ 855 15

Element abundance ratios of magnesium to neon (Mg/Ne) and neon to oxygen (Ne/O) in the transition region of the quiet Sun have been derived by re-assessing previously published data from the Coronal Diagnostic Spectrometer on board the Solar and Heliospheric Observatory in the light of new atomic data. The quiet Sun Mg/Ne ratio is important for assessing the effect of magnetic activity on the mechanism of the first ionization potential (FIP) effect, while the Ne/O ratio can be used to infer the solar photospheric abundance of neon, which cannot be measured directly. The average Mg/Ne ratio is found to be 0.52 ± 0.11, which applies over the temperature region 0.2–0.7 MK, and is consistent with the earlier study. The Ne/O ratio is, however, about 40% larger, taking the value 0.24 ± 0.05 that applies to the temperature range 0.08–0.40 MK. The increase is mostly due to changes in ionization and recombination rates that affect the equilibrium ionization balance. If the Ne/O ratio is interpreted as reflecting the photospheric ratio, then the photospheric neon abundance is 8.08 ± 0.09 or 8.15 ± 0.10 (on a logarithmic scale for which hydrogen is 12), according to whether the oxygen abundances of M. Asplund et al. or E. Caffau et al. are used. The updated photospheric neon abundance implies a Mg/Ne FIP bias for the quiet Sun of 1.6 ± 0.6.

Solar Analogs as a Tool to Understand the Sun mini Review

Allison **Youngblood**, Steve Cranmer, Sam Van Kooten, James Paul Mason, J. Sebastian Pineda, Kevin France, Dmitry Vorobiev, Frank Eparvier, Yuta Notsu

Heliophysics 2050 Workshop **2020**

https://arxiv.org/ftp/arxiv/papers/2009/2009.05672.pdf

Solar analogs, broadly defined as stars similar to the Sun in mass or spectral type, provide a useful laboratory for exploring the range of Sun-like behaviors and exploring the physical mechanisms underlying some of the Sun's most elusive processes like coronal heating and the dynamo. We describe a series of heliophysics-motivated, but astrophysics-like studies of solar analogs. We argue for a range of stellar observations, including (a) the identification and fundamental parameter determination of new solar analogs, and (b) characterizing emergent properties like activity, magnetism, and granulation. These parameters should be considered in the framework of statistical studies of the dependences of these observables on fundamental stellar parameters like mass, metallicity, and rotation.

Input Selection Based on Information Theory for Constructing Predictor Models of Solar and Geomagnetic Activity Indices

Mohammadmahdi Rezaei **Yousefi** · Babak Salehi Kasmaei · Abdolhossein Vahabie · Caro Lucas · Babak Nadjar Araabi

Solar Phys (**2009**) 258: 297–318

Various phenomena with solar origin and their mutual dependence must be studied in order to predict behaviors in solar – terrestrial system. Linear statistical methods prevalent in analyzing natural systems may not be able to detect nonlinear dependencies among solar and geomagnetic processes. When relations, whether linear or nonlinear, between indices and their changes over time are revealed, better predictions can be made through appropriate modeling techniques. Selection of nonredundant input variables to build suitable models for prediction of solar and geomagnetic activity is of utmost importance. Mutual information is a tool that is capable of capturing all dependencies for detecting nonlinear relations and selecting the best subset of input variables by means of an applicable algorithm that maximizes information about the output and minimizes the shared information between inputs. High generalization power and improved interpretability of the selected inputs are the consequences of this analysis.

Image Desaturation for SDO/AIA Using Deep Learning

Xuexin **Yu**, Long Xu & Yihua Yan

Solar Physics volume 296, Article number: 56 (**2021**)

https://doi.org/10.1007/s11207-021-01808-2

https://link.springer.com/content/pdf/10.1007/s11207-021-01808-2.pdf

The Atmospheric Imaging Assembly (AIA) on board the Solar Dynamics Observatory (SDO) (launched in February 2010) provides uninterrupted full-disk solar images over 10 wavebands. In the case of violent solar flares, saturation would happen to SDO/AIA images in their core regions, which leads to signal loss, hindering us to understand physical mechanism behind solar flares. This paper introduces a deep learning based image restoration model which can recover signal of saturation region by referring to other normal/valid region within an image. The proposed model, namely PCGAN, combines partial convolution (PC) and conditional generative adversarial network (GAN). The PC module was originally designed for image inpainting, for repairing images with scratches and holes. In addition, a new comprehensive loss function consists of an adversarial loss, a pixel reconstruction loss, a gradient loss, a perceptual loss, a style loss and a total variation loss. Moreover, for validating the proposed model, a new dataset consisting of paired saturated and normal SDO/AIA images is established. Experimental results demonstrate

that the proposed PCGAN can get appealing desaturated solar images with respect to both objective and subjective validations. **September 6 2011**

Resonant Damping of Kink Modes in Solar Coronal Slabs

Hui **Yu**, Bo Li, Shaoxia Chen, Mingzhe Guo
Solar Phys. **296**, Article number: 95 **2021**
https://arxiv.org/pdf/2102.00222.pdf
https://link.springer.com/content/pdf/10.1007/s11207-021-01839-9.pdf
We examine resonantly damped kink modes in straight coronal slabs, paying special attention to the effects of the formulation for the transverse density distribution ("profile" for brevity). We work in the framework of pressure-less, gravity-free, resistive magnetohydrodynamics, and adopt the dissipative eigenmode perspective. The density profile is restricted to be one-dimensional, but nonetheless allowed to take a generic form characterized by a continuous transition layer connecting a uniform interior to a uniform exterior. A dispersion relation (DR) is derived in the thin-boundary limit, yielding analytical expressions for the eigenfrequencies that generalize known results in various aspects. We find that the analytical rather than the numerical solutions to the thin-boundary DR serve better the purpose for validating our self-consistent resistive solutions. More importantly, the eigenfrequencies are found to be sensitive to profile specifications, the ratio of the imaginary to the real part readily varying by a factor of two when one profile is used in place of another. Our eigenmode computations are also examined in the context of impulsively excited kink waves, suggesting the importance of resonant absorption for sufficiently oblique components when the spatial scale of the exciter is comparable to the slab half-width.

Excitation of negative energy surface magnetohydrodynamic waves in an incompressible cylindrical plasma

Yu, D.J., Nakariakov, V.M.
ApJ **2020**
https://arxiv.org/pdf/2004.13552.pdf
Negative energy wave phenomena may appear in shear flows in the presence of a wave decay mechanism and external energy supply. We study the appearance of negative energy surface waves in a plasma cylinder in the incompressible limit. The cylinder is surrounded by an axial magnetic field and by a plasma of different density. Considering flow inside and viscosity outside the flux tube, we derive dispersion relations, and obtain analytical solutions for the phase speed and growth rate (increment) of the waves. It is found that the critical speed shear for the occurrence of the dissipative instability associated with negative energy waves (NEWs) and the threshold of Kelvin-Helmholtz instability (KHI) depend on the axial wavelength. The critical shear for the appearance of sausage NEW is lowest for the longest axial wavelengths, while for kink waves the minimum value of the critical shear is reached for the axial wavelength comparable to the diameter of the cylinder. The range between the critical speed of the dissipative instability and the KHI threshold is shown to depend on the difference of the Alfvén speeds inside and outside of the cylinder. For all axial {wavenumbers}, NEW appears for the shear flow speeds lower than the KHI threshold. It is easier to excite NEW in an underdense cylinder than in an overdense one. The negative energy surface waves can be effectively generated for azimuthal number m=0 with a large axial wave number and for higher modes (m>0) with a small axial wave number.

Resonant Absorption of Surface Sausage and Surface Kink Modes under Photospheric Conditions

Dae Jung **Yu**1,2, Tom Van Doorsselaere1, and Marcel Goossens
2017 ApJ 850 44
http://sci-hub.cc/http://iopscience.iop.org/0004-637X/850/1/44/
We study the effect of resonant absorption of surface sausage and surface kink modes under photospheric conditions where the slow surface sausage modes undergo resonant damping in the slow continuum and the surface kink modes in the slow and Alfvén continua at the transitional layers. We use recently derived analytical formulas to obtain the damping rate (time). By considering linear density and linear pressure profiles for the transitional layers, we show that resonant absorption in the slow continuum could be an efficient mechanism for the wave damping of the slow surface sausage and slow surface kink modes while the damping rate of the slow surface kink mode in the Alfvén continuum is weak. It is also found that the resonant damping of the fast surface kink mode is much stronger than that of the slow surface kink mode, showing a similar efficiency as under coronal conditions. It is worth noting that the slow body sausage and kink modes can also resonantly damp in the slow continuum for those linear profiles.
Correction: A&A 626, C2 (**2019**) https://www.aanda.org/articles/aa/pdf/2019/06/aa30355e-16.pdf

Resonant absorption of the slow sausage wave in the slow continuum

D. J. **Yu**, T. Van Doorsselaere and M. Goossens
A&A 602, A108 (**2017**)

Aims. General analytical formulas for the damping rate by resonant absorption of slow sausage modes in the slow (cusp) continuum are derived and the resonant damping of the slow surface mode under photospheric conditions is investigated.
Methods. The connection formula across the resonant layer is used to derive the damping rate for the slow sausage mode in the slow continuum by assuming a thin boundary.
Results. It is shown that the effect of the resonant damping on the slow surface sausage mode in the slow continuum, which has been underestimated in previous interpretations, could be efficient under magnetic pore conditions. A simplified analytical formula for the damping rate of slow surface mode in the long wavelength limit is derived. This formula can be useful for a rough estimation of the damping rate due to resonant absorption for observational wave damping.

Impulsively Generated Wave Trains in Coronal Structures: I. Effects of Transverse Structuring on Sausage Waves in Pressureless Tubes

Hui **Yu**, Bo Li, Shao-Xia Chen, Ming Xiong, Ming-Zhe Guo
ApJ **836** 1 **2017**
https://arxiv.org/pdf/1612.09479v1.pdf
The behavior of the axial group speeds of trapped sausage modes plays an important role in determining impulsively generated wave trains, which have often been invoked to account for quasi-periodic signals with quasi-periods of order seconds in a considerable number of coronal structures. We conduct a comprehensive eigenmode analysis, both analytically and numerically, on the dispersive properties of sausage modes in pressureless tubes with three families of continuous radial density profiles. We find a rich variety of the dependence on the axial wavenumber k of the axial group speed vgr. Depending on the density contrast and profile steepness as well as on the detailed profile description, the vgr−k curves either possess or do not possess cutoff wavenumbers, and they can behave in either a monotonical or non-monotonical manner. With time-dependent simulations, we further show that this rich variety of the group speed characteristics heavily influences the temporal evolution and Morlet spectra of impulsively generated wave trains. In particular, the Morlet spectra can look substantially different from "crazy tadpoles" found for the much-studied discontinuous density profiles. We conclude that it is necessary to re-examine available high-cadence data to look for the rich set of temporal and spectral features, which can be employed to discriminate between the unknown forms of the density distributions transverse to coronal structures.

Impulsively generated sausage waves in coronal tubes with transversally continuous structuring

Hui **Yu**, Bo Li, Shao-Xia Chen, Ming Xiong, Ming-Zhe Guo
ApJ 833 51 **2016**
https://arxiv.org/pdf/1610.04316v1.pdf
The frequency dependence of the longitudinal group speeds of trapped sausage waves plays an important role in determining impulsively generated wave trains, which have often been invoked to account for quasi-periodic signals in coronal loops. We examine how the group speeds (v
gr) depend on angular frequency (ω) for sausage modes in pressureless coronal tubes with continuous transverse density distributions by solving the dispersion relation pertinent to the case where the density inhomogeneity of arbitrary form takes place in a transition layer of arbitrary thickness. We find that in addition to the transverse lengthscale l and density contrast ρi/ρe, the group speed behavior depends also on the detailed form of the density inhomogeneity. For parabolic profiles, vgr always decreases with ω first before increasing again, as happens for the much studied top-hat profiles. For linear profiles, however, the behavior of the ω−v
gr curves is more complex. When ρi/ρe≲6, the curves become monotonical for large values of
l. On the other hand, for higher density contrasts, a local maximum vmaxgr exists in addition to a local minimum vmingr when coronal tubes are diffuse. With time-dependent computations, we show that the different behavior of group speed curves, the characteristic speeds vmingr and vmaxgr in particular, is reflected in the temporal evolution and Morlet spectra of impulsively generated wave trains. We conclude that the observed quasi-periodic wave trains not only can be employed to probe such key parameters as density contrasts and profile steepness, but also have the potential to discriminate between the unknown forms of the transverse density distribution.

Case studies of EUV cyclones and their associated magnetic fields

Xin-Ting **Yu**, Jun Zhang, Ting Li, Shu-Hong Yang
Research in Astronomy and Astrophysics (RAA) Vol 15, No 9 1525-1536 (**2015**)
EUV cyclones are rotating structures in the solar corona, and they are usually rooted in the underlying rotating network magnetic fields in the photosphere. However, their connection with the surrounding magnetic fields remains unknown. Here we report an observational study of four typical cyclones which are rooted in different kinds

of magnetic fields. We use Solar Dynamics Observatory/Atmospheric Imaging Assembly data to investigate the rotation of EUV features in cyclones and Helioseismic and Magnetic Imager data to study the associated magnetic fields. The results show that, (1) an EUV cyclone rooted in a sunspot rotates with the photospheric magnetic field; (2) two EUV cyclones in two faculae of an active region are connected to the same sunspot of the active region but rotate oppositely; (3) an EUV cyclone is rooted in a coronal hole with weak open magnetic fields; (4) a pair of conjugated cyclones is rooted in magnetic fields that have opposite polarity with opposite directions of rotation. The differences in the spatial extent of a cyclone, characteristics of its rotation and underlying fields indicate that cyclones are ubiquitous over the solar atmosphere and that the magnetic structures relevant to the cyclones are more complicated than expected.

Homologous Cyclones in the Quiet Sun

Xinting **Yu**1,2, Jun Zhang1, Ting Li1, Yuzong Zhang1, and Shuhong Yang
2014 ApJ 782 L15
http://iopscience.iop.org/2041-8205/782/2/L15/pdf/apjl_782_2_15.pdf
Through observations with the Solar Dynamics Observatory Atmospheric Imaging Assembly (AIA) and Helioseismic and Magnetic Imager, we tracked one rotating network magnetic field (RNF) near the solar equator. It lasted for more than 100 hr, from **2013 February 23 to 28**. During its evolution, three cyclones were found to be rooted in this structure. Each cyclone event lasted for about 8 to 10 hr. While near the polar region, another RNF was investigated. It lasted for a shorter time (~70 hr), from **2013 July 7 to 9**. There were two cyclones rooted in the RNF and each lasted for 8 and 11 hr, respectively. For the two given examples, the cyclones have a similar dynamic evolution, and thus we put forward a new term: homologous cyclones. The detected brightening in AIA 171 Å maps indicates the release of energy, which is potentially available to heat the corona.

Advanced Γ Method for Small-scale Vortex Detection in the Solar Atmosphere

Yuyang **Yuan**1, Suzana de Souza e Almeida Silva2, Viktor Fedun2, Irina N. Kitiashvili3, and Gary Verth1
2023 ApJS 267 35
https://iopscience.iop.org/article/10.3847/1538-4365/acc835/pdf
Ubiquitous vortical structures are considered to act as a natural source of various solar plasma phenomena, for example, a wide range of magnetohydrodynamic waves and jet excitations. This work aims to develop an advanced vortex detection algorithm based on the Γ method and using a separable convolution kernel technique. This method is applied to detect and analyze the photospheric vortices in 3D realistic magnetoconvection numerical and observational data. We present the advanced Γ method (AGM), and our results indicate that the AGM performs with better accuracy in comparison with the original Γ method. The AGM allows us to identify small- and large-scale vortices with no vortex interposition and without requiring the changing of the threshold. In this way, the nondetection issue is mostly prevented. It was found that the Γ method failed to identify the large and longer-lived vortices, which were detected by the AGM. The size of the detected vortical structures tends to vary over time, with most vortices shrinking toward their end. The vorticity at the center is also not constant, presenting a sharp decay as the vortex ceases to exist. Due to its capability of identifying vortices with minimum nondetection, the vortex properties—such as lifetime, geometry, and dynamics—are better captured by the AGM than by the Γ method. In this era of new high-resolution observation, the AGM can be used as a precise technique for identifying and performing statistical analysis of solar atmospheric vortices.

Multilayered Kelvin–Helmholtz Instability in the Solar Corona

Ding **Yuan**1,2,8, Yuandeng Shen3,8, Yu Liu3, Hongbo Li4, Xueshang Feng1, and Rony Keppens5
2019 ApJL 884 L51
https://doi.org/10.3847/2041-8213/ab4bcd
https://arxiv.org/pdf/1910.05710.pdf
The Kelvin–Helmholtz (KH) instability is commonly found in many astrophysical, laboratory, and space plasmas. It could mix plasma components of different properties and convert dynamic fluid energy from large-scale structure to smaller ones. In this study, we combined the ground-based New Vacuum Solar Telescope (NVST) and the Solar Dynamic Observatories/Atmospheric Imaging Assembly (AIA) to observe the plasma dynamics associated with active region 12673 on **2017 September 9**. In this multitemperature view, we identified three adjacent layers of plasma flowing at different speeds, and detected KH instabilities at their interfaces. We could unambiguously track a typical KH vortex and measure its motion. We found that the speed of this vortex suddenly tripled at a certain stage. This acceleration was synchronized with the enhancements in emission measure and average intensity of the 193 Å data. We interpret this as evidence that KH instability triggers plasma heating. The intriguing feature in this event is that the KH instability observed in the NVST channel was nearly complementary to that in the AIA 193 Å. Such a multithermal energy exchange process is easily overlooked in previous studies, as the cold plasma component is usually not visible in the extreme-ultraviolet channels that are only sensitive to high-temperature plasma emissions.

Our finding indicates that embedded cold layers could interact with hot plasma as invisible matters. We speculate that this process could occur at a variety of length scales and could contribute to plasma heating.

Investigating Sub-Pixel 45-Second Periodic Wobble in SDO/AIA Data from January to August 2012

Ding **Yuan**, Wei Liu, Robert Walsh

Solar Physics October **2018**, 293:147 DOI /10.1007/s11207-018-1368-4

Artifacts could mislead interpretations in astrophysical observations. A thorough understanding of an instrument will help in distinguishing physical processes from artifacts. In this article, we investigate an artifact of the Atmospheric Imaging Assembly (AIA) onboard the Solar Dynamics Observatory. Time-series data and wavelet spectra revealed periodic intensity perturbations in small regions over the entire image in certain AIA extreme ultraviolet (EUV) passbands at a period of about 45 seconds. These artificial intensity variations are prominently detected in regions with sharp intensity contrast, such as sunspot light bridges. This artifact was caused by a periodic pointing wobble of the two AIA telescopes ATA 2 (193 and 211 Å channels) and ATA 3 (171 Å and UV channels), to a lesser extent, while the other two telescopes were not found to be affected. The peak-to-peak amplitude of the wobble was about 0.2 pixel in ATA 2 and 0.1 pixel in ATA 3. This artifact was intermittent and affected the data of seven months from 18 January to 28 August 2012, as a result of a thermal adjustment to the telescopes. We recommend that standard pointing-correction techniques, such as local correlation tracking, should be applied before any detailed scientific analysis that requires sub-pixel pointing accuracy. Specifically, this artificial 45-second periodicity was falsely interpreted as abnormal sub-minute oscillations in a light bridge of a sunspot (Yuan and Walsh in Astron. Astrophys.594, A101, 2016).

Abnormal oscillation modes in a waning light bridge

Ding **Yuan** and Robert W. Walsh

A&A 594, A101 (**2016**)

Context. A sunspot acts as a waveguide in response to the dynamics of the solar interior; the trapped waves and oscillations could reveal its thermal and magnetic structures.
Aims. We study the oscillations in a sunspot intruded by a light bridge, and the details of these oscillations could reveal the fine structure of the magnetic topology.
Methods. We used the Solar Dynamics Observatory/Atmospheric Imaging Assembly data to analyse the oscillations in the emission intensity of light bridge plasma at different temperatures, and we investigated their spatial distributions.
Results. The extreme ultraviolet emission intensity exhibits two persistent oscillations at five-minute and sub-minute ranges. The spatial distribution of the five-minute oscillation follows the spine of the bridge, whereas the sub-minute oscillations overlap with two flanks of the bridge. Moreover, the sub-minute oscillations are highly correlated in spatial domain, however, the oscillations at the eastern and western flanks are asymmetric with regard to the lag time. In the meantime, jet-like activities are only found at the eastern flank.
Conclusions. Asymmetries in the form of oscillatory pattern and jet-like activities are found between two flanks of a granular light bridge. Based on our study and recent findings, we propose a new model of twisted magnetic field for a light bridge and its dynamic interactions with the magnetic field of a sunspot.

Secondary fast magnetoacoustic waves trapped in randomly structured plasmas

Ding **Yuan**, Bo Li, Robert W. Walsh

ApJ **2016**
http://arxiv.org/pdf/1606.06059v1.pdf

Fast magnetoacoustic wave is an important tool for inferring solar atmospheric parameters. We numerically simulate the propagation of fast wave pulses in randomly structured plasmas mimicking the highly inhomogeneous solar corona. A network of secondary waves is formed by a series of partial reflections and transmissions. These secondary waves exhibit quasi-periodicities in both time and space. Since the temporal and spatial periods are related simply through the fast wave speed, we quantify the properties of secondary waves by examining the dependence of the average temporal period ($\bar{p}$) on the initial pulse width (w0) as well as the density contrast ($\delta\rho$) and correlation length (Lc) that characterize the randomness of the equilibrium density profiles. For small-amplitude pulses, $\delta\rho$ does not alter $\bar{p}$ significantly. Large-amplitude pulses, on the other hand, enhance the density contrast when $\delta\rho$ is small but have a smoothing effect when $\delta\rho$ is sufficiently large. We found that $\bar{p}$ scales linearly with Lc and that the scaling factor is larger for a narrower pulse. However, in terms of the absolute values of $\bar{p}$, broader pulses generate secondary waves with longer periods, and this effect is stronger in random plasmas with shorter correlation lengths. Secondary waves carry the signatures of both the leading wave pulse and background plasma, our study may find applications in MHD seismology by exploiting the secondary waves detected in the dimming regions after CMEs or EUV waves.

Stochastic transients as a source of quasi-periodic processes in the solar atmosphere

Ding **Yuan**, Jiangtao Su, Fangran Jiao, Robert W. Walsh

2016 ApJS

http://arxiv.org/pdf/1603.08977v1.pdf

Solar dynamics and turbulence occur at all heights of the solar atmosphere and could be described as stochastic processes. We propose that finite lifetime transients recurring at a certain place could trigger quasi-periodic processes in the associated structures. In this study, we developed a mathematical model for finite lifetime and randomly occurring transients, and found that quasi-periodic processes, with period longer than the time scale of the transients, are detectable intrinsically in form of trains. We simulate their propagation in an empirical solar atmospheric model with chromosphere, transition region and corona. We found that, due to the filtering effect of the chromospheric cavity, only the resonance period of the acoustic resonator is able to propagate to the upper atmosphere, such a scenario is applicable to slow magnetoacoustic waves in sunspots and active regions. If the thermal structure of the atmosphere is less wild and acoustic resonance does not take effect, the long period oscillations could propagate to the upper atmosphere. Such case would be more likely to occur at polar plumes.

Forward Modelling of Standing Kink Modes in Coronal Loops I. Synthetic Views

Ding **Yuan**, Tom Van Doorsselaere

2016

http://arxiv.org/pdf/1603.01632v1.pdf

Kink magnetohydrodynamic (MHD) waves are frequently observed in various magnetic structures of the solar atmosphere. They may contribute significantly to coronal heating and could be used as a tool to diagnose the solar plasma. In this study, we synthesise the \ion{Fe}{9} λ171.073 emission of a coronal loop supporting a standing kink MHD mode. The kink MHD wave solution of a plasma cylinder is mapped into a semi-torus structure to simulate a curved coronal loop. We decompose the solution into a quasi-rigid kink motion and a quadrupole term, which dominate the plasma inside and outside the flux tube, respectively. At the loop edges, the line-of-sight integrates relatively more ambient plasma, and the background emission becomes significant. The plasma motion associated with the quadrupole term causes spectral line broadening and emission suppression. The periodic intensity suppression will modulate the integrated intensity and the effective loop width, which both exhibit oscillatory variations at half of the kink period. The quadrupole term can be directly observed as a pendular motion at front view.

Evolution of fast magnetoacoustic pulses in randomly structured coronal plasmas

D. **Yuan**, D.J. Pascoe, V.M. Nakariakov, B. Li, R. Keppens

2015 *ApJ* **799** 221

http://arxiv.org/pdf/1411.4152v1.pdf

Magnetohydrodynamic waves interact with structured plasmas and reveal the internal magnetic and thermal structures therein, thereby having seismological applications in the solar atmosphere. We investigate the evolution of fast magnetoacoustic pulses in randomly structured plasmas, in the context of large-scale propagating waves in the solar atmosphere. We perform one dimensional numerical simulations of fast wave pulses propagating perpendicular to a constant magnetic field in a low-beta plasma with a random density profile across the field. Both linear and nonlinear regimes are considered. We study how the evolution of the pulse amplitude and width depends on their initial values and the parameters of the random structuring. A randomly structured plasma acts as a dispersive medium for a fast magnetoacoustic pulse, causing amplitude attenuation and broadening of the pulse width. After the passage of the main pulse, secondary propagating and standing fast waves appear in the plasma. Width evolution of both linear and nonlinear pulses can be well approximated by linear functions; however, narrow pulses may have zero or negative broadening. This arises because a narrow pulse is prone to splitting, while a broad pulse usually deviates less from their initial Gaussian shape and form ripple structures on top of the main pulse. A linear pulse decays at almost a constant rate, while a nonlinear pulse decays exponentially. A pulse interacts most efficiently with a random medium which has a correlation length of about half of its initial pulse width. The development of a detailed model of a fast MHD pulse propagating in highly structured medium substantiates the interpretation of EIT waves as fast magnetoacoustic waves. Evolution of a fast pulse provides us with a novel method to diagnose the sub-resolution filamentation of the solar atmosphere.

Multi-height observations of magnetoacoustic cut-off frequency in a sunspot atmosphere

D. **Yuan**1,2, R. Sych2,3, V. E. Reznikova4 and V. M. Nakariakov

A&A 561, A19 (**2014**)
Context. The cut-off frequency of magnetoacoustic gravity (MAG) waves could be decreased by the inclined magnetic field, and therefore, low-frequency waves could penetrate into the upper atmosphere.
Aims. We observe the distribution of the cut-off frequency of compressive waves at various heights and reconstruct the magnetic field inclination, according to the MAG wave theory in a stratified atmosphere permeated by a uniform magnetic field.
Methods. We analysed the emission intensity oscillations of sunspot AR11131 (**08 Dec. 2010**) observed at the 1700 Å, 1600 Å, and 304 Å bandpasses of the Atmospheric Imaging Assembly (AIA) onboard the Solar Dynamics Observatory (SDO), and computed the narrow-band power maps with the pixelised wavelet filtering method. The distribution of the cut-off frequency was defined as the median contour in the azimuthally-averaged oscillation power. The magnetic field inclination was estimated with the local cut-off frequency according to the MAG wave theory in the low-β limit and was compared to the potential field extrapolation.
Results. Shorter period oscillations dominate in the sunspot umbra, while longer period oscillations form an annular shape approximately concentric with the sunspot. Oscillations with longer periods are distributed further away from the sunspot centre. The 5 min oscillations appear to originate at or lower than the photosphere. The magnetic field inclinations determined with the cut-off frequency theory are about 30−40% larger than the values obtained by the potential field extrapolation.
Conclusions. The oscillation power distribution in a sunspot atmosphere reflects its magnetic and thermal structure. The cut-off frequency could be used to probe the magnetic field inclination, however, other factors have to be included to fully understand this phenomenon. The existence of return magnetic flux at the outer penumbra was evidenced by the cut-off frequency distribution.

Leakage of long-period oscillations from the chromosphere to the corona

D. **Yuan**1, V. M. Nakariakov1,2, N. Chorley1 and C. Foullon1
A&A 533, A116 (**2011**)
Long-period oscillations in a coronal diffuse structure are detected with the Transition Region And Coronal Explorer (TRACE). The EUV images of the NOAA active region 8253 are available in 171 Å and 195 Å bandpasses from 30 June to 4 July 1998. The average intensity variation is found to be connected with the CCD temperature, which varies with the orbital motion of the spacecraft. Hence, oscillations with the orbital period and its higher harmonics appear as artifacts in the light curves. After the exclusion of the orbital effects, we identified several long-period oscillations in the diffuse fan-like structure of the active region. Similar periodicities were detected in the radio emission from the chromospheric part of that active region, observed with the ground-based Nobeyama Radioheliograph (NoRH) in the 17 GHz channel. It was found that 0.221, 0.312 and 0.573 mHz oscillations were present in both EUV emission lines in the corona and the radio signal from the sunspot in the chromosphere, just beneath the active region. From the frequency values, the 1st and 3rd detected oscillations could be associated with the $l = 2$, $n = -3$ or $l = 3$, $n = -5$ and $l = 1$ gravity-driven solar interior modes, respectively. The appearance of these oscillations in the coronal part of the active region can be connected with the wave leakage or the evanescence of chromospheric oscillations.

Using Potential Field Extrapolations to Explore the Origin of Type II Spicules

Vasyl **Yurchyshyn**1, Anneliese Schmidt2, Jiasheng Wang2, Xu Yang1, Eun-Kyung Lim3, and Wenda Cao1
2024 ApJ 961 79
https://iopscience.iop.org/article/10.3847/1538-4357/ad0da2/pdf
We used 29 high-resolution line-of-sight magnetograms acquired with the Goode Solar Telescope (GST) in a quiet-Sun area to extrapolate a series of potential field configurations and study their time variations. The study showed that there are regions that consistently exhibit changes in loop connectivity, whereas other vast areas do not show such changes. Analysis of the topological features of the potential fields indicates that the photospheric footprint of the separatrix between open- and closed-loop systems closely matches the roots of rapid blue- and redshifted excursions, which are disk counterparts of type II spicules. There is a tendency for the footpoints of the observed Hα features to be cospatial with the footpoints of the loops that most frequently change their connectivity, while the area occupied by the open fields that did not show any significant and persistent connectivity changes is void of prominent jet and spicular activity. We also detected and tracked magnetic elements using the Southwest Automatic Magnetic Identification Suite and GST magnetograms, which allowed us to construct artificial magnetograms and calculate the corresponding potential field configurations. Analysis of the artificial data showed tendencies similar to those found for the observed data. The present study suggests that a significant amount of chromospheric activity observed in the far wings of the Hα spectral line may be generated by reconnecting closed-loop systems and canopy fields consisting of "open" field lines. **2017 June 19**

Rapid Evolution of Type II Spicules Observed in Goode Solar Telescope On-Disk Hα Images

Vasyl **Yurchyshyn**, 1 Wenda Cao, 1 Valentina Abramenko, 2 Xu Yang, 1 and Kyung-Suk Cho
ApJ **891** L21 **2020**
http://www.bbso.njit.edu/~vayur/spicules2019.pdf
https://doi.org/10.3847/2041-8213/ab7931
https://arxiv.org/pdf/2005.04253.pdf
We analyze ground-based chromospheric data acquired at a high temporal cadence of 2 s in wings of the Hα spectral line using Goode Solar Telescope (GST) operating at the Big Bear Solar Observatory. We inspected a 30 minute long Hα-0.08 nm data set to find that rapid blue-shifted Hα excursions (RBEs), which are a cool component of type II spicules, experience very rapid morphological changes on the time scales of the order of 1 second. Unlike typical reconnection jets, RBEs very frequently appear in situ without any clear evidence of Hα material being injected from below. Their evolution includes inverted "Y", "V", "N", and parallel splitting (doubling) patterns as well as sudden formation of a diffuse region followed by branching. We also find that the same feature may undergo several splitting episodes within about 1 min time interval. **June 7 2019**

Disentangling flows in the solar transition region A110

P. **Zacharias**, V. H. Hansteen, J. Leenaarts, M. Carlsson and B. V. Gudiksen
A&A 614, A110 (**2018**)
Context. The measured average velocities in solar and stellar spectral lines formed at transition region temperatures have been difficult to interpret. The dominant redshifts observed in the lower transition region naturally leads to the question of how the upper layers of the solar (and stellar) atmosphere can be maintained. Likewise, no ready explanation has been made for the average blueshifts often found in upper transition region lines. However, realistic three-dimensional radiation magnetohydrodynamics (3D rMHD) models of the solar atmosphere are able to reproduce the observed dominant line shifts and may thus hold the key to resolve these issues. Aims. These new 3D rMHD simulations aim to shed light on how mass flows between the chromosphere and corona and on how the coronal mass is maintained. These simulations give new insights into the coupling of various atmospheric layers and the origin of Doppler shifts in the solar transition region and corona.
Methods. The passive tracer particles, so-called corks, allow the tracking of parcels of plasma over time and thus the study of changes in plasma temperature and velocity not only locally, but also in a co-moving frame. By following the trajectories of the corks, we can investigate mass and energy flows and understand the composition of the observed velocities.
Results. Our findings show that most of the transition region mass is cooling. The preponderance of transition region redshifts in the model can be explained by the higher percentage of downflowing mass in the lower and middle transition region. The average upflows in the upper transition region can be explained by a combination of both stronger upflows than downflows and a higher percentage of upflowing mass. The most common combination at lower and middle transition region temperatures are corks that are cooling and traveling downward. For these corks, a strong correlation between the pressure gradient along the magnetic field line and the velocity along the magnetic field line has been observed, indicating a formation mechanism that is related to downward propagating pressure disturbances. Corks at upper transition region temperatures are subject to a rather slow and highly variable but continuous heating process.
Conclusions. Corks are shown to be an essential tool in 3D rMHD models in order to study mass and energy flows. We have shown that most transition region plasma is cooling after having been heated slowly to upper transition region temperatures several minutes before. Downward propagating pressure disturbances are identified as one of the main mechanisms responsible for the observed redshifts at transition region temperatures.

On the Verge of a Grand Solar Minimum: A Second Maunder Minimum?

L. **Zachilas**, A. Gkana
Solar Phys. May 2015, Volume 290, Issue 5, pp 1457-1477 **2015**
We analyze the yearly mean sunspot-number data covering the period 1700 to 2012. We show that the yearly sunspot number is a low-dimensional deterministic chaotic system. We perform future predictions trying to forecast the solar activity during the next five years (2013 – 2017). We provide evidence that the yearly sunspot-number data can be used for long-term predictions. To test and prove that our model is able to predict the Maunder Minimum period (1645 – 1715), we perform long-term post-facto predictions comparing them with the observed sunspot-number values. We also perform long-term future predictions trying to forecast the solar activity up to 2102. Our predictions indicate that the present Cycle 24 is expected to be a low-peak cycle. We conclude that the level of solar activity is likely to be reduced significantly during the next 90 years, somewhat resembling theMaunder Minimum period.

On the Role of the Neutral Plasma Component in the Electric Current Dissipation and the Formation of a Transition Region in the Solar Atmosphere.

Zaitsev, V.V., Stepanov, A.V. & Kupriyanova, E.G.

Geomagn. Aeron. 63, 947–952 (**2023**).
https://doi.org/10.1134/S0016793223070319
A mechanism of the formation of a transition region between the chromosphere and the corona, which relies on the dissipation of electric currents in a partially ionized plasma is proposed. It has been demonstrated that the transition region experiences the enhanced level of Joule dissipation due to an increased Cowling resistivity caused by ion-neutral particle collisions. This leads to effective heating of current-carrying open magnetic flux tubes, the type II spicules, which are responsible for the formation of a thin transition layer. An estimation is provided for the width of this transition region, which depends on the power of Joule dissipation, i.e., the magnitude of the electric current.

On the Possibility of Heating the Solar Corona by Heat Fluxes from Coronal Magnetic Structures

V. V. **Zaitsev**, A. V. Stepanov & P. V. Kronshtadtov
Solar Physics volume 295, Article number: 166 (**2020**)
https://link.springer.com/content/pdf/10.1007/s11207-020-01732-x.pdf
We estimate the role of heat flux from hot magnetic loops and open flux tubes into the surrounding corona as a possible source of heating of the corona. We show that hot magnetic-flux tubes (Type-II spicules) provide a more efficient source of coronal heating than hot magnetic loops, as the closed magnetic structure of a loop substantially restricts the heat flux into the corona. In order to compensate for radiation and thermal-conduction losses, approximately 104104 Type-II spicules with a temperature of several million Kelvin are required, which is about 1% of the number of spicules simultaneously observed on the solar disk. Our analysis shows that the principal source of energy that heats the coronal plasma is photospheric convection, which generates electric currents of about 10101010 – 10121012 A in magnetic loops and spicules. Dissipation of the currents increases significantly in the partially ionized plasma, i.e. when ion–atom collisions and the associated Cowling conductivity occur. This results in two important effects: heating of plasma in magnetic structures up to several million Kelvin, and ejection of hot plasma from open magnetic-flux tubes to the corona, replenishing the corona with hot plasma. The ejection of hot plasma results from the heating of the spicule foot-point by electric-current dissipation, which grows with a sporadic increase in the velocity of photospheric convection, for example, due to five-minute oscillations or the Rayleigh–Taylor instability. As a result, the rate of heating the photospheric foot-points of the spicules by ring currents exceeds radiation losses, which leads to a jump in the pressure gradient and the ejection of hot plasma into the corona from the open tips of the magnetic-flux tubes.

Constraining Time Dependent Dark Matter Signals from the Sun

Mohammadreza **Zakeri**, Yu-Feng Zhou
2021
https://arxiv.org/pdf/2109.11662.pdf
Dark matter (DM) particles captured by the Sun can produce high energy electrons outside the Sun through annihilating into meta-stable mediators. The corresponding cosmic-ray electron signals observed by the space-based experiments will be time dependent due to the orbital motion of the space-based detectors. The shape of this time dependence is predictable given the orbital information of the detectors. Since the high-energy CR electron (with energy E>100 GeV) fluxes are expected to be constant in time, non-observation of such time variation can be used to place upper limits on the DM annihilation cross section. We analyze the time dependence of dark matter cosmic-ray signals in three space-based experiments: AMS-02, DAMPE and CALET. Under the assumption that no time dependent signal is observed, we derive the 95% C.L. exclusion limits on the signal strength from the current data. We map our limits onto the parameter space of the dark photon model and find that the constraints are comparable with that derived from the supernova SN1987A.

Contribution of polar plumes to fast solar wind

L. **Zangrilli** and S. M. Giordano
A&A 643, A104 (**2020**)
https://www.aanda.org/articles/aa/pdf/2020/11/aa37653-20.pdf
https://doi.org/10.1051/0004-6361/202037653
Context. Several physical properties of solar polar plumes have been identified by different published studies, however such studies are rare and sometimes in disagreement.
Aims. The purpose of the present work is to analyze a set of SOHO/UVCS data dedicated to the observation of plumes and to obtain a picture of the physical properties of plumes in the intermediate solar corona through a self-consistent analysis.
Methods. We applied the Doppler Dimming technique to data acquired by SOHO/UVCS in **April 1996**, which was during the very early phases of the mission. From this we derived outflow speeds and electron densities. We used SOHO/LASCO images as context data in order to better identify plume and interplume regions in the UVCS field of view.

Results. The results we obtain demonstrate that in three cases out of four plumes expand with outflow speeds comparable to those of interplumes, and in a single case with lower speeds. We estimate that the contribution of plumes to the wind coming from the solar poles is about 20%, and that different plumes provide a different contribution, possibly according to different stages of their evolution.
Conclusions. We conclude that plumes are not static structures, and that they contribute significantly to the wind coming from the solar poles.

Evolution of active region outflows throughout an active region lifetime

L. **Zangrilli**, G. Poletto
A&A 594, A40 **2016**
http://arxiv.org/pdf/1608.07408v1.pdf
We have shown previously that SOHO/UVCS data allow us to detect active region (AR) outflows at coronal altitudes higher than those reached by other instrumentation. These outflows are thought to be a component of the slow solar wind. Our purpose is to study the evolution of the outflows in the intermediate corona from AR 8100, from the time the AR first forms until it dissolves, after several transits at the solar limb. Data acquired by SOHO/UVCS at the time of the AR limb transits, at medium latitudes and at altitudes ranging from 1.5 to 2.3 R_sun, were used to infer the physical properties of the outflows through the AR evolution. To this end, we applied the Doppler dimming technique to UVCS spectra. These spectra include the H I Lyman alpha line and the O VI doublet lines at 1031.9 and 1037.6 A. Plasma speeds and electron densities of the outflows were inferred over several rotations of the Sun. AR outflows are present in the newly born AR and persist throughout the entire AR life. Moreover, we found two types of outflows at different latitudes, both possibly originating in the same negative polarity area of the AR. We also analyzed the behavior of the Si XII 520 A line along the UVCS slit in an attempt to reveal changes in the Si abundance when different regions are traversed. Although we found some evidence for a Si enrichment in the AR outflows, alternative interpretations are also plausible. Our results demonstrate that outflows from ARs are detectable in the intermediate corona throughout the whole AR lifetime. This confirms that outflows contribute to the slow wind.

A SOHO/UVCS study of coronal outflows at the edge of an active region complex

L. **Zangrilli**1 and G. Poletto
A&A 545, A8 (**2012**)
Context. In the past, active regions (ARs) have been suggested as a possible source of the slow solar wind. Their role as solar wind contributors has recently been supported by HINODE observations at low coronal levels.
Aims. Our purpose is to determine whether outflows at the edges of ARs can be detected in higher layers of the corona, supporting the low-corona evidence for the occurrence of wind streams from ARs.
Methods. Data acquired by SOHO/UVCS on January 2, 1998, at altitudes ranging from 1.5 to 2.3 solar radii at mid latitudes, were used to infer the physical properties of an AR complex at the time of its limb passage. To this end, the Doppler dimming technique was applied to UVCS observations of the H i Lyα and O vi doublet lines at 1031.9 and 1037.6 Å.
Results. Outflow speeds (and electron densities) were inferred: outflows, at speeds increasing with height, turn out to be confined within a narrow channel at the edge of closed loop systems within the AR. Our results are compared with those obtained by other authors with different techniques.
Conclusions. Our results support the assumption that ARs are sources of slow wind. To our knowledge these are the first direct measurements of AR flows in the intermediate corona. Tentative profiles of the speed vs. heliocentric altitudes at heliocentric distances between ≈ 1.5 and ≈ 2.3 solar radii show that AR flows are faster than streams from equatorial coronal holes.

Spectral Anisotropy in 2D plus Slab Magnetohydrodynamic Turbulence in the Solar Wind and Upper Corona

G. P. **Zank**1,2, M. Nakanotani1, L.-L. Zhao1, L. Adhikari1, and D. Telloni3
2020 ApJ 900 115
https://doi.org/10.3847/1538-4357/abad30
The 2D + slab superposition model of solar wind turbulence has its theoretical foundations in nearly incompressible magnetohydrodynamics (NI MHD) in the plasma beta ~1 or $\ll 1$ regimes. Solar wind turbulence measurements show that turbulence in the inertial range is anisotropic, for which the superposition model offers a plausible explanation. We provide a detailed theoretical analysis of the spectral characteristics of the Elsässer variables in the 2D + NI/slab model. We find that (1) the majority 2D component has a power spectrum $G^{\infty}(k_{\perp}) \sim k_{\perp}^{-5/3}$ in perpendicular wavenumber k⊥; (2) the strongly imbalanced minority NI/slab turbulence has power spectra $G^{*}(k_{\perp}) \sim k_{\perp}^{-5/3}$ and $G^{*}(k_{z}) \sim k_{z}^{-5/3}$, where kz is aligned with the mean magnetic field; (3) NI/slab turbulence can exhibit a double-power-law spectrum, with the steeper part being G*(k) ~ k−5/3 and corresponding

to strong turbulence and the flatter spectrum satisfying G*(k) ~ k−3/2 and corresponding to weak turbulence; (4) there is a critical balance regime for NI/slab turbulence that satisfies $G^*(k_z) \sim k_z^{-2}$ and $G^*(k_\perp) \sim k_\perp^{-5/3}$; and (5) the forward and backward Elsässer power spectra can have different spectral forms provided that the triple-correlation times for each are different. We use the spectral analysis to compute the total power spectra in frequency parallel to the solar wind flow for the superposition model, showing that strongly imbalanced turbulence yields an f−5/3 spectrum for all angles between the mean flow and magnetic field, and that double power laws are possible when the nonlinear and Alfvén timescales are both finite.

Theory and Transport of Nearly Incompressible Magnetohydrodynamic Turbulence. IV. Solar Coronal Turbulence

G. P. **Zank**, L. Adhikari, P. Hunana, S. K. Tiwari, R. Moore, D. Shiota, R. Bruno, and D. Telloni
2018 ApJ 854 32

A new model describing the transport and evolution of turbulence in the quiet solar corona is presented. In the low plasma beta environment, transverse photospheric convective fluid motions drive predominantly quasi-2D (nonpropagating) turbulence in the mixed-polarity "magnetic carpet," together with a minority slab (Alfvénic) component. We use a simplified sub-Alfvénic flow velocity profile to solve transport equations describing the evolution and dissipation of turbulence from 1 to $15\,R_\odot$ (including the Alfvén surface). Typical coronal base parameters are used, although one model uses correlation lengths derived observationally by Abramenko et al., and the other assumes values 10 times larger. The model predicts that (1) the majority quasi-2D turbulence evolves from a balanced state at the coronal base to an imbalanced state, with outward fluctuations dominating, at and beyond the Alfvén surface, i.e., inward turbulent fluctuations are dissipated preferentially; (2) the initially imbalanced slab component remains imbalanced throughout the solar corona, being dominated by outwardly propagating Alfvén waves, and wave reflection is weak; (3) quasi-2D turbulence becomes increasingly magnetized, and beyond $\sim 6\,R_\odot$, the kinetic energy is mainly in slab fluctuations; (4) there is no accumulation of inward energy at the Alfvén surface; (5) inertial range quasi-2D rather than slab fluctuations are preferentially dissipated within $\sim 3\,R_\odot$; and (6) turbulent dissipation of quasi-2D fluctuations is sufficient to heat the corona to temperatures $\sim 2 \times 10^6$ K within $2\,R_\odot$, consistent with observations that suggest that the fast solar wind is accelerated most efficiently between ~ 2 and $4\,R_\odot$.

Kink instability of triangular jets in the solar atmosphere

T. V. **Zaqarashvili**, S. Lomineishvili, P. Leitner, A. Hanslmeier, P. Gömöry, M. Roth
A&A **2021**
https://arxiv.org/pdf/2102.09952.pdf

It is known that hydrodynamic triangular jets are unstable to antisymmetric kink perturbations. The inclusion of magnetic field may lead to the stabilisation of the jets. Jets and complex magnetic fields are ubiquitous in the solar atmosphere, which suggests the possibility of the kink instability in certain cases. The aim of the paper is to study the kink instability of triangular jets sandwiched between magnetic tubes/slabs and its possible connection to observed properties of the jets in the solar atmosphere. A dispersion equation governing the kink perturbations is obtained through matching of analytical solutions at the jet boundaries. The equation is solved analytically and numerically for different parameters of jets and surrounding plasma. The analytical solution is accompanied by a numerical simulation of fully nonlinear MHD equations for a particular situation of solar type II spicules. MHD triangular jets are unstable to the dynamic kink instability depending on the Alfven Mach number (the ratio of flow to Alfven speeds) and the ratio of internal and external densities. When the jet has the same density as the surrounding plasma, then only super Alfvenic flows are unstable. However, denser jets are unstable also in sub Alfvenic regime. Jets with an angle to the ambient magnetic field have much lower thresholds of instability than field-aligned flows. Growth times of the kink instability are estimated as 6-15 min for type I spicules and 5-60 s for type II spicules matching with their observed life times. Numerical simulation of full nonlinear equations shows that the transverse kink pulse locally destroys the jet in less than a minute in the conditions of type II spicules. Dynamic kink instability may lead to full breakdown of MHD flows and consequently to observed disappearance of spicules in the solar atmosphere.

Dynamic kink instability and transverse motions of solar spicules

T. V. **Zaqarashvili**
ApJL **893** L46 **2020**
https://arxiv.org/pdf/2004.04401.pdf
https://doi.org/10.3847/2041-8213/ab881d

Hydrodynamic jets are unstable to the kink instability (m=1 mode in cylindrical geometry) owing to the centripetal force, which increases the transverse displacement of the jet. When the jet moves along a magnetic field, then the Lorentz force tries to decrease the displacement and stabilises the instability of sub-Alfvenic flows. The threshold of the instability depends on the Alfven Mach number (the ratio of Alfven and jet speeds). We suggest that the dynamic kink instability may be of importance to explain observed transverse motions of type II spicules in the solar

atmosphere. We show that the instability may start for spicules which rise up at the peripheries of vertically expanding magnetic flux tubes owing to the decrease of the Alfven speed in both, the vertical and the radial directions. Therefore, inclined spicules may be more unstable and have more higher transverse speeds. Periods and growth times of unstable modes in the conditions of type II spicules have the values of 30 s and 25-100 s, respectively, which are comparable to the life time of the structures. This may indicate to the interconnection between high speed flow and rapid disappearance of type II spicules in chromospheric spectral lines.

Magneto-Rossby Waves and Seismology of Solar Interior

Teimuraz V. **Zaqarashvili** and Eka Gurgenashvili
Front. Astron. Space Sci. **2018**
https://doi.org/10.3389/fspas.2018.00007
https://doi.org/10.3389/fspas.2018.00007
Eleven-year Schwabe cycle in solar activity is not yet fully understood despite of its almost two century discovery. It is generally interpreted as owing to some sort of magnetic dynamo operating below or inside the convection zone. The magnetic field strength in the dynamo layer may determine the importance of the tachocline in the model which is responsible for the cyclic magnetic field, but the direct measurement is not possible. On the other hand, solar activity also displays short term variations over time scale of months (Rieger-type periodicity), which significantly depend on solar activity level: stronger cycles (or more active hemisphere in each cycle) generally show shorter periodicity and vice versa. The periodicity is probably connected to Rossby-type waves in the dynamo layer, therefore alongside with wave dispersion relations it might be used to estimate the dynamo magnetic field strength. We performed the wavelet analysis of hemispheric sunspot areas during solar cycles 13–24 and corresponding hemispheric values of Rieger-type periodicity are found in each cycle. Two different Rossby-type waves could lead to observed periodicities: spherical fast magneto-Rossby waves and equatorial Poincare-Rossby waves. The dispersion relation of spherical fast magneto-Rossby waves gives the estimated field strength of >40 kG in stronger cycles (or in more active hemisphere) and <40 kG in weaker cycles (or in less active hemisphere). The equatorial Poincare-Rossby waves lead to >20 kG and <15 kG, respectively. Future perspectives of Rieger-type periodicities and Rossby-type waves in testing various dynamo models are discussed.

Long-term variation in the Sun's activity caused by magnetic Rossby waves in the tachocline

T. V. **Zaqarashvili**, R. Oliver, A. Hanslmeier, M. Carbonell, J. L. Ballester, T. Gachechiladze, I. G. Usoskin
ApJL **805** L14 **2015**
http://arxiv.org/pdf/1505.02652v1.pdf
Long-term records of sunspot number and concentrations of cosmogenic radionuclides (10Be and 14C) on the Earth reveal the variation of the Sun's magnetic activity over hundreds and thousands of years. We identify several clear periods in sunspot, 10Be, and 14C data as 1000, 500, 350, 200 and 100 years. We found that the periods of the first five spherical harmonics of the slow magnetic Rossby mode in the presence of a steady toroidal magnetic field of 1200-1300 G in the lower tachocline are in perfect agreement with the time scales of observed variations. The steady toroidal magnetic field can be generated in the lower tachocline either due to the steady dynamo magnetic field for low magnetic diffusivity or due to the action of the latitudinal differential rotation on the weak poloidal primordial magnetic field, which penetrates from the radiative interior. The slow magnetic Rossby waves lead to variations of the steady toroidal magnetic field in the lower tachocline, which modulate the dynamo magnetic field and consequently the solar cycle strength. This result constitutes a key point for long-term prediction of the cycle strength. According to our model, the next deep minimum in solar activity is expected during the first half of this century.

Mixed Properties of Slow Magnetoacoustic and Entropy Waves in a Plasma with Heating/Cooling Misbalance

D. **Zavershinskii**, D. Kolotkov, D. Riashchikov & N. Molevich
Solar Physics volume 296, Article number: 96 (**2021**)
https://link.springer.com/content/pdf/10.1007/s11207-021-01841-1.pdf
The processes of coronal plasma heating and cooling were previously shown to significantly affect the dynamics of slow magnetoacoustic (MA) waves, causing amplification or attenuation, and also dispersion. However, the entropy mode is also excited in such a thermodynamically active plasma and is affected by the heating/cooling misbalance too. This mode is usually associated with the phenomenon of coronal rain and formation of prominences. Unlike adiabatic plasmas, the properties and evolution of slow MA and entropy waves in continuously heated and cooling plasmas get mixed. Different regimes of the misbalance lead to a variety of scenarios for the initial perturbation to evolve. In order to describe properties and evolution of slow MA and entropy waves in various regimes of the misbalance, we obtained an exact analytical solution of the linear evolutionary equation. Using the characteristic

timescales and the obtained exact solution, we identified regimes with qualitatively different behaviour of slow MA and entropy modes. For some of those regimes, the spatio-temporal evolution of the initial Gaussian pulse is shown. In particular, it is shown that slow MA modes may have a range of non-propagating harmonics. In this regime, perturbations caused by slow MA and entropy modes in a low-ββ plasma would look identical in observations, as non-propagating disturbances of the plasma density (and temperature) either growing or decaying with time. We also showed that the partition of the initial energy between slow MA and entropy modes depends on the properties of the heating and cooling processes involved. The exact analytical solution obtained could be further applied to the interpretation of observations and results of numerical modelling of slow MA waves in the corona and the formation and evolution of coronal rain.

Formation of quasi-periodic slow magnetoacoustic wave trains by the heating/cooling misbalance

D. I. **Zavershinskii**, D. Y. Kolotkov, V. M. Nakariakov, N. E. Molevich, D. S. Ryashchikov
Physics of Plasmas **2019**
https://arxiv.org/pdf/1907.08168.pdf
https://warwick.ac.uk/fac/sci/physics/research/cfsa/people/kolotkov/eprints/disp_pop_r1.pdf
Slow magnetoacoustic waves are omnipresent in both natural and laboratory plasma systems. The wave-induced misbalance between plasma cooling and heating processes causes the amplification or attenuation, and also dispersion, of slow magnetoacoustic waves. The wave dispersion could be attributed to the presence of characteristic time scales in the system, connected with the plasma heating or cooling due to the competition of the heating and cooling processes in the vicinity of the thermal equilibrium. We analysed linear slow magnetoacoustic waves in a plasma in a thermal equilibrium formed by a balance of optically thin radiative losses, field-align thermal conduction, and an unspecified heating. The dispersion is manifested by the dependence of the effective adiabatic index of the wave on the wave frequency, making the phase and group speeds frequency-dependent. The mutual effect of the wave amplification and dispersion is shown to result into the occurrence of an oscillatory pattern in an initially broadband slow wave, with the characteristic period determined by the thermal misbalance time scales, i.e. by the derivatives of the combined radiation loss and heating function with respect to the density and temperature, evaluated at the equilibrium. This effect is illustrated by estimating the characteristic period of the oscillatory pattern, appearing because of thermal misbalance in the plasma of the solar corona. It is found that by an order of magnitude the period is about the typical periods of slow magnetoacoustic oscillations detected in the corona.

Evidence for Energy Supply by Active Region Spicules to the Solar Atmosphere

S. **Zeighami**, A. R. Ahangarzadeh Maralani, E. Tavabi, A. Ajabshirizadeh
Solar Phys. Volume 291, Issue 3, pp 847-858 **2016**
http://arxiv.org/pdf/1602.03157v1.pdf
We investigate the role of active region spicules in the mass balance of the solar wind and energy supply for heating the solar atmosphere. We use high cadence observations from the Solar Optical Telescope (SOT) onboard the Hinode satellite in the Ca II H line filter obtained on **26 January 2007**. The observational technique provides the high spatio-temporal resolution required to detect fine structures such as spicules. We apply Fourier power spectrum and wavelet analysis to SOT/Hinode time series of an active region data to explore the existence of coherent intensity oscillations. The presence of coherent waves could be an evidence for energy transport to heat the solar atmosphere. Using time series, we measure the phase difference between two intensity profiles obtained at two different heights, which gives information about the phase difference between oscillations at those heights as a function of frequency. The results of a fast Fourier transform (FFT) show peaks in the power spectrum at frequencies in the range from 2 to 8 mHz at four different heights (above the limb), while the wavelet analysis indicate dominant frequencies similar to those of the Fourier power spectrum results. A coherency study indicates the presence of coherent oscillations at about 5.5 mHz (3 min). We measure mean phase speeds in the range 250 TO 425km/s increasing with height.

Update on Galactic Cosmic Ray Integral Flux Measurements in Lunar Orbit With CRaTER

C. **Zeitlin**,, N. A. Schwadron, H. E. Spence, A. P. Jordan, M. D. Looper, J. Wilson, J. E. Mazur, L. W. Townsend
Space Weather **2019**
sci-hub.se/10.1029/2019SW002223
We report updated measurements of the integral fluxes of energetic protons, helium ions, and heavier ions as measured by the Cosmic Ray Telescope for the Effects of Radiation (CRaTER). CRaTER is a particle telescope that has been operating aboard the Lunar Reconnaissance Orbiter since 2009. In an earlier report, we presented the methodology used to extract linear energy transfer spectra and integral fluxes for particles with sufficient energies to fully penetrate the telescope. Results were presented for the time span from late 2009 to the end of calendar year

2014, a period that encompassed the rise of solar activity from deep solar minimum to the weak maximum of Cycle 24. Here, we update the results with data obtained from that point in time through the end of 2018, in the declining phase of Cycle 24. Fluxes obtained in the most recent data are approaching the peak levels observed in late 2009 and early 2010. The results can be used as input to models of solar modulation of galactic cosmic rays and are also relevant to human exploration of deep space.

Segmentation of photospheric magnetic elements corresponding to coronal features to understand the EUV and UV irradiance variability⋆

J. J. **Zender**1, R. Kariyappa2, G. Giono3, M. Bergmann4, V. Delouille5, L. Damé6, J.-F. Hochedez6,5 and S. T. Kumara

A&A 605, A41 (**2017**)

Context. The magnetic field plays a dominant role in the solar irradiance variability. Determining the contribution of various magnetic features to this variability is important in the context of heliospheric studies and Sun-Earth connection.

Aims. We studied the solar irradiance variability and its association with the underlying magnetic field for a period of five years (January 2011–January 2016). We used observations from the Large Yield Radiometer (LYRA), the Sun Watcher with Active Pixel System detector and Image Processing (SWAP) on board PROBA2, the Atmospheric Imaging Assembly (AIA), and the Helioseismic and Magnetic Imager (HMI) on board the Solar Dynamics Observatory (SDO).

Methods. The Spatial Possibilistic Clustering Algorithm (SPoCA) is applied to the extreme ultraviolet (EUV) observations obtained from the AIA to segregate coronal features by creating segmentation maps of active regions (ARs), coronal holes (CHs) and the quiet sun (QS). Further, these maps are applied to the full-disk SWAP intensity images and the full-disk (FD) HMI line-of-sight (LOS) magnetograms to isolate the SWAP coronal features and photospheric magnetic counterparts, respectively. We then computed full-disk and feature-wise averages of EUV intensity and line of sight (LOS) magnetic flux density over ARs/CHs/QS/FD. The variability in these quantities is compared with that of LYRA irradiance values.

Results. Variations in the quantities resulting from the segmentation, namely the integrated intensity and the total magnetic flux density of ARs/CHs/QS/FD regions, are compared with the LYRA irradiance variations. We find that the EUV intensity over ARs/CHs/QS/FD is well correlated with the underlying magnetic field. In addition, variations in the full-disk integrated intensity and magnetic flux density values are correlated with the LYRA irradiance variations.

Conclusions. Using the segmented coronal features observed in the EUV wavelengths as proxies to isolate the underlying magnetic structures is demonstrated in this study. Sophisticated feature identification and segmentation tools are important in providing more insights into the role of various magnetic features in both the short- and long-term changes in the solar irradiance.

Solar disk center shows scattering polarization in the Sr~{\sc i} 4607~Å~line

Franziska **Zeuner**, Rafael Manso Sainz, Alex Feller, Michiel van Noort, Sami K. Solanki, Francisco A. Iglesias, Kevin Reardon, Valentín Martínez Pillet

ApJ **2020**

https://arxiv.org/pdf/2004.03679.pdf

Magnetic fields in turbulent, convective high-β plasma naturally develop highly tangled and complex topologies---the solar photosphere being the paradigmatic example. These fields are mostly undetectable by standard diagnostic techniques with finite spatio-temporal resolution due to cancellations of Zeeman polarization signals. Observations of resonance scattering polarization have been considered to overcome these problems. But up to now, observations of scattering polarization lack the necessary combination of high sensitivity and high spatial resolution in order to directly infer the turbulent magnetic structure at the resolution limit of solar telescopes. Here, we report the detection of clear spatial structuring of scattering polarization in a magnetically quiet solar region at disk center in the Sr~{\sc i} 4607~Å spectral line on granular scales, confirming theoretical expectations. We find that the linear polarization presents a strong spatial correlation with the local quadrupole of the radiation field. The result indicates that polarization survives the dynamic and turbulent magnetic environment of the middle photosphere and is thereby usable for spatially-resolved Hanle observations. This is an important step towards the long-sought goal of directly observing turbulent solar magnetic fields at the resolution limit and investigating their spatial structure.

Detection of spatially structured scattering polarization of Sr I 4607.3 Åwith the Fast Solar Polarimeter

Franziska **Zeuner**, Alex Feller, Francisco A. Iglesias, Sami K. Solanki

A&A 619, A179 **2018**

https://arxiv.org/pdf/1808.06539.pdf

Scattering polarization in the Sr I 4607.3 \AA line observed with high resolution is an important diagnostic of the Sun's atmosphere and magnetism at small spatial scales. At present, spatially resolved observations of this

diagnostic are rare and have not been reported as close to the disk center as for μ=0.6. Our aim is to measure the scattering polarization in the Sr I line at μ=0.6 and to identify the spatial fluctuations with a statistical approach. Using the Fast Solar Polarimeter (FSP) mounted on the TESOS filtergraph at the German Vacuum Tower Telescope (VTT) in Tenerife, Spain, we measured both the spatially resolved full Stokes parameters of the Sr I line at μ=0.6 and the center-to-limb variation of the spatially averaged Stokes parameters.
We find that the center-to-limb variation of the scattering polarization in the Sr I line measured with FSP is consistent with previous measurements. A statistical analysis of Stokes Q/I (i.e., the linear polarization component parallel to the solar limb), sampled with 0.16" pixel−1 in the line core of Sr I reveals that the signal strength is inversely correlated with the intensity in the continuum. We find stronger linear polarimetric signals corresponding to dark areas (intergranular lanes) in the Stokes I continuum image. In contrast, independent measurements at μ=0.3 show a positive correlation of Q/I with respect to the continuum intensity. We estimate that the patch diameter responsible for the excess Q/I signal is on the order of 0.5"-1". The presented observations and the statistical analysis of Q/I signals at μ=0.6 complement reported scattering polarization observations as well as simulations. **6 May 2015**

Observations of Magnetic Helicity Proxies in Solar Photosphere: Helicity with Solar Cycles

Review

Hongqi **Zhang**, Shangbin Yang, Haiqing Xu, Xiao Yang, Jie Chen, Jihong Liu
2023
https://arxiv.org/pdf/2311.07131.pdf
Observations of magnetic helicity transportation through the solar photosphere reflect the interaction of turbulent plasma movements and magnetic fields in the solar dynamo process. In this chapter, we have reviewed the research process of magnetic helicity inferred from the observed solar magnetic fields in the photosphere and also the solar morphological configurations with solar cycles. After introducing some achievements in the study of magnetic helicity, some key points would like to be summarized.
The magnetic (current) helicity in the solar surface layer presents a statistical distribution similar to that of the sunspot butterfly diagram, but its maximum value is delayed from the extreme value of the sunspot butterfly diagram and corresponds in the phase with the statistical eruption of solar flares. During the spatial transport of magnetic (current) helicity from the interior of the sun into the interplanetary space at the time-space scale of the solar cycle, it shows the statistical distribution and the fluctuation with the hemispheric sign rule. These show that the current helicity and magnetic helicity transport calculation methods are complementary to each other.
We also notice that the study of the inherent relationship between magnetic helicity and the solar cycle still depends on the observed accuracy of the solar magnetic field.

The force-freeness of the solar photosphere: Revisit with new approach and large datasets

Mei **Zhang**, Haocheng Zhang
ApJ Letters **956** L17 **2023**
https://arxiv.org/pdf/2309.15407.pdf
https://iopscience.iop.org/article/10.3847/2041-8213/acfcbd/pdf
Although it is generally believed that the solar photosphere is not magnetically force-free owning to its high plasma β, the estimations of force-freeness using observed magnetograms have produced disputable results. Some studies confirmed that the photosphere is largely not force-free whereas some authors argued that the photosphere is not far away from being force-free. In a previous paper of ours we demonstrated that, due to the fact that the noise levels of the transverse field in the magnetograms are much larger than those of the vertical field, wrong judgements on the force-freeness could be made: a truly force-free field could be judged as being not-force-free and a truly not-force-free field could be judged as being force-free. Here in this letter we propose an approach to overcome this serious problem. By reducing the spatial resolution to lower the noise level, the heavy influence of the measurement noise on the force-freeness judgement can be significantly suppressed. We first use two analytical solutions to show the success and the effectiveness of this approach. Then we apply this new approach to two large datasets of active region magnetograms, obtained with the HMI/SDO and SP/Hinode, respectively. Our analysis shows that the photospheric magnetic fields are actually far away from being force-free. Particularly and most notably, the mean value of Fz/Fp (where Fz the net Lorentz force in the vertical direction and Fp the total Lorentz force) is as low as -0.47, with more than 98% of the active regions having |Fz/Fp|>0.1, when using the SP/Hinode magnetograms of true field strength.

Temporal Variation of the Rotation in the Solar Transition Region

Xiaojuan **Zhang**1,2, Linhua Deng1,2, Yu Fei3, Chun Li3, and Xinan Tian4
2023 ApJL 951 L3
https://iopscience.iop.org/article/10.3847/2041-8213/acd9a3/pdf
The temporal variations of solar rotation in the photosphere, chromosphere, and corona have been widely investigated, whereas the rotation of the solar transition region is rarely studied. Here, we perform a primary study

about the long-term variation of the rotation in the transition region using Lyα irradiance from 1947 February 14 to 2023 February 20. Correlation techniques are used, and the main results are as follows. (1) The sidereal rotation period of the solar transition region varies between 22.24 and 31.49 days, and the mean sidereal rotation period is 25.50 days for the studied time interval 1947–2022. (2) The rotation period of the transition region exhibits a clear downward trend during 1947–2022, which might be caused by the reduced heliospheric pressure and the weaker solar global magnetic fields. (3) Significant periodic signal of the quasi-Schwabe cycle is found in the rotation periods of the transition region. (4) The cross-correlation between the rotation periods of the solar transition region and sunspot activity corroborates a strong correlation with the Schwabe cycle. Possible mechanisms responsible for these results are discussed.

A Potential New Mechanism for the Butterfly Diagram of the Solar Cycle: Latitude-dependent Radial Flux Transport

Zebin **Zhang**, Jie Jiang, Haowei Zhang
ApJL **941** L3 **2022**
https://arxiv.org/pdf/2212.00948
https://iopscience.iop.org/article/10.3847/2041-8213/aca47a/pdf
The butterfly diagram of the solar cycle is the equatorward migration of the emergence latitudes of sunspots as the solar cycle evolves. Revealing the mechanism for the butterfly diagram is essential for understanding the solar and stellar dynamo. The equatorward meridional flow at the base of the convection zone (CZ) was believed to be responsible for the butterfly diagram. However, helioseismological studies indicate controversial forms of the flow, and even present poleward flow at the base of the CZ, which poses a big challenge to the widely accepted mechanism. This motivates us to propose a new mechanism in this study. Using a data-driven Babcock-Leighton-type dynamo model, we carry out numerical simulations to explore how the latitude-dependent radial flux transport affects the latitudinal migration of the toroidal field, under different meridional flow profiles. The results indicate that when the radial transport of the poloidal field at higher latitudes is sufficiently faster, the toroidal fields of a new cycle at higher latitudes are generated earlier than that at lower latitudes, and vice versa. Thus, the butterfly diagram is suggested to correspond to the time- and latitude-dependent regeneration of the toroidal field due to the latitude-dependent radial transport of the poloidal flux.

Propagating and Stationary Bright Knots in the Quiet Sun

Jun **Zhang**1, Yijun Hou2, Yue Fang1, Feng Chen3, Ting Li2 +++
2023 ApJL 942 L2
https://iopscience.iop.org/article/10.3847/2041-8213/aca97b/pdf
The question of what heats the solar chromosphere and corona remains one of the most important puzzles in solar physics and astrophysics. Up to now, two mechanisms are considered to work in heating the chromosphere and corona: magnetic reconnection and wave (turbulent flow) dissipation. But it is still not understood which mechanism is dominant. To solve the heating problem, one important topic at this stage is that we should understand how much energy is contributing from the two mechanisms respectively to the heating. In the quiet Sun, the thermal energy signal is observed as brightenings. Here we report two kinds of bright knots with a total of 3605 in the chromosphere of the quiet Sun, using the data from the New Vacuum Solar Telescope at Yunnan Observatories. The first kind of 1537 bright knots, which is first detected in chromospheric fibrils where waves and their dissipation are ubiquitous, propagates along these fibrils with velocities from 5 to 69 km s−1. The second kind of 2068 knots keeps stationary, and always appears at the footpoints of these fibrils where network magnetic fields exist, suggesting that magnetic reconnection locally produces these stationary knots. Based on the observations of thousands of bright knots, we display the different distribution patterns of the two kinds of bright knots in the quiet Sun, and deduce that half of the energy for heating the chromosphere is supplied by wave dissipation, and the other half by magnetic reconnection. **4 Sep 2019**

Hemispheric asymmetry of long-term sunspot activity: sunspot relative numbers for 1939–2019

X J **Zhang**, L H Deng, Y Fei, C Li, X A Tian, Z J Wan
Monthly Notices of the Royal Astronomical Society, Volume 514, Issue 1, July **2022**, Pages 1140–1147, https://doi.org/10.1093/mnras/stac1231
Hemispheric asymmetry of solar magnetic structures is an important feature of solar cycles, and it involves dynamical processes in the interior of the Sun. For the first time, the data of the monthly sunspot relative numbers derived from the National Astronomical Observatory of Japan (NAOJ) is used to perform a long-term study (1939 March–2019 November) of the north–south asymmetry. The results show the following: (1) the sunspot relative numbers derived from NAOJ/Mitaka observatory are highly correlated with the international sunspot numbers obtained from the World Data Center Sunspot Index and Long-term Solar Observations, which justifies the use of Mitaka sunspot time series for hemispheric variation; (2) the change in the signs of the slopes of the regression lines fitted to the absolute asymmetry index suggest a kind of periodic variation in the hemispheric asymmetry, but the

time interval of the current data base is not long enough to derive 8 or 12 cycles periodicity; and (3) for mid-term periods, there are enhanced powers for the period ranges around 3.7 yr, around 9 yr, between 30 and 50 yr. Our analysis results implicate a possible mechanism responsible for the generation and variation of the hemispheric coupling in the Sun.

A Babcock–Leighton-type Solar Dynamo Operating in the Bulk of the Convection Zone

Zebin **Zhang**1 and Jie Jiang1,2
2022 ApJ 930 30
https://iopscience.iop.org/article/10.3847/1538-4357/ac6177/pdf
The toroidal magnetic field is assumed to be generated in the tachocline in most Babcock–Leighton (BL)-type solar dynamo models, in which the poloidal field is produced by the emergence and subsequent dispersal of sunspot groups. However, magnetic activity of fully convective stars and MHD simulations of global stellar convection have recently raised serious doubts regarding the importance of the tachocline in the generation of the toroidal field. In this study, we aim to develop a new BL-type dynamo model, in which the dynamo operates mainly within the bulk of the convection zone. Our 2D model includes the effect of solar-like differential rotation, one-cell meridional flow, near-surface radial pumping, strong turbulent diffusion, BL-type poloidal source, and nonlinear back-reaction of the magnetic field on its source with a vertical outer boundary condition. The model leads to a simple dipolar configuration of the poloidal field that has the dominant latitudinal component, which is wound up by the latitudinal shear within the bulk of the convection zone to generate the toroidal flux. As a result, the tachocline plays a negligible role in the model. The model reproduces the basic properties of the solar cycle, including (a) approximately 11 yr cycle period and 18 yr extended cycle period; (b) equatorward propagation of the antisymmetric toroidal field starting from high latitudes; and (c) polar field evolution that is consistent with observations. Our model opens the possibility for a paradigm shift in understanding the solar cycle to transition from the classical flux transport dynamo.

Diagnostic of Spectral Lines in Magnetized Solar Atmosphere: Formation of the H\b{eta} Line in Sunspots

Hongqi **Zhang**
SCIENCE CHINA, Physics, Mechanics & Astronomy, November **2020** Vol. 63 No. 11: 119611
https://arxiv.org/pdf/2009.03573.pdf
Formation of the Hβ λ4861.34 Å line is an important topic related to the diagnosis of the basic configuration of magnetic fields in the solar and stellar chromospheres. Specifically, broadening of the Hβ λ4861.34 Å line occurs due to the magnetic and micro-electric fields in the solar atmosphere. The formation of Hβ in the model umbral atmosphere is presented based on the assumption of non-local thermodynamic equilibrium. It is found that the model umbral chromosphere is transparent to the Stokes parameters of the Hβ line, which implies that the observed signals of magnetic fields at sunspot umbrae via the Hβ line originate from the deep solar atmosphere, where $\lg\tau_c \approx -1$ (about 300 km in the photospheric layer for our calculations). This is in contrast to the observed Stokes signals from non-sunspot areas, which are thought to primarily form in the solar chromosphere.

Solar models with convective overshoot, the solar-wind mass loss, and a PMS disk accretion: helioseismic quantities, Li depletion and neutrino fluxes

Qian-Sheng **Zhang**, Yan Li, Jørgen Christensen-Dalsgaard
ApJ 881:103 **2019**
https://arxiv.org/pdf/1907.02166.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ab2f77/pdf
Helioseismic observations have revealed many properties of the Sun: the depth and the helium abundance of the convection zone, the sound-speed and the density profiles in the solar interior. Those constraints have been used to judge the stellar evolution theory. With the old solar composition (e.g., GS98), the solar standard model is in reasonable agreement with the helioseismic constraints. However, a solar model with revised composition (e.g., AGSS09) with low abundance Z of heavy elements cannot be consistent with those constraints. This is the so-called "solar abundance problem", standing for more than ten years even with the recent upward revised Ne abundance. Many mechanisms have been proposed to mitigate the problem. However, there is still not a low-Z solar model satisfying all helioseismic constraints. In this paper, we report a possible solution to the solar abundance problem. With some extra physical processes that are not included in the standard model, solar models can be significantly improved. Our new solar models with convective overshoot, the solar wind, and an early mass accretion show consistency with helioseismic constraints, the solar Li abundance, and observations of solar neutrino fluxes.

Particle Heating and Energy Partition in Low-β Guide Field Reconnection with Kinetic Riemann Simulations

Qile **Zhang**, J. F. Drake, M. Swisdak
2019

https://arxiv.org/pdf/1904.12922.pdf
Kinetic Riemann simulations have been completed to explore particle heating during guide field reconnection in the low-β environment of the inner heliosphere and the solar corona. The reconnection exhaust is bounded by two rotational discontinuities (RD) and two slow shocks (SS) form within the exhaust as in magnetohydrodynamic (MHD) models. At the RDs, ions are accelerated by the magnetic field tension to drive the reconnection outflow as well as flows in the out-of-plane direction. The out-of-plane flows stream toward the midplane and meet to drive the SSs. The SSs differ greatly from those in the MHD model. The turbulence at the shock fronts and both upstream and downstream is weak so the shocks are laminar and produce little dissipation. Downstream of the SSs the counterstreaming ion beams lead to higher density, which leads to a positive potential between the SSs that acts to confine the downstream electrons to maintain charge neutrality. The potential accelerates electrons from upstream of the SSs to downstream region and traps a small fraction but only modestly increases the downstream electron temperature above the upstream value. In the low-β limit the released magnetic energy is split between bulk flow and ion heating with little energy going to electrons. That the model does not produce strong electron heating nor an energetic electron component as seen in large flares suggests the multiple x-line reconnection scenario is required to explain energetic particle production in flares. The model can be tested with the expected data from the Parker Solar Probe.

Intelligent Recognition of Time Stamp Characters in Solar Scanned Images from Film

JiaFeng **Zhang**, GuangZhong Lin, ShuGuang Zeng, Sheng Zheng, Xiao Yang, GangHua Lin, XiangYun Zeng, HaiMin Wang
Advances in Astronomy **2019**
https://arxiv.org/pdf/1909.00316.pdf
Prior to the availability of digital cameras, the solar observational images are typically recorded on films, and the information such as date and time were stamped in the same frames on film. It is significant to extract the time stamp information on the film so that the researchers can efficiently use the image data. This paper introduces an intelligent method for extracting time stamp information, namely, the Convolutional Neural Network (CNN), which is an algorithm in deep learning of multilayer neural network structures and can identify time stamp character in the scanned solar images. We carry out the time stamp decoding for the digitized data from the National Solar Observatory from 1963 to 2003. The experimental results show that the method is accurate and quick for this application. We finish the time stamp information extraction for more than 7 million images with the accuracy of 98\%.

Solar Kinetic Energy and Cross Helicity Spectra

Hongqi **Zhang**1 and Axel Brandenburg
2018 ApJL 862 L17
https://arxiv.org/pdf/1804.10321.pdf
http://sci-hub.tw/http://iopscience.iop.org/article/10.3847/2041-8213/aad337/meta
We develop a formalism that treats the calculation of solar kinetic energy and cross helicity spectra in an equal manner to that of magnetic energy and helicity spectra. The magnetic helicity spectrum is shown to be equal to the vertical part of the current helicity spectrum divided by the square of the wavenumber. For the cross helicity, we apply the recently developed two-scale approach globally over an entire active region to account for the sign change between the two polarities. Using vector magnetograms and Dopplergrams of NOAA 11158 and 12266, we show that kinetic and magnetic energy spectra have similar slopes at intermediate wavenumbers, where the contribution from the granulation velocity has been removed. At wavenumbers around $0.3\ \mathrm{Mm}^{-1}$, the magnetic helicity is found to be close to its maximal value. The cross helicity spectra are found to be within about 10% of the maximum possible value. Using the two-scale method for NOAA 12266, the global cross helicity spectrum is found to be particularly steep, similarly to what has previously been found in theoretical models of spot generation. In the quiet Sun, by comparison, the cross helicity spectrum is found to be small. **2011 February 14, 2015 January 19**

Evolution of Magnetic Helicity and Energy Spectra of Solar Active Regions

Hongqi **Zhang**, Axel Brandenburg, D.D. Sokoloff
2016 *ApJ* **819** 146
http://arxiv.org/pdf/1503.00846v1.pdf
We adopt an isotropic representation of the Fourier-transformed two-point correlation tensor of the magnetic field for estimating magnetic energy and helicity spectra as well as current helicity spectra of individual active regions and the change of their spectral indices with the solar cycle. The departure of the spectral index of current helicity from 5/3 is analyzed, and it is found that it is lower than that of magnetic energy. There is no obvious relationship between the change of the normalized magnetic helicity and the integral scale of the magnetic field for individual active regions. The evolution of the spectral index reflects the development and distribution of various scales of

magnetic structures in active regions. It is found that around solar maximum the magnetic energy and helicity spectra are steeper. 11-15 February 2011. 30 June - 4 July 2012.

Coronal Heating By the Interaction between Emerging Active Regions and the Quiet Sun Observed By the Solar Dynamics Observatory

Jun **Zhang**1, Bin Zhang1,2, Ting Li1, Shuhong Yang1, Yuzong Zhang1, Leping Li1,3, Feng Chen3, and Hardi Peter

2015 ApJ 799 L27

The question of what heats the solar corona remains one of the most important puzzles in solar physics and astrophysics. Here we report Solar Dynamics Observatory Atmospheric Imaging Assembly observations of coronal heating by the interaction between emerging active regions (EARs) and the surrounding quiet Sun (QS). The EARs continuously interact with the surrounding QS, resulting in dark ribbons which appear at the boundary of the EARs and the QS. The dark ribbons visible in extreme-ultraviolet wavelengths propagate away from the EARs with speeds of a few km s−1. The regions swept by the dark ribbons are brightening afterward, with the mean temperature increasing by one quarter. The observational findings demonstrate that uninterrupted magnetic reconnection between EARs and the QS occurs. When the EARs develop, the reconnection continues. The dark ribbons may be the track of the interface between the reconnected magnetic fields and the undisturbed QS's fields. The propagating speed of the dark ribbons reflects the reconnection rate and is consistent with our numerical simulation. A long-term coronal heating which occurs in turn from nearby the EARs to far away from the EARs is proposed.

Solar surface rotation: N-S asymmetry and recent speed-up

L. **Zhang**, K. Mursula, I. Usoskin

Astron. Astrophys. Lett. 575, L2 **2015**

http://arxiv.org/pdf/1501.02698v1.pdf

Context. The relation between solar surface rotation and sunspot activity still remains open. Sunspot activity has dramatically reduced in solar cycle 24 and several solar activity indices and flux measurements experienced unprecedentedly low levels during the last solar minimum.

Aims. We aim to reveal the momentary variation of solar surface rotation, especially during the recent years of reducing solar activity. Methods. We used a dynamic, differentially rotating reference system to determine the best-fit annual values of the differential rotation parameters of active longitudes of solar X-ray flares and sunspots in 1977-2012.

Results. The evolution of rotation of solar active longitudes obtained with X-ray flares and with sunspots is very similar. Both hemispheres speed up since the late 1990s, with the southern hemisphere rotating slightly faster than the north. Earlier, in 1980s, rotation in the northern hemisphere was considerably faster, but experienced a major decrease in the early 1990s. On the other hand, little change was found in the southern rotation during these decades. This led to a positive asymmetry in north-south rotation rate in the early part of the time interval studied.

Conclusions. The rotation of both hemispheres has been speeding up at roughly the same rate since late 1990s, with the southern hemisphere rotating slightly faster than the north. This period coincides with the start of dramatic weakening of solar activity, as observed in sunspots and several other solar, interplanetary and geomagnetic parameters.

The solar abundance problem: the effect of the turbulent kinetic flux on the solar envelope model

Q.S. **Zhang**

ApJ 787 L28 **2014**

http://arxiv.org/pdf/1404.4996v1.pdf

Recent 3D-simulations have shown that the turbulent kinetic flux (TKF) is significant. We discuss the effects of TKF on the size of convection zone and find that the TKF may help to solve the solar abundance problem. The solar abundance problem is that, with new abundances, the solar convection zone depth, sound speed in the radiative interior, the helium abundance and density in the convective envelope are not in agreement with helioseismic inversions. We have done Monte Carlo simulations on solar convective envelope models with different profile of TKF to test the effects. The solar abundance problem is revealed in the standard solar convective envelope model with AGSS09 composition, which shows significant differences ($\rm{\sim 10 %}$) on density from the helioseicmic inversions, but the differences in the model with old composition GN93 is small ($\rm{\sim 0.5 %}$). In the testing models with different imposed TKF, it is found that the density profile is sensitive to the value of TKF at the base of convective envelope and insensitive to the structure of TKF in the convection zone. Required value of turbulent kinetic luminosity at the base is about $\rm{-13%\sim-19%L_{\odot}}$. Comparing with the 3D-simulations, this value is plausible. This study is for the solar convective envelope only. The evolutionary solar

models with TKF are required for investigating its effects on the solar interior structure below the convection zone and the whole solar abundance problem, but the profile of TKF in the overshoot region is needed.

Consistent long-term variation in the hemispheric asymmetry of solar rotation

L. **Zhang1**,2, K. Mursula1 and I. Usoskin

A&A 552, A84 (**2013**)

Context. Solar active longitudes and their rotation have been studied for a long time using various forms of solar activity. However, the results on the long-term evolution of rotation rates and the hemispheric asymmetry obtained by earlier authors differ significantly from each other.

Aims. We aim to find a consistent result on the long-term migration of active longitudes of sunspots in 1877−2008 separately for the two hemispheres.

Methods. We used a dynamic, differentially rotating reference system to determine the best-fit values of the differential rotation parameters of active longitudes for each year in 1877−2008. With these parameters we determined the momentary rotation rates at the reference latitude of 17° and calculated the non-axisymmetries of active longitudes. We repeated this with five different fit intervals and two weighting methods and compared the results.

Results. The evolution of solar surface rotation in each hemisphere suggests a quasi-periodicity of about 80−90 years. The long-term variations of solar rotation in the northern and southern hemisphere have a close anti-correlation, leading to a significant 80−90-year quasi-periodicity in the north-south asymmetry of solar rotation. The north-south asymmetry of solar rotation is found to have an inverse relationship with the area of large sunspots. The latitudinal contrast of differential rotation is also found to be anti-correlated with the sunspot area. Different fit and weight methods yield similar results.

Conclusions. Our results give strong evidence for the anti-correlation of the rotation of the two solar hemispheres. The long-term oscillation of solar rotation suggests that a systematic interchange of angular momentum takes place between the two hemispheres at a period of about 80−90 years.

Solar cycle variation of the GPS cycle slip occurrence in China low-latitude region

Zhang, D. H.; Cai, L.; Hao, Y. Q.; Xiao, Z.; Shi, L. Q.; Yang, G. L.; Suo, Y. C.

Space Weather, Vol. 8, No. 10, S10D10, **2010**

http://dx.doi.org/10.1029/2010SW000583

Using the Global Positioning System (GPS) cycle slip data detected from the observations of two GPS stations over China low-latitude region from 1999 to 2005, the solar cycle variation of cycle slip occurrence is studied. It is found that the cycle slip occurrence in these two stations varies with solar cycle and shows good temporal correlation; the cycle slip occurs in solar maximum years (1999–2002) much more frequently than that in solar minimum years (2003–2005). In solar maximum years, the seasonal and diurnal dependences of cycle slip occurrence are obvious as shown by previous studies; that is, for seasonal dependence cycle slip mainly occurs in the equinox months and for diurnal dependence cycle slip mainly occurs from 1900 LT to midnight. In solar minimum years, the similar diurnal dependence of cycle slip still exists, nevertheless, the seasonal dependence of cycle slip is not obvious due to small cycle slip occurrence. In the meantime, the spread F occurrence also shows seasonal and diurnal dependence, but there are some differences compared with cycle slip occurrence. During the period from 2000 to 2002, the Q-type spread F mainly occurs in the equinox months; from 2003 to 2005, the Q-type spread F occurs mainly in summer months. As for the diurnal distribution, the Q-type spread F mainly occurs from 2000 LT to sunrise time and lasts much longer than the cycle slip does, and the F-type spread F mainly occurs after midnight and is very different with the cycle slip occurrence. Considering the reasons for cycle slip phenomenon in GPS observations, it is thought that the statistical results of cycle slip occurrence with solar cycle, season, and local time just reflect the temporal distribution of the ionospheric irregularities above a certain intense level over the observing region.

Statistical analysis of corotating interaction regions and their geoeffectiveness during solar cycle 23,

Zhang, Y., W. Sun, X. S. Feng, C. S. Deehr, C. D. Fry, and M. Dryer

J. Geophys. Res., 113, A08106, **2008**

http://dx.doi.org/10.1029/2008JA013095

This is an investigation of the effects of corotating interaction regions (CIRs) in the heliosphere (<1 AU) on geomagnetic disturbances during solar cycle 23 (1996–2005). Three kinds of interplanetary structures, “pure” CIR, interaction of CIR with ICME, and “pure” ICME by transient events, are identified by using the Hakamada-Akasofu-Fry (HAF) solar wind model. Yearly occurrence of 157 “pure” CIRs has a minimum value in 2001 and a peak value in 2003 at the declining phase during the 23rd solar cycle. The maximum correlation coefficient of the

daily sum of *Kp* indices between consecutive Carrington Rotations indicates that recurrent geomagnetic disturbances are dominant during the declining phase near solar minimum. Eighty percent of storms that are related to “pure” CIRs belong to weak and moderate storms. The statistical analysis shows that about 50% of CIRs produce classical interplanetary shocks during the descending phase and 89% of the CIR-related shocks are followed by geomagnetic storms. These results demonstrate that CIR-related shock is not a necessary condition for generating a magnetic storm, but most CIR-related shocks are related to a storm. The *Dst* index that corresponds to CIR-related storms has a better linear relationship with IMF *Bz*, *Ey*, and the coupling function (-динамо с учетом меридиональных потоков. Для полученной системы уравнений генерации магнитного поля построено уравнение Гамильтона Якоби с помощью асимптотического метода, аналогичного методу ВКБ. Это уравнение позволяет аналитически исследовать влияние меридиональных потоков на длительность цикла магнитной активности Солнца и эволюцию волн магнитного поля.

The Extreme Stellar-Signals Project III. Combining Solar Data from HARPS, HARPS-N, EXPRES, and NEID

Lily L. **Zhao**, Xavier Dumusque, Eric B. Ford, Joe Llama, Annelies Mortier, +++
ApJ **2023**
https://arxiv.org/pdf/2309.03762.pdf
We present an analysis of Sun-as-a-star observations from four different high-resolution, stabilized spectrographs -- HARPS, HARPS-N, EXPRES, and NEID. With simultaneous observations of the Sun from four different instruments, we are able to gain insight into the radial velocity precision and accuracy delivered by each of these instruments and isolate instrumental systematics that differ from true astrophysical signals. With solar observations, we can completely characterize the expected Doppler shift contributed by orbiting Solar System bodies and remove them. This results in a data set with measured velocity variations that purely trace flows on the solar surface. Direct comparisons of the radial velocities measured by each instrument show remarkable agreement with residual intra-day scatter of only 15-30 cm/s. This shows that current ultra-stabilized instruments have broken through to a new level of measurement precision that reveals stellar variability with high fidelity and detail. We end by discussing how radial velocities from different instruments can be combined to provide powerful leverage for testing techniques to mitigate stellar signals. **May 25 and June 23, 2021,**

Phase Shifts Measured in Evanescent Acoustic Waves above the Solar Photosphere and Their Possible Impacts on Local Helioseismology

Junwei **Zhao**1, S. P. Rajaguru2, and Ruizhu Chen1
2022 ApJ 933 109
https://iopscience.iop.org/article/10.3847/1538-4357/ac722d/pdf
A set of 464 minutes of high-resolution high-cadence observations were acquired for a region near the Sun's disk center using the Interferometric BI-dimensional Spectrometer installed at the Dunn Solar Telescope. Ten sets of Dopplergrams are derived from the bisector of the spectral line corresponding approximately to different atmospheric heights, and two sets of Dopplergrams are derived using an MDI-like algorithm and center-of-gravity method. These data are then filtered to keep only acoustic modes, and phase shifts are calculated between Doppler velocities of different atmospheric heights as a function of acoustic frequency. The analysis of the frequency- and height-dependent phase shifts shows that, for evanescent acoustic waves, oscillations in the higher atmosphere lead those in the lower atmosphere by an order of 1 s when their frequencies are below about 3.0 mHz, and lags behind by about 1 s when their frequencies are above 3.0 mHz. Nonnegligible phase shifts are also found in areas with systematic upward or downward flows. All these frequency-dependent phase shifts cannot be explained by vertical flows or convective blueshifts, but are likely due to complicated hydrodynamics and radiative transfer in the nonadiabatic atmosphere in and above the photosphere. These phase shifts in the evanescent waves pose great challenges to the interpretation of some local helioseismic measurements that involve data acquired at different atmospheric heights or in regions with systematic vertical flows. More quantitative characterization of these phase shifts is needed so that they can either be removed during measuring processes or be accounted for in helioseismic inversions.

Long-Term Variation of Helioseismic Far-Side Images and What Causes It

Junwei **Zhao**, Grace Y. Jing, Ruizhu Chen
Solar Phys. **296**, Article number: 186 **2021**
https://arxiv.org/pdf/2112.06985.pdf
https://link.springer.com/content/pdf/10.1007/s11207-021-01937-8.pdf
https://doi.org/10.1007/s11207-021-01937-8
A new time--distance far-side imaging technique was recently developed by utilizing multiple multi-skip acoustic waves. The measurement procedure is applied to 11 years of Doppler observations from the Solar Dynamics Observatory / Helioseismic and Magnetic Imager, and over 8000 far-side images of the Sun have been obtained with

a 12-hour temporal cadence. The mean travel-time shifts in these images unsurprisingly vary with the solar cycle. However, the temporal variation does not show good correlations with the magnetic activity in their respective northern or southern hemisphere, but show very good anti-correlation with the global-scale magnetic activity. We investigate four possible causes of this travel-time variation. Our analysis demonstrates that the acoustic waves that are used for mapping the Sun's far side experience surface reflections around the globe, where they may interact with surface or near-surface magnetic field, and carry travel-time deficits with them. The mean far-side travel-time shifts from these acoustic waves therefore vary in phase with the Sun's magnetic activity.

A New Website Hosting HMI Time-Distance Pipeline Products

Junwei **Zhao** & Ruizhu Chen

HMI Science Nuggets #163 Oct **2021** http://hmi.stanford.edu/hminuggets/?p=3634

A new website was recently developed to host SDO/HMI's time-distance pipeline products, including real-time far-side images, near-real-time full-disk subsurface flow fields, synoptic subsurface flow maps, long-term near-surface zonal and meridional flows, as well as the interior meridional circulation profile. These results or data cover the period starting from 2010 May 1, when the HMI was commissioned, till the present and are ongoing. The website is at: http://jsoc.stanford.edu/data/timed.

Simulating the Solar Minimum Corona in UV Wavelengths with Forward Modeling II. Doppler Dimming and Microscopic Anisotropy Effect

Jie **Zhao**7,1,2, Sarah E. Gibson7,2, Silvano Fineschi3, Roberto Susino3, Roberto Casini7,2, Steven R. Cranmer4, Leon Ofman5,6, and Hui Li

2021 ApJ 912 141

https://doi.org/10.3847/1538-4357/abf143

In ultraviolet (UV) spectropolarimetric observations of the solar corona, the existence of a magnetic field, solar wind velocity, and temperature anisotropies modify the linear polarization associated with resonant scattering. Unlike previous empirical models or global models, which present blended results of the above physical effects, in this work, we forward-model expected signals in the H i Lyα line (121.6 nm) by adopting an analytic model that can be adjusted to test the roles of different effects separately. We find that the impact of all three effects is most evident in the rotation of the linear polarization direction. In particular, (1) for magnetic fields between ~10 and ~100 G, the Hanle effect modifies the linear polarization at low coronal heights, rotating the linear polarization direction clockwise (counterclockwise) when the angle between the magnetic field and the local vertical is greater (less) than the van Vleck angle, which is consistent with the result of Zhao et al.; (2) solar wind velocity, which increases with height, has a significant effect through the Doppler dimming effect at higher coronal heights, rotating the linear polarization direction in an opposite fashion to the Hanle effect; and (3) kinetic temperature anisotropies are most significant at lower heights in open nonradial magnetic field regions, producing tilt opposite to isotropic Doppler dimming. The fact that the three effects operate differently in distinct spatial regimes opens up the possibility for using linear polarization measurements in UV lines to diagnose these important physical characteristics of the solar corona.

Magnetic Helicity Signature and Its Role in Regulating Magnetic Energy Spectra and Proton Temperatures in the Solar Wind

G. Q. **Zhao**1,2, Y. Lin3, X. Y. Wang3, H. Q. Feng1, D. J. Wu4, H. B. Li1, A. Zhao1, and Q. Liu1

2021 ApJ 906 123

https://iopscience.iop.org/article/10.3847/1538-4357/abca3b/pdf

In a previous paper, we found that perpendicular and parallel proton temperatures are clearly associated with the proton-scale turbulence in the solar wind, and magnetic helicity signature appears to be an important indicator in the association. Based on 15 yr of in situ measurements, the present paper further investigates the magnetic helicity of solar wind turbulence and its role in regulating magnetic energy spectra and proton temperatures. Results show that the presence of the helicity signature is very common in solar wind turbulence at scales $0.3 \lesssim k\rho_p \lesssim 1$, with k being the wavenumber and ρ p the proton gyroradius. The sign of the helicity is mostly positive, indicating the dominance of right-handed polarization of the turbulence. The helicity magnitude usually increases with k and $\beta_{\parallel p}$ (the proton parallel beta) when $k\rho_p$ and $\beta_{\parallel p}$ are less than unity. As helicity magnitude increases, the power index of the energy spectrum becomes more negative, and the proton temperatures $T_{\perp p}$ and $T_{\parallel p}$ rise significantly, where $T_{\perp p}$ and $T_{\parallel p}$ are the perpendicular and parallel temperatures with respect to the background magnetic field. In particular, the rise of $T_{\perp p}$ is faster than $T_{\parallel p}$ when $\beta_{\parallel p} < 1$ is satisfied. The faster rise of $T_{\perp p}$ with the helicity magnitude may be interpreted as the result of the preferentially perpendicular heating of solar wind protons by kinetic Alfvén wave turbulence.

Imaging the Sun's Far-Side Active Regions by Applying Multiple Measurement Schemes on Multi-Skip Acoustic Waves

Junwei **Zhao**, Dominick Hing, Ruizhu Chen, Shea Hess Webber
ApJ **887** 216 **2019**
https://arxiv.org/pdf/1912.06736.pdf
https://doi.org/10.3847/1538-4357/ab5951
Being able to image active regions on the Sun's far side is useful for modeling the global-scale magnetic field around the Sun, and for predicting the arrival of major active regions that rotate around the limb onto the near side. Helioseismic methods have already been developed to image the Sun's far-side active regions using near-side high-cadence Doppler-velocity observations; however, the existing methods primarily explore the 3-, 4-, and 5-skip helioseismic waves, leaving room for further improvement in the imaging quality by including waves with more multi-skip waves. Taking advantage of the facts that 6-skip waves have the same target-annuli geometry as 3- and 4-skip waves, and that 8-skip waves have the same target-annuli geometry as 4-skip waves, we further develop a time--distance helioseismic code to include a total of 14 sets of measurement schemes. We then apply the new code on the SDO/HMI-observed Dopplergrams, and find that the new code provides substantial improvements over the existing codes in mapping newly-emerged active regions and active regions near both far-side limbs. Comparing 3 months of far-side helioseismic images with the STEREO/EUVI-observed 304A images, we find that 97.3% of the helioseismically detected far-side active regions that are larger than a certain size correspond to an observed region with strong EUV brightening. The high reliability of the new imaging tool will potentially allow us to further calibrate the far-side helioseismic images into maps of magnetic flux. **2014 February 7-14, 2014 March 13**

Conditions for Coronal Observations at the Lijiang Observatory in 2011

M. Y. **Zhao**, Y. Liu, A. Elmhamdi, A. S. Kordi, X. F. Zhang, T. F. Song, Z. J. Tian
Solar Physics January **2018**, 293:1
The sky brightness is a critical parameter for estimating the coronal observation conditions for a solar observatory. As part of a site-survey project in Western China, we measured the sky brightness continuously at the Lijiang Observatory in Yunnan province in 2011. A sky brightness monitor (SBM) was adopted to measure the sky brightness in a region extending from 4.5 to 7.0 apparent solar radii based on the experience of the Daniel K. Inouye Solar Telescope (DKIST) site survey. Every month, the data were collected manually for at least one week. We collected statistics of the sky brightness at four bandpasses located at 450, 530, 890, and 940 nm. The results indicate that aerosol scattering is of great importance for the diurnal variation of the sky brightness. For most of the year, the sky brightness remains under 20 millionths per airmass before local Noon. On average, the sky brightness is less than 20 millionths, which accounts for 40.41% of the total observing time on a clear day. The best observation time is from 9:00 to 13:00 (Beijing time). The Lijiang Observatory is therefore suitable for coronagraphs investigating the structures and dynamics of the corona.

Observational Evidence of Magnetic Reconnection for Brightenings and Transition Region Arcades in IRIS observations

Jie **Zhao**, Brigitte Schmieder, Hui Li, Etienne Pariat, Xiaoshuai Zhu, Li Feng, Michalina Grubecka
ApJ **2017**
https://arxiv.org/pdf/1701.08356v1.pdf
By using a new method of forced-field extrapolation, we study the emerging flux region AR 11850 observed by the Interface Region Imaging Spectrograph (IRIS) and Solar Dynamical Observatory (SDO). Our results suggest that the bright points (BPs) in this emerging region have responses in lines formed from the upper photosphere to the transition region, with a relatively similar morphology. They have an oscillation of several minutes according to the Atmospheric Imaging Assembly (AIA) data at 1600 and 1700 Å . The ratio between the BP intensities measured in 1600 Å and 1700 Å filtergrams reveals that these BPs are heated differently. Our analysis of the Helioseismic and Magnetic Imager (HMI) vector magnetic field and the corresponding topology in AR11850 indicates that the BPs are located at the polarity inversion line (PIL) and most of them related with magnetic reconnection or cancelation. The heating of the BPs might be different due to different magnetic topology. We find that the heating due to the magnetic cancelation would be stronger than the case of bald patch reconnection. The plasma density rather than the magnetic field strength could play a dominant role in this process. Based on physical conditions in the lower atmosphere, our forced-field extrapolation shows consistent results between the bright arcades visible in slit-jaw image (SJI) 1400 Å and the extrapolated field lines that pass through the bald patches. It provides a reliable observational evidence for testing the mechanism of magnetic reconnection for the BPs and arcades in emerging flux region, as proposed in simulation works. **September 24, 2013**

Tracing p-Mode Waves from the Photosphere to the Corona in Active Regions

Junwei **Zhao**1, Tobías Felipe2,3, Ruizhu Chen4,1, & Elena Khomenko
HMI Science Nuggets #62 October 30, **2016**
http://hmi.stanford.edu/hminuggets/?p=1745
Through analyzing a suite of space- and ground-based observations, the authors report that above sunspots, helioseismic waves of different frequencies are able to channel up through the chromosphere and transition region into corona. General pictures of how the waves make into corona are also shown. **2013 September 2**

Periodicities in Solar Activity, Solar Radiation and Their Links with Terrestrial Environment

Valentina V. **Zharkova**1,2*, Irina Vasilieva2,3, Simon J. Shepherd2,4, Elena Popova5
Natural Science > Vol.15 No.3, 111-147. **2023**
doi: 10.4236/ns.2023.153010
https://www.scirp.org/journal/paperinformation.aspx?paperid=124007
Solar magnetic activity is expressed via variations of sunspots and active regions varying on different timescales. The most accepted is an 11-year period supposedly induced by the electromagnetic solar dynamo mechanism. There are also some shorter or longer timescales detected: the biennial cycle (2 - 2.7 years), Gleisberg cycle (80 - 100 years), and Hallstatt's cycle (2100 - 2300 years). Recently, using Principal Component Analysis (PCA) of the observed solar background magnetic field (SBMF), another period of 330 - 380 years, or Grand Solar Cycle (GSC), was derived from the summary curve of two eigenvectors of SBMF. In this paper, a spectral analysis of the averaged sunspot numbers, solar irradiance, and the summary curve of eigenvectors of SBMF was carried out using Morlet wavelet and Fourier transforms. We detect a 10.7-year cycle from the sunspots and modulus summary curve of eigenvectors as well a 22-year-cycle and the grand solar cycle of 342 - 350-years from the summary curve of eigenvectors. The Gleissberg centennial cycle is only detected on the full set of averaged sunspot numbers for 400 years or by adding a quadruple component to the summary curve of eigenvectors. Another period of 2200 - 2300 years is detected in the Holocene data of solar irradiance measured from the abundance of 14C isotope. This period was also confirmed with the period of about 2000 - 2100 years derived from a baseline of the solar background magnetic field, supposedly, caused by the solar inertial motion (SIM) induced by the gravitation of large planets. The implication of these findings for different deposition of solar radiation into the northern and southern hemispheres of the Earth caused by the combined effects of the solar activity and solar inertial motion on the terrestrial atmosphere is also discussed.

Comparison of solar activity proxies: eigen vectors versus averaged sunspot numbers

Zharkova V.V, Vasilieva I., Shepherd S.J., Popova E
Monthly Notices of the Royal Astronomical Society, Volume 521, Issue 4, June **2023**, Pages 6247–6265,
https://doi.org/10.1093/mnras/stad1001https://arxiv.org/pdf/2207.14708.pdf
https://watermark.silverchair.com/stad1001.pdf
We attempt to establish links between a summary curve, or modulus summary curve, MSC, of the solar background magnetic field (SBMF) derived from Principal Component Analysis, with the averaged sunspot numbers (SSN). The comparison of MSC with the whole set of SSN reveals rather close correspondence of cycle timings, duration and maxima times for the cycles 12- 24, 6,7 and -4,-3. Although, in 1720-1760 and 1830-1860 there are discrepancies in maximum amplitudes of the cycles, durations and shifts of the maximum times between MSC and SSN curves. The MSC curve reveals pretty regular cycles with double maxima (cycles 1-4), triple maximum amplitude distributions for cycles 0 and 1 and for cycles -1 and -2 just before Maunder minimum. The MSC cycles in 1700-1750 reveal smaller maximal magnitudes in cycles -3 to 0 and in cycle 1-4 than the amplitudes of SSN, while cycles -2 to 0 have reversed maxima with minima with SSN. Close fitting of MSC or Bayesian models to the sunspot curve distorts the occurrences of either Maunder Minimum or/and modern grand solar minimum (2020-2053). These discrepancies can be caused by poor observations and by difference in solar magnetic fields responsible for these proxies. The dynamo simulations of toroidal and poloidal magnetic field in the grand solar cycle (GSC) from 1650 until 2050 demonstrate the clear differences between their amplitude variations during the GSC. The use of eigen vectors of SBMF can provide additional information to that derived from SSN that can be useful for understanding solar activity.

Eigen vectors of solar magnetic field in cycles 21-24 and their links to solar activity indices

Zharkova V.V. and Shepherd S.J.
MNRAS Volume 512, Issue 4, June **2022**, Pages 5085–5099,
https://doi.org/10.1093/mnras/stac781
https://solargsm.com/wp-content/uploads/2022/04/zharkova_shepherd_mnras22.pdf

Using full disk synoptic maps of solar background magnetic field (SBMF) captured from the Wilcox Solar Observatory for 30 latitudinal bands for cycles 21-24 principal components (PCs), or eigen vectors of magnetic oscillations are obtained. The PCs are shown to come in pairs assigned to magnetic waves produced by dipole, quadruple, sextuple and octuple magnetic sources. The first pair is linked to dipole magnetic waves with their summary curve revealing a reasonable fit to the averaged sunspot numbers in cycles 21-24. This verifies the previous results and confirms the summary curve as additional proxy of solar activity decreasing towards grand solar minimum in cycles 25-27. There is also a noticeable asymmetry in latitudinal distributions of these PCs showing an increased activity in northern hemisphere in odd cycles and in southern hemisphere in even ones similar to the N-S asymmetries observed in sunspots. The second pair of PCs linked to quadruple magnetic sources, has 50% smaller amplitudes than the first, while their summary curve correlate closely with SXR fluxes in solar flares. Flare occurrences are also linked to variations of the next two pairs of eigen vectors, quadruple and sextuple components, revealing additional periodicity of about 2.75-3.1 years similar to observed oscillations in flares. Strong latitudinal asymmetries in quadruple and sextuple components are correlating with the N-S asymmetries of flare occurrences skewed to southern hemisphere in even cycles and to northern hemisphere in odd ones. PCA of solar magnetic field raises perspectives for simultaneous prediction of general and flaring solar activity.

Millennial Oscillations of Solar Irradiance and Magnetic Field in 600–2600 Book Chapter

Valentina **Zharkova**

Solar System Planets and Exoplanets **2021**

https://www.intechopen.com/chapters/75534

Daily ephemeris of Sun-Earth distances in two millennia (600–2600) showed significant decreases in February–June by up to 0.005 au in millennium M1 (600– 1600) and 0.011au in millennium M2 (1600–2600). The Earth's aphelion in M2 is shorter because shifted towards mid-July and perihelion longer because shifted to mid-January naturally explaining two-millennial variations (Hallstatt's cycle) of the baseline solar magnetic field measured from Earth. The S-E distance variations are shown imposed by shifts of Sun's position towards the spring equinox imposed by the gravitation of large planets, or solar inertial motion (SIM). Daily variations of total solar irradiance (TSI) calculated with these S-E distances revealed TSI increases in February–June by up to 10–12 W/m^2 in M1 and 14–18 W/m^2 in M2. There is also positive imbalance detected in the annual TSI magnitudes deposited to Earth in millennium M2 compared to millennium M1: up to 1.3 W/m^2, for monthly, and up to 20–25 W/m^2 for daily TSI magnitudes. This imbalance confirms an ascending phase of the current TSI (Hallstatt's) cycle in M2. The consequences for terrestrial atmosphere of this additional solar forcing induced by the annual TSI imbalances are evaluated. The implications of extra solar forcing for two modern grand solar minima in M2 are also discussed.

Solar activity, solar irradiance and terrestrial temperature Book Chapter

In this study we overview recent advances with prediction of solar activity using as a proxy solar background magnetic field and detection of grand solar cycles of about 400 years separated by grand solar minima (GSMs).The previous GSM known as the Maunder minimum was recorded from 1645 to 1715. The terrestrial temperature during Maunder Minimum was reduced by up to 1.0C that led to freezing rivers, cold winters and summers. The modern GSM started in 2020 and will last for three solar cycles until 2053. During this GSM two processes will affect the input of solar radiation: a decrease of solar activity and an increase in total solar irradiance because of solar inertial motion (SIM). For evaluation of the latter this study uses daily ephemeris of the Sun-Earth (SE) distances in two millennia from 600 to 2600 showing significant decreases of SE distances in the first 6 months of a year by 0.005 au in 600 to 1600 and by more than 0.01 au in 1600 to 2600 with consequent increases of SE distances in the second halves of a year. Although, these increases are not fully symmetric in the second millennium (1600 to 2600), during which the longest SE distances are gradually shifted from 21 June to 12 July while the shortest ones from 21 December to 12 January. These distance variations impose significant increases of solar irradiance in the first six months of each year in the two millennia, which are not fully offset by the solar radiation decreases in the last six

months in millennium 1600 to 2600. This misbalance creates an annual surplus of solar radiation to be processed by the terrestrial atmosphere and ocean environments that can lead to an increase of terrestrial temperature. We estimate that decrease of solar activity during GSM combined with its increase imposed by SIM will lead to a reduction of terrestrial temperature during the modern GSM to the levels of 1700.

Oscillations of the baseline of solar magnetic field and solar irradiance on a millennial timescale

V. V. **Zharkova**, S. J. Shepherd, S. I. Zharkov & E. Popova
Scientific Reports volume 9, Article number: 9197, **2019**
sci-hub.se/10.1038/s41598-019-45584-3
https://www.nature.com/articles/s41598-019-45584-3
https://arxiv.org/pdf/2002.06550.pdf

Recently discovered long-term oscillations of the solar background magnetic field associated with double dynamo waves generated in inner and outer layers of the Sun indicate that the solar activity is heading in the next three decades (2019-2055) to a Modern grand minimum similar to Maunder one. On the other hand, a reconstruction of solar total irradiance suggests that since the Maunder minimum there is an increase in the cycle-averaged total solar irradiance (TSI) by a value of about 1?1.5 Wm-2 closely correlated with an increase of the baseline (average) terrestrial temperature. In order to understand these two opposite trends, we calculated the double dynamo summary curve of magnetic field variations backward one hundred thousand years allowing us to confirm strong oscillations of solar activity in regular (11 year) and recently reported grand (350?400 year) solar cycles caused by actions of the double solar dynamo. In addition, oscillations of the baseline (zero-line) of magnetic field with a period of 1950 ? 95 years (a super-grand cycle) are discovered by applying a running averaging filter to suppress large-scale oscillations of 11 year cycles. Latest minimum of the baseline oscillations is found to coincide with the grand solar minimum (the Maunder minimum) occurred before the current super-grand cycle start. Since then the baseline magnitude became slowly increasing towards its maximum at 2600 to be followed by its decrease and minimum at ~3700. These oscillations of the baseline solar magnetic field are found associated with a long-term solar inertial motion about the barycenter of the solar system and closely linked to an increase of solar irradiance and terrestrial temperature in the past two centuries. This trend is anticipated to continue in the next six centuries that can lead to a further natural increase of the terrestrial temperature by more than 2.5-3.0∘C.

Reply to comment by Usoskin (2017) on the paper "On a role of quadruple component of magnetic field in defining solar activity in grand cycles"

Zharkova V.V., Popova E., Shepherd S.J. and Zharkov S.
2017
http://computing.unn.ac.uk/staff/slmv5/kinetics/zharkova_etal_reply_jastp17.pdf

In this communication we provide our answers to the comments by Usoskin (2017) on our recent paper (Popova et al, 2017a). We show that Principal Component Analysis (PCA) allows us to derive eigen vectors with eigen values assigned to variance of solar magnetic field waves from full disk solar magnetograms obtained in cycles 21-23 which came in pairs. The current paper (Popova et al, 2017a) adds the second pair of magnetic waves generated by quadruple magnetic sources. This allows us to recover a centennial cycle, in addition to the grand cycle, and to produce a closer fit to the solar and terrestrial activity features in the past millennium.

Reinforcing the double dynamo model with solar-terrestrial activity in the past three millennia

V.V. **Zharkova**, S.J. Shepherd, E. Popova, S.I Zharkov
2017
https://arxiv.org/pdf/1705.04482.pdf

Using a summary curve of two eigen vectors of solar magnetic field oscillations derived with Principal Components Analysis (PCA) from synoptic maps for solar cycles 21-24 as a proxy of solar activity, we extrapolate this curve backwards three millennia revealing 9 grand cycles lasting 350-400 years each. The summary curve shows a remarkable resemblance to the past sunspot and terrestrial activity: grand minima - Maunder Minimum (1645-1715 AD), Wolf minimum (1280-1350 AD), Oort minimum (1010-1050 AD) and Homer minimum (800-900 BC); grand maxima - modern warm period (1990-2015), medieval warm period (900-1200 AD), Roman warm period (400-10 BC) and others. We verify the extrapolated activity curve by the pre-telescope observations of large sunspots with naked eye, by comparing the observed and simulated butterfly diagrams for Maunder Minimum (MM), by a maximum of the terrestrial temperature and extremely intense terrestrial auroras seen in the past grand cycle occurred in 14-16 centuries. We confirm the occurrence of upcoming Modern grand minimum in 2020-2053, which will have a shorter duration (3 cycles) and, thus, higher solar activity compared to MM. We argue that Sporer minimum (1450-1550) derived from the increased abundances of isotopes 14C and 10Be is likely produced by a strong increase of the terrestrial background radiation caused by the galactic cosmic rays of powerful supernovae.

Can high-mode magnetohydrodynamic waves propagating in a rotating microspicule become unstable against Kelvin--Helmholtz instability?

I. **Zhelyazkov**, R. Chandra

Solar Phys. 294:20 **2019**

https://arxiv.org/pdf/1810.01101.pdf

We investigate the conditions under which high-mode magnetohydrodynamic (MHD) waves propagating in a rotating solar microspicule become unstable against the Kelvin--Helmholtz instability (KHI). We model the microspicule as a weakly twisted cylindrical magnetic flux tube moving along and rotating around its axis. We use the dispersion relation of MHD modes obtained from the linearized MHD equations of incompressible plasma for the jet and cool (zero beta) plasma for its environment by assuming real wave numbers and complex angular wave frequencies/complex wave phase velocities. The dispersion equation is solved numerically at appropriate input parameters to find out an instability region/window that accommodates suitable unstable wavelengths of the order of microspicule's width. It is established that a m=39MHD mode propagating in a microspicule with width of 6~Mm, axial velocity of 75~km\,s−1 and rotating one of 40~km\,s−1 can become unstable against KHI with instability growth times of 3.4 and 0.73~min at 3 and 5~Mm unstable wavelengths, respectively. These growth times are much shorter than the macrospicule lifetime of around 15~min. An increase/decease in the width of the jet would change the KHI growth times remaining more or less of the same order when are evaluated at wavelengths equal to the width/radius of the macrospicule. It is worth noticing that the excited MHD modes are supper-Alfv\'enic waves. A change in the background magnetic field can lead to another MHD mode number m that ensures the required instability window.

Recommending Low-Cost Compact Space Environment and Space Weather Effects Sensor Suites for NASA Missions

Yihua **Zheng**, Michael Xapsos, Insoo Jun, T. P. O'Brien, Linda Parker, Wousik Kim, Justin Likar, Joseph Minow, Thomas Chen, Douglas Rowland

White paper submitted to Decadal Survey for Solar and Space Physics (Heliophysics) 2024-2033 **2023**

https://arxiv.org/ftp/arxiv/papers/2303/2303.11875.pdf

As miniaturized spacecraft (e.g., cubesats and smallsats) and instrumentation become an increasingly indispensable part of space exploration and scientific investigations, it is important to understand their potential susceptibility to space weather impacts resulting from the sometimes volatile space environment. There are multitude of complexities involved in how space environment interacts with different space hardware/electronics. Measurements of such impacts, however, have been lacking. Therefore, we recommend developing and/or procuring low-cost, low-power consumption, and compact sensor suites (mainly for space weather and impact purposes) and flying them on all future NASA (and U.S in general) missions in order to measure and quantify space weather impacts, in addition to the main instrumentation.

Solar Extreme UV radiation and quark nugget dark matter model

Ariel **Zhitnitsky**

2017

https://arxiv.org/pdf/1707.03400.pdf

We advocate the idea that the surprising emission of extreme ultra violet (EUV) radiation and soft x-rays from the Sun are powered externally by incident dark matter (DM) particles. The energy and the spectral shape of this otherwise unexpected solar irradiation is estimated within the quark nugget dark matter model. This model was originally invented as a natural explanation of the observed ratio Ωdark∼Ωvisible when the DM and visible matter densities assume the same order of magnitude values. This generic consequence of the model is a result of the common origin of both types of matter which are formed during the same QCD transition and both proportional to the same fundamental dimensional parameter ΛQCD. We also present arguments suggesting that the transient brightening-like "nano-flares" in the Sun may be related to the annihilation events which inevitably occur in the solar atmosphere within this dark matter scenario.

Discriminating between Babcock-Leighton-type solar dynamo models by torsional oscillations

Congyi **Zhong**, Jie jiang, Zebin Zhang

ApJ **969** 75 **2024**

https://arxiv.org/pdf/2405.17747

https://iopscience.iop.org/article/10.3847/1538-4357/ad4f88/pdf

The details of the dynamo process in the Sun are an important aspect of research in solar-terrestrial physics and astrophysics. The surface part of the dynamo can be constrained by direct observations, but the subsurface part lacks

direct observational constraints. The torsional oscillations, a small periodic variation of the Sun's rotation with the solar cycle, are thought to result from the Lorentz force of the cyclic magnetic field generated by the dynamo. In this study, we aim to discriminate between three Babcock-Leighton (BL) dynamo models by comparing the zonal acceleration of the three models with the observed one. The property that the poleward and equatorward branches of the torsional oscillations originate from about ±55∘ latitudes with their own migration time periods serves as an effective discriminator that could constrain the configuration of the magnetic field in the convection zone. The toroidal field, comprising poleward and equatorward branches separated at about ±55∘ latitudes can generate the two branches of the torsional oscillations. The alternating acceleration and deceleration bands in time is the other property of the torsional oscillations that discriminate between the dynamo models. To reproduce this property, the phase difference between the radial (Br) and toroidal (Bϕ) components of the magnetic field near the surface should be about π/2.

Polarisation of decayless kink oscillations of solar coronal loops

Sihui **Zhong**, Valery M. Nakariakov, Dmitrii Y. Kolotkov, Lakshmi Pradeep Chitta, Patrick Antolin, Cis Verbeeck, David Berghmans

Nature Communications **2023**

https://arxiv.org/pdf/2308.10573.pdf

https://warwick.ac.uk/fac/sci/physics/research/cfsa/people/valery/natcomm23.pdf

Decayless kink oscillations of plasma loops in the solar corona may contain an answer to the enigmatic problem of solar and stellar coronal heating. The polarisation of the oscillations gives us a unique information about their excitation mechanisms and energy supply. However, unambiguous determination of the polarisation has remained elusive. Here, we show simultaneous detection of a 4-min decayless kink oscillation from two non-parallel lines-of-sights, separated by about 104\textdegree, provided by unique combination of the High Resolution Imager on Solar Orbiter and the Atmospheric Imaging Assembly on Solar Dynamics Observatory. The observations reveal a horizontal or weakly oblique linear polarisation of the oscillation. This conclusion is based on the comparison of observational results with forward modelling of the observational manifestation of various kinds of polarisation of kink oscillations. The revealed polarisation favours the sustainability of these oscillations by quasi-steady flows which may hence supply the energy for coronal heating. **1 Apr 2022**

30-min Decayless Kink Oscillations in a Very Long Bundle of Solar Coronal Plasma Loops

Sihui **Zhong**, Valery M. Nakariakov, Yuhu Miao, Libo Fu, Ding Yuan

Scientific Reports **2023**

https://arxiv.org/pdf/2308.05479.pdf

https://warwick.ac.uk/fac/sci/physics/research/cfsa/people/valery/Zhong_VLL.pdf

The energy balance in the corona of the Sun is the key to the long-standing coronal heating dilemma, which could be potentially revealed by observational studies of decayless kink oscillations of coronal plasma loops. A bundle of very long off-limb coronal loops with the length of 736±80 Mm and a lifetime of about 2 days are found to exhibit decayless kink oscillations. The oscillations were observed for several hours. The oscillation amplitude was measured at 0.3-0.5 Mm, and the period at 28-33 min. The existence of 30-min periodicity of decayless kink oscillations indicates that the mechanism compensating the wave damping is still valid in such a massive plasma structure. It provides important evidence for the non-resonant origin of decayless kink oscillations with 2-6min periods, i.e., the lack of their link with the leakage of photospheric and chromospheric oscillations into the corona and the likely role of the broadband energy sources. Magnetohydrodynamic seismology based on the reported detection of the kink oscillation, with the assistance of the differential emission measure analysis and a background coronal model provides us with a comprehensive set of plasma and magnetic field diagnostics, which is of interest as input parameters of space weather models. **2022-11-08-10**

The dynamics of AR 12700 in its early emerging phase II: fan-shaped activities relevant to arch filament systems

Sihui **Zhong**, Yijun Hou, Leping Li, Jun Zhang, Yongyuan Xiang

ApJ **882** 110 **2019**

https://arxiv.org/pdf/1907.10345.pdf

The emergence of active regions (ARs) closely relates to the solar dynamo and the dynamical atmospheric phenomena.With high-resolution and long-lasting observations from the New Vacuum Solar Telescope, we report a new dynamic activity phenomenon named "fan-shaped activity (FSA)" in the emerging phase of NOAA AR 12700. The FSAs are clearly observed at Ha wavelength and are closely related to the dynamics of the adjacent arch filament system (AFS), including threads deformation and materials downward motions. On **2018 February 26**, the two most representative FSAs appeared around 05:21 UT and 06:03 UT, respectively, and they firstly ascended and

then decayed in around 10 minutes. At the ascending phase, accompanied by the uplifting of an adjacent AFS, each FSA launches up at one end of the AFS and extends for up to 11 Mm. At the decaying phase, the FSA gradually vanishes, and materials downflows towards the other end of the AFS are detected. After checking the evolution of the magnetic fields of AR 12700, we find that each FSA is located between the end of an AFS and an adjacent magnetic patch with the same polarity and launches at the onset of the collision and compression between these two magnetic patches. We propose that the collision lifts up the AFS, and then the initially compact AFS laterally expands, resulting in the formation of FSA. A cartoon model is proposed to depict the activities.

Frozen-field Modeling of Coronal Condensations with MPI-AMRVAC II: Optimization and application in three-dimensional models

Yuhao **Zhou**, Xiaohong Li, Jack M. Jenkins, Jie Hong, Rony Keppens

ApJ **2024**

https://arxiv.org/pdf/2411.16415

The frozen-field hydrodynamic (ffHD) model is a simplification of the full magnetohydrodynamical (MHD) equations under the assumption of a rigid magnetic field, which significantly reduces computational complexity and enhances efficiency. In this work, we combine the ffHD prescription with hyperbolic thermal conduction (TC) and the Transition Region Adaptive Conduction (TRAC) method to achieve further optimization. A series of two-dimensional tests are done to evaluate the performance of the hyperbolic TC and the TRAC method. The results indicate that hyperbolic TC, while showing limiter-affected numerical dissipation, delivers outcomes comparable to classic parabolic TC. The TRAC method effectively compensates for the underestimation of enthalpy flux in low-resolution simulations, as evaluated on tests that demonstrate prominence formation. We present an application of the ffHD model that forms a three-dimensional prominence embedded in a magnetic flux rope, which develops into a stable slab-like filament. The simulation reveals a prominence with an elongated spine and a width consistent with observations, highlighting the potential of the ffHD model in capturing the dynamics of solar prominences. Forward modeling of the simulation data produces synthetic images at various wavelengths, providing insights into the appearance of prominences and filaments in different observational contexts. The ffHD model, with its computational efficiency and the demonstrated capability to simulate complex solar phenomena, offers a valuable tool for solar physicists, and is implemented in the open-source MPI-AMRVAC framework.

3D Stagger model atmospheres with FreeEOS I. Exploring the impact of microphysics on the Sun

Yixiao **Zhou**, Anish M. Amarsi, Victor Aguirre Børsen-Koch, Klara G. Karlsmose, Remo Collet, Thomas Nordlander

A&A **2023**

https://arxiv.org/pdf/2307.05403.pdf

Three-dimensional radiation-hydrodynamics (3D RHD) simulations of stellar surface convection provide valuable insights into many problems in solar and stellar physics. However, almost all 3D near-surface convection simulations to date are based on solar-scaled chemical compositions, which limit their application on stars with peculiar abundance patterns. To overcome this difficulty, we implement the robust and widely-used FreeEOS equation of state and our Blue opacity package into the Stagger 3D radiation-magnetohydrodynamics code. We present a new 3D RHD model of the solar atmosphere, and demonstrate that the mean stratification as well as the distributions of key physical quantities are in good agreement with those of the latest Stagger solar model atmosphere. The new model is further validated by comparing against solar observations. The new model atmospheres reproduce the observed flux spectrum, continuum centre-to-limb variation, and hydrogen line profiles at a satisfactory level, thereby confirming the realism of the model and the underlying input physics. These implementations open the prospect for studying other stars with different α-element abundance, carbon-enhanced metal-poor stars and population II stars with peculiar chemical compositions using 3D Stagger model atmospheres.

Transition region adaptive conduction (TRAC) in multidimensional magnetohydrodynamic simulations

Yu-Hao **Zhou**, Wen-Zhi Ruan, Chun Xia, Rony Keppens

A&A **2021**

https://arxiv.org/pdf/2102.07549.pdf

In solar physics, a severe numerical challenge for modern simulations is properly representing a transition region between the million-degree hot corona and a much cooler plasma of about 10000 K (e.g., the upper chromosphere or a prominence). In previous 1D hydrodynamic simulations, the transition region adaptive conduction (TRAC) method has been proven to capture aspects better that are related to mass evaporation and energy exchange. We aim to extend this method to fully multidimensional magnetohydrodynamic (MHD) settings, as required for any realistic application in the solar atmosphere. Because modern MHD simulation tools efficiently exploit parallel supercomputers and can handle automated grid refinement, we design strategies for any-dimensional block grid-

adaptive MHD simulations. We propose two different strategies and demonstrate their working with our open-source MPI-AMRVAC code. We benchmark both strategies on 2D prominence formation based on the evaporation--condensation scenario, where chromospheric plasma is evaporated through the transition region and then is collected and ultimately condenses in the corona. A field-line-based TRACL method and a block-based TRACB method are introduced and compared in block grid-adaptive 2D MHD simulations. Both methods yield similar results and are shown to satisfactorily correct the underestimated chromospheric evaporation, which comes from a poor spatial resolution in the transition region. Because fully resolving the transition region in multidimensional MHD settings is virtually impossible, TRACB or TRACL methods will be needed in any 2D or 3D simulations involving transition region physics.

The Relationship between Chirality, Sense of Rotation, and Hemispheric Preference of Solar Eruptive Filaments

Zhenjun **Zhou**, Rui Liu, Xing Cheng, Chaowei Jiang, Yuming Wang, Lijuan Liu, Jun Cui
ApJ **891** 180 **2020**
https://arxiv.org/pdf/2002.05007.pdf
https://iopscience.iop.org/article/10.3847/1538-4357/ab7666/pdf
The orientation, chirality, and dynamics of solar eruptive filaments is a key to understanding the magnetic field of coronal mass ejections (CMEs) and therefore to predicting the geoeffectiveness of CMEs arriving at Earth. However, confusion and contention remain over the relationship between the filament chirality, magnetic helicity, and sense of rotation during eruption. To resolve the ambiguity in observations, in this paper, we used stereoscopic observations to determine the rotation direction of filament apex and the method proposed by Chen et al. (2014) to determine the filament chirality. Our sample of 12 eruptive active-region filaments establishes a strong one-to-one relationship, i.e., during the eruption, sinistral/dextral filaments (located in the southern/northern hemisphere) rotate clockwise/counterclockwise when viewed from above, and corroborates a weak hemispheric preference, i.e., a filament and related sigmoid both exhibit a forward (reverse) S shape in the southern (northern) hemisphere, which suggests that the sigmoidal filament is associated with a low-lying magnetic flux rope with its axis dipped in the middle. As a result of rotation, the projected S shape of a filament is anticipated to be reversed during eruption.
Table 1. Characteristics of 12 selected active-region filaments.

The amplitude of solar p-mode oscillations from three-dimensional convection simulations

Yixiao **Zhou**, Martin Asplund, Remo Collet
ApJ **880** 13 **2019**
https://arxiv.org/pdf/1905.13397.pdf
sci-hub.se/10.3847/1538-4357/ab262c
The amplitude of solar p-mode oscillations is governed by stochastic excitation and mode damping, both of which take place in the surface convection zone. However, the time-dependent, turbulent nature of convection makes it difficult to self-consistently study excitation and damping processes through the use of traditional one-dimensional hydrostatic models. To this end, we carried out \textit{ab initio} three-dimensional, hydrodynamical numerical simulations of the solar atmosphere to investigate how p-modes are driven and dissipated in the Sun. The description of surface convection in the simulations is free from the tuneable parameters typically adopted in traditional one-dimensional models. Mode excitation and damping rates are computed based on analytical expressions whose ingredients are evaluated directly from the three-dimensional model. With excitation and damping rates both available, we estimate the theoretical oscillation amplitude and frequency of maximum power, vmax, for the Sun. We compare our numerical results with helioseismic observations, finding encouraging agreement between the two. The numerical method presented here provides a novel way to investigate the physical processes responsible for mode driving and damping, and should be valid for all solar-type oscillating stars.

Forecasting Solar Cycle 25 Using an Optimized Long Short-term Memory Mode Based on F10.7 and Sunspot Area Data

Hongbing **Zhu**1, Wenwei Zhu2, Haoze Chen2, and Mu He3
2023 ApJS 265 35
https://iopscience.iop.org/article/10.3847/1538-4365/acb650/pdf
In this paper, an optimized long short-term memory model is proposed to deal with the smoothed monthly F10.7 and nonsmoothed monthly sunspot area (SSA) data, aiming to forecast the peak amplitude of both solar activities and the occurring time for Solar Cycle 25 (SC-25), as well as to obtain the maximum amplitude of sunspot number (SSN) and the reaching time according to the relationships between them. The "reforecast" process in the model uses the latest forecast results obtained from the previous forecast as the input for the next forecasting calculation. The forecasting errors between the forecast and observed peak amplitude of F10.7 for SC-23 and SC-24 are 2.87% and 1.09%, respectively. The results of this evaluation indicator of SSA for SC-21 to SC-24 were 8.85%, 4.49%, 2.88%, and 4.57%, respectively, and the errors for the occurring time were all within 6 months. The forecast peak amplitude of F10.7 and SSA for SC-25 is 156.3 and 2562.5 respectively, and the maximum values of SSN are calculated as

147.9 and 213 based on F10.7 and SSA respectively, which implies that SC-25 will be stronger than SC-24, and that SC-25 will reach its peak at the beginning of 2025.

Solar Cycle 25 Prediction Using an Optimized Long Short-Term Memory Mode with F10.7

Hongbing **Zhu**, Wenwei Zhu & Mu He
Solar Physics volume 297, Article number: 157 (**2022**)
https://link.springer.com/content/pdf/10.1007/s11207-022-02091-5.pdf
In this paper, an optimized long short-term memory (LSTM) model is proposed to deal with the smoothed monthly F10.7F10.7 data, aiming to predict the peak amplitude of F10.7 and the occurring time for Solar Cycle 25 (SC-25) to obtain the maximum amplitude of sunspot number (SSN) and the reaching time. The "re-prediction" process in the model uses the latest prediction results obtained from the previous prediction as the input for the next prediction calculation. The prediction errors between the predicted and observed peak amplitude of F10.7 for SC-23 and SC-24 are 2.87% and 1.09%, respectively. The predicted peak amplitude of F10.7 for SC-25 is 156.3, and the maximum value of SSN is calculated as 147.9, which implies that SC-25 will be stronger than SC-24. SC-25 will reach its peak in July 2025.

Fe xii and Fe xiii Line Widths in the Polar Off-limb Solar Corona up to 1.5 R⊙

Yingjie **Zhu**, Judit Szente1, and Enrico Landi1
2021 ApJ 913 74
https://doi.org/10.3847/1538-4357/abf1e3
The nonthermal broadening of spectral lines formed in the solar corona is often used to seek evidence of Alfvén waves propagating in the corona. To have a better understanding of the variation of line widths at different altitudes, we measured the line widths of the strong Fe xii 192.4, 193.5, and 195.1 Å and Fe xiii 202.0 Å in an off-limb southern coronal hole up to 1.5 R⊙ observed by the Extreme Ultraviolet Spectrometer on board the Hinode satellite. We compared our measurements to the predictions from the Alfvén Wave Solar Model (AWSoM) and the SPECTRUM module. We found that the Fe xii and Fe xiii line widths first increase monotonically below 1.1 R⊙ and then keep fluctuating between 1.1 and 1.5 R⊙. The synthetic line widths of Fe xii and Fe xiii below 1.3 R⊙ are notably lower than the observed ones. We found that the emission from a streamer in the line of sight significantly contaminates the coronal hole line profiles even up to 1.5 R⊙ both in observations and simulations. We suggest that either the discrepancy between the observations and simulations is caused by insufficient nonthermal broadening at the streamer in the AWSoM simulation or the observations are less affected by the streamer. Our results emphasize the importance of identifying the origin of the coronal EUV emission in off-limb observations.

A New Approach for the Regression of the Center Coordinates and Radius of the Solar Disk Using a Deep Convolutional Neural Network

Gaofei **Zhu**1,2, Ganghua Lin1, Dongguang Wang1, and Xiao Yang1
2020 ApJ 902 72
https://doi.org/10.3847/1538-4357/abb2a0
This paper presents a new approach for the regression of the center coordinates and radius of the solar disk in Hα solar full-disk images by using a Deep Convolutional Neural Network. We use ~100,000 original Hα solar full-disk images obtained from Huairou Solar Observing Station as the experimental data set. The data set includes two parts: the original image and three numeric values (center coordinates and radius). In order to deal with the uneven distribution of the solar disk position in the original image, we randomly shift the solar disk during image preprocessing. Furthermore, data augmentation is also used to increase the robustness of the model. By evaluating the model with R-square and relative error, the center coordinates and the radius of the solar disk are proved to be effectively regressed. The data sets we constructed and source code are available as open source on GitHub.

On the Extrapolation of Magnetohydrostatic Equilibria on the Sun

Xiaoshuai **Zhu** and Thomas Wiegelmann
2018 ApJ 866 130
sci-hub.tw/10.3847/1538-4357/aadf7f
Modeling the interface region between the solar photosphere and corona is challenging because the relative importance of magnetic and plasma forces change by several orders of magnitude. While the solar corona can be modeled by the force-free assumption, we need to take plasma forces into account (pressure gradient and gravity) in photosphere and chromosphere, here within the magnetohydrostatic (MHS) model. We solve the MHS equations with the help of an optimization principle and use vector magnetogram as the boundary condition. Positive pressure and density are ensured by replacing them with two new basic variables. The Lorentz force during optimization is used to update the plasma pressure on the bottom boundary, which makes the new extrapolation work even without pressure measurements on the photosphere. Our code is tested using a linear MHS model as reference. From the detailed analyses, we find that the newly developed MHS extrapolation recovers the reference model at high

accuracy. The MHS extrapolation is, however, numerically more expensive than the nonlinear force-free field extrapolation and consequently one should limit their application to regions where plasma forces become important, e.g., in a layer of about 2 Mm above the photosphere.

Chirality, extended MHD statistics and solar wind turbulence

Jian-Zhou **Zhu**
MNRAS **2017**
https://arxiv.org/pdf/1703.01705.pdf
We unite the one-flow-dominated-state (OFDS) argument of \citet{MeyrandGaltierPRL12} with the one-chiral-sector-dominated-state \citep[OCSDS:][]{hydrochirality} one to form a nonlinear extended-magnetohydrodynamics (XMHD) theory for the solar wind turbulence (SWT), both in the Hall MHD regime and in the electron inertial MHD regime \citep[modifying the theory of][]{AbdelhamidLingamMahajanAPJ16}. `Degenerate states' in \citet{MiloshevichLingamMorrisonNJP17}'s XMHD absolute equilibria are exposed by helical mode decomposition technique, and the `chiroids absolute equilibria' offer the statistical dynamics basis to replace the linear wave (of infinitesimal or arbitrarily finite amplitudes) arguments of previous theories with OCSDS, suggested here to unite OFDS with careful analyses for the physics of (generalized) helicity and chirality in SWT.

Stereoscopy of extreme UV quiet Sun brightenings observed by Solar Orbiter/EUI

A. N. **Zhukov**, M. Mierla, F. Auchère, S. Gissot, L. Rodriguez, E. Soubrié, W. T. Thompson, B. Inhester, B. Nicula, P. Antolin, S. Parenti, É. Buchlin, K. Barczynski, C. Verbeeck, E. Kraaikamp, P. A&A **2021**
https://arxiv.org/pdf/2109.02169.pdf
The 3D fine structure of the solar atmosphere is still not fully understood as most of the available observations are taken from a single vantage point. The goal of the paper is to study the 3D distribution of small-scale brightening events ("campfires") discovered in the EUV quiet Sun by the Extreme Ultraviolet Imager (EUI) aboard Solar Orbiter. We used a first commissioning data set acquired by the EUI's High Resolution EUV telescope on 30 May 2020 in the 174 Å passband and we combined it with simultaneous data taken by the Atmospheric Imaging Assembly (AIA) aboard the Solar Dynamics Observatory in a similar 171 Å passband. The two-pixel spatial resolution of the two telescopes is 400 km and 880 km, respectively, which is sufficient to identify the campfires in both data sets. The two spacecraft had an angular separation of around 31.5 degrees (essentially in heliographic longitude), which allowed for the 3D reconstruction of the campfire position. These observations represent the first time that stereoscopy was achieved for brightenings at such a small scale. Manual and automatic triangulation methods were used to characterize the campfire data. The height of the campfires is located between 1000 km and 5000 km above the photosphere and we find a good agreement between the manual and automatic methods. The internal structure of campfires is mostly unresolved by AIA; however, for a particularly large campfire, we were able to triangulate a few pixels, which are all in a narrow range between 2500 and 4500 km. The low height of EUI campfires suggests that they belong to the previously unresolved fine structure of the transition region and low corona of the quiet Sun. They are probably apexes of small-scale dynamic loops heated internally to coronal temperatures. This work demonstrates that high-resolution stereoscopy of structures in the solar atmosphere has become feasible. **30 May 2020**

Hemispheric analysis of the magnetic flux in regular and irregular solar active regions

A. **Zhukova**
MNRAS Volume 532, Issue 2, August **2024**, Pages 2032–2043,
https://doi.org/10.1093/mnras/stae1604
https://arxiv.org/pdf/2406.18277
https://academic.oup.com/mnras/article-pdf/532/2/2032/58513501/stae1604.pdf
Studying the hemispheric distribution of active regions (ARs) with different magnetic morphology may clarify the features of the dynamo process that is hidden under the photospheric level. The magnetic flux data for 3047 ARs from the CrAO catalog between May 1996 and December 2021 (cycles 23 and 24) were used to study ARs cyclic variations and perform correlation analysis. According to the magneto-morphological classification (MMC) of ARs proposed earlier, subsets of the regular (obeying empirical rules for sunspots) and irregular (violating these rules) ARs were considered separately. Our analysis shows the following. For ARs of each MMC type, in each of the hemispheres, time profiles demonstrate a multi-peak structure. The double-peak structure of a cycle is formed by ARs of both MMC types in both hemispheres. For the irregular ARs, the pronounced peaks occur in the second maxima (close to the polar field reversal). Their significant hemispheric imbalance might be caused by a weakening of the toroidal field in one of the hemispheres due to the interaction between the dipolar and quadrupolar components of the global field, which facilitates the manifestation of the turbulent component of the dynamo. The similarity of the irregular ARs activity that was found in adjacent cycles in different hemispheres also hints at

realization of the mix-parity dynamo solution. For the quadrupolar-like component of the flux (compiled in the simple axisymmetric approximation), signs of oscillations with a period of about 15 years are found, and they are pronounced specifically for the irregular groups. This MMC type ARs might also contribute in α-quenching.

The north-south asymmetry of active regions of different magneto-morphological types in solar cycles 23 and 24 //

Zhukova, A. V., Sokoloff, D. D., Abramenko, V. I., Khlystova, A. I.
Adv. in Space Res., Volume 71, Issue 4, 15 February **2023**, Pages 1984-1994
https://doi.org/10.1016/j.asr.2022.09.013.

We used the elaborated earlier catalog of the magneto-morphological classes (MMC) of active regions (ARs) to study 2046 ARs of the solar cycle (SC) 23 and 1507 ARs of the SC24. According to empiric rules for sunspot groups (Hale's polarity law, Joy's law, etc.) and MMC, all ARs (except for unipolar spots) were sorted out between two categories: A-type – regular bipolar ARs; B-type – all the rest irregular ARs. We found that the number of both regular and irregular ARs follows the cycle with the Pearson's correlation coefficient of 0.92 and 0.78, respectively. The regular ARs are distributed evenly between the two maxima of each cycle. The irregular ARs are also distributed evenly between the two maxima in the SC 23, however their number is enhanced in the second maximum of the SC 24. Both regular and irregular ARs exhibit strong north-south (N-S) asymmetry. The significance of asymmetry is confirmed using Pearson's χ-square test and one more test based on the normal approximation to a binomial distribution. During the two maxima of a cycle, the peaks in two hemispheres for both regular and irregular ARs number do not vary synchronously. This can be explained by the fluctuations in the Babcock-Leighton mechanism. In general, there are more irregular ARs in the S-hemisphere in both cycles, which might be the result of an additional weakening of the toroidal field due to interplay between the dipole and quadrupole components of the global magnetic field.

Synthetic solar cycle for active regions violating the Hale's polarity law

A. **Zhukova**, A. Khlystova, V. Abramenko, D. Sokoloff
MNRAS Volume 512, Issue 1, May 2022, Pages 1365–1370, **2022**
https://arxiv.org/pdf/2203.01274.pdf
https://doi.org/10.1093/mnras/stac597

Long observational series for bipolar active regions (ARs) provide significant information about the mutual transformation of the poloidal and toroidal components of the global solar magnetic field. The direction of the toroidal field determines the polarity of leading sunspots in ARs in accordance with the Hale's polarity law. The vast majority of bipolar ARs obey this regularity, whereas a few percent of ARs have the opposite sense of polarity (anti-Hale ARs). However, the study of these ARs is hampered by their poor statistics. The data for five 11-year cycles (16-18 and 23,24) were combined here to compile a synthetic cycle of unique time length and latitudinal width. The synthetic cycle comprises data for 14838 ARs and 367 of them are the anti-Hale ARs. A specific routine to compile the synthetic cycle was demonstrated. We found that, in general, anti-Hale ARs follow the solar cycle and are spread throughout the time-latitude diagram evenly, which implies their fundamental connection with the global dynamo mechanism and the toroidal flux system. The increase in their number and percentage occurs in the second part of the cycle, which is in favour of their contribution to the polar field reversal. The excess in the anti-Hale ARs percentage at the edges of the butterfly diagram and near an oncoming solar minimum (where the toroidal field weakens) might be associated with strengthening of the influence of turbulent convection and magnetic field fluctuations on the arising flux tubes. The evidence of the misalignment between the magnetic and heliographic equators is also found.

A Catalog of Bipolar Active Regions Violating the Hale Polarity Law, 1989-2018

A. **Zhukova**, A. Khlystova, V. Abramenko, D. Sokoloff
Solar Phys. **295**, Article number: 165 **2020**
https://arxiv.org/pdf/2010.14413.pdf
https://link.springer.com/content/pdf/10.1007/s11207-020-01734-9.pdf

There is no list of bipolar active regions (ARs) with reverse polarity (anti-Hale regions), although statistical investigations of such ARs (bearing the imprint of deep subphotospheric processes) are important for understanding solar-cycle mechanisms. We studied 8606 ARs from 1 January 1989 to 31 December 2018 to detect anti-Hale regions and to compile a catalog. The Solar and Heliospheric Observatory (SOHO) and the Solar Dynamics Observatory (SDO) data, as well as the Debrecen Photoheliographic Data, the Mount Wilson Observatory catalog and drawings, and the USAF/NOAA Solar Region Summary were used. Complex, ambiguous cases related to anti-Hale region identification were analyzed. Two basic and four additional criteria to identify an AR as an anti-Hale region were formulated. The basic criteria assume that: i) dominating features of an AR have to form a bipole of reverse polarity with sunspots/pores of both polarities being present; ii) magnetic connections between the opposite polarities has to be observed. A catalog of anti-Hale regions (275 ARs) is compiled. The catalog contains: NOAA number, date of the greatest total area of sunspots, coordinates, and corrected sunspot area for this date. The tilt and

the most complex achieved Mount Wilson magnetic class are also provided. The percentage of anti-Hale groups meeting the proposed criteria is ~3.0% from all studied ARs, which is close to early estimations by authors who had examined each AR individually: ~2.4% by Hale and Nicholson (Ap.J. 62, 270, 1925) and ~3.1% by Richardson (Ap.J. 107, 78, 1948). The enchancement of the anti-Hale percentage in later research might be related to: i) increasing sensitivity of instruments (considering smaller and smaller bipoles); ii) the ambiguities in the anti-Hale region identification.

Two-dipole model of the asymmetric Sun

Bertalan **Zieger**1,2* and Kalevi Mursula2
J. Space Weather Space Clim. **2020**, 10, 40
https://www.swsc-journal.org/articles/swsc/pdf/2020/01/swsc200015.pdf
The large-scale photospheric magnetic field is commonly thought to be mainly dipolar during sunspot minima, when magnetic fields of opposite polarity cover the solar poles. However, recent studies show that the octupole harmonics contribute comparably to the spatial power of the photospheric field at these times. Also, the even harmonics are non-zero, indicating that the Sun is hemispherically asymmetric with systematically stronger fields in the south during solar minima. We present here an analytical model of two eccentric axial dipoles of different strength, which is physically motivated by the dipole moments produced by decaying active regions. With only four parameters, this model closely reproduces the observed large-scale photospheric field and all significant coefficients of its spherical harmonics expansion, including the even harmonics responsible for the solar hemispheric asymmetry. This two-dipole model of the photospheric magnetic field also explains the southward shift of the heliospheric current sheet observed during recent solar minima.

Chapter 1

Discoveries and Concepts: The Sun's Role in Astrophysics **Review**

Jack B. **Zirker**1 , Oddbjørn Engvold2
In: ***The Sun as a Guide to Stellar Physics*** ***Book***
Eds. Oddbjørn Engvold, Jean-Claude Vial, and Andrew Skumanich
Elsevier , November **2018**
https://www.sciencedirect.com/book/9780128143346/the-sun-as-a-guide-to-stellar-physics
The Sun has had an important role in the development of stellar astrophysics. The discoveries of solar magnetism, solar wind, and global acoustic vibrations, to name only a few, have launched completely new topics for research in stellar physics. In addition, concepts such as magnetic reconnection and neutrino mass first arose in attempts to explain puzzling solar phenomena.
This volume is intended to remind astronomers, physicists, and students of the Sun's key role, which is based in part on its proximity and its commonality with other stars. After a short survey of the subject, successive chapters will describe the status and future progress in several topics in solar physics that are relevant to stellar physics. We begin with the simplest characteristic of the Sun, its luminosity.

Indirect solar wind measurements using archival cometary tail observations

N.V. **Zolotova**, Yu.V. Sizonenko, M.V. Vokhmyanin, I.S. Veselovsky
Solar Physics 293:85 **2018**
https://arxiv.org/pdf/1805.04684.pdf
https://link.springer.com/content/pdf/10.1007%2Fs11207-018-1307-4.pdf
The paper addressed to the problem of the solar wind behaviour during the Maunder Minimum. Records on plasma tails of comets would allow to shed light on the physical parameters of the solar wind in the past. We analyse descriptions and drawings of comets to the eighteenth century. To differentiate dust and plasma tails, we address to their color, shape and orientation. Basing on the calculations made by F.A. Bredikhin, we found that deviation of cometary tails from the antisolar direction on average exceeded 10 degrees, that is typical for dust tails. Catalogues of Hevelius and Lubieniecki are also examined. The first indication of plasma tail was revealed only for Great comet C/1769 P1.

How Deep Was the Maunder Minimum?

N. V. **Zolotova**, D. I. Ponyavin
Solar Physics November **2016**, Volume 291, Issue 9, pp 2869–2890
One of the most enigmatic features of the solar history is the Maunder minimum (MM). We analyze reports of solar observers from the group-sunspot-number database. Particular attention is given to short notes that resulted in an underestimation of the sunspot activity. These reports by Derham, Flamsteed, Hevelius, Picard, G.D. Cassini, and Fogel are found to address the absence of sunspots of great significance, which could signify a secular minimum

with a majority of small short-lived spots. Up to Schwabe's discovery of the solar cycle, sunspots were considered as an irregular phenomenon; sunspot observations were not dedicated to the task of sunspot monitoring and counting. Here, we argue that the level of the solar activity in the past is significantly underestimated.

Solar Coronal Heating Fueled by Random Bursts of Fine-scale Magnetic Reconnection in Turbulent Plasma Regions

Jitong **Zou1**, Aohua Mao1,2, Xiaogang Wang1, Yangyang Hua3, and Tianchun Zhou1
2023 ApJ 943 155
https://iopscience.iop.org/article/10.3847/1538-4357/acaec2/pdf
Coronal heating is a longstanding issue in solar physics as well as plasma physics in general. In recent years, significant resolution improvements of satellite observations have contributed to a deeper understanding of small-scale physics, e.g., magnetic reconnection processes on fine scales inside the turbulent geo-magnetosheath. Coronal plasmas feature turbulent complexity of flows and magnetic fields with similar fine scales, and thus electron magnetic reconnection is very likely to be excited in the coronal region working as one of the ways to heat the solar corona, which offers a possible new mechanism for the nanoflare model proposed by Parker. We in this paper simulate and analyze the magnetic reconnection processes on a fine scale of the electron skin depth, with a particle-in-cell treatment, and estimate its contribution to coronal heating. The result shows that the electron magnetic reconnection can provide substantial heating efficiency for heating the corona to its observed temperature, once the reconnection events are reasonably spread.

The Solar Orbiter Science Activity Plan: translating solar and heliospheric physics questions into action **Review**

I. **Zouganelis**, A. De Groof, A. P. Walsh, D. R. Williams, D. Mueller, et al.
A&A 642, A3 **2020**
https://arxiv.org/pdf/2009.10772.pdf
https://www.aanda.org/articles/aa/pdf/2020/10/aa38445-20.pdf
https://doi.org/10.1051/0004-6361/202038445
Solar Orbiter is the first space mission observing the solar plasma both in situ and remotely, from a close distance, in and out of the ecliptic. The ultimate goal is to understand how the Sun produces and controls the heliosphere, filling the Solar System and driving the planetary environments. With six remote-sensing and four in-situ instrument suites, the coordination and planning of the operations are essential to address the following four top-level science questions: (1) What drives the solar wind and where does the coronal magnetic field originate? (2) How do solar transients drive heliospheric variability? (3) How do solar eruptions produce energetic particle radiation that fills the heliosphere? (4) How does the solar dynamo work and drive connections between the Sun and the heliosphere? Maximising the mission's science return requires considering the characteristics of each orbit, including the relative position of the spacecraft to Earth (affecting downlink rates), trajectory events (such as gravitational assist manoeuvres), and the phase of the solar activity cycle. Furthermore, since each orbit's science telemetry will be downloaded over the course of the following orbit, science operations must be planned at mission level, rather than at the level of individual orbits. It is important to explore the way in which those science questions are translated into an actual plan of observations that fits into the mission, thus ensuring that no opportunities are missed. First, the overarching goals are broken down into specific, answerable questions along with the required observations and the so-called Science Activity Plan (SAP) is developed to achieve this. The SAP groups objectives that require similar observations into Solar Orbiter Observing Plans (SOOPs), resulting in a strategic, top-level view of the optimal opportunities for science observations during the mission lifetime.

MHD Wave Propagation and the Kelvin–Helmholtz Instability in an Asymmetric Magnetic Slab System

Noémi Kinga **Zsámberger**1,2,3,4, Yihui Tong5, Balázs Asztalos6, and Róbert Erdélyi1,4,6
2022 ApJ 935 41
https://iopscience.iop.org/article/10.3847/1538-4357/ac7ebf/pdf
Magnetohydrodynamic waves are ubiquitously detected in the finely structured solar atmosphere. At the same time, our Sun is a highly dynamic plasma environment, giving rise to flows of various magnitudes, which can lead to the instability of waveguides. Recent studies have employed the method of introducing waveguide asymmetry to generalize "classical" symmetric descriptions of the fine structuring within the solar atmosphere, with some of them introducing steady flows as well. Building on these recent studies, here we investigate the magnetoacoustic waves guided by a magnetic slab within an asymmetric magnetic environment, in which the slab is under the effect of a steady flow. We provide an analytical investigation of how the phase speeds of the guided waves are changed, and where possible, determine the limiting flow speeds required for the onset of the Kelvin–Helmholtz instability. Furthermore, we complement the study with initial numerical results, which allows us to demonstrate the validity of our approximations and extend the investigation to a wider parameter regime. This configuration is part of a series

of studies aimed to generalize, step-by-step, well-known symmetric waveguide models and understand the additional physics stemming from introducing further sources of asymmetry.

Solar Magneto-seismology of a Magnetic Slab in an Asymmetric Magnetic Environment

Noémi Kinga **Zsámberger**1,2,3 and Róbert Erdélyi1,4,5

2022 *ApJ* **934** 155

https://iopscience.iop.org/article/10.3847/1538-4357/ac7be3/pdf

Diagnosing the solar atmospheric plasma remains one of the major challenges in solar physics. In recent years, new methods have been developed to apply the powerful concept of solar magneto-seismology (SMS) to obtain information about plasma parameters in solar structures guiding magnetohydrodynamic (MHD) waves that would otherwise be difficult to measure. This paper uses the Cartesian model of a magnetic slab placed in an asymmetric magnetic environment to generalize recently discovered SMS techniques. Utilizing the fact that the asymmetric environment changes the character of the classical kink and sausage eigenmodes, we describe two spatial seismology methods built upon this mixed character of quasi-sausage and quasi-kink modes. First, we present the amplitude ratio technique, which compares the oscillation amplitudes measured at the two boundaries of the slab, and we provide expressions to estimate the internal Alfvén speed in the thin slab and in the incompressible plasma approximations. The second main technique relies on the changed distribution of wave power throughout the slab under the effect of waveguide asymmetry. This minimum perturbation shift technique is then also utilized to provide Alfvén speed estimates that depend on the plasma and magnetic parameters of the environment, as well as the measured slab width and oscillation frequency. Finally, we perform a brief investigation of how the amplitude ratio and the minimum perturbation shift depend on the different sources of waveguide asymmetry, and illustrate our findings with numerical results.

Magnetoacoustic Waves in a Magnetic Slab Embedded in an Asymmetric Magnetic Environment. III. Applications to the Solar Atmosphere

Noémi Kinga **Zsámberger**1,2,3 and Róbert Erdélyi1,4,5

2021 ApJ 906 122

https://doi.org/10.3847/1538-4357/abca9d

Analytical and numerical modeling of the behavior of magnetohydrodynamic waves in various magnetic geometries can offer a valuable contribution to the field of solar magnetoseismology. Based on analytical results from our previous studies, here we illustrate a few solar applications of these findings concerning the propagation of magnetoacoustic waves in a magnetic slab embedded in an asymmetric environment. Bearing in mind the simplifying assumptions made, this asymmetric model incorporating external magnetic fields can be used to describe a wide variety of multilayered solar features, some of which are observable and have already been studied in solar structures. Specific potential applications are: prominences, polar plumes and their environment, magnetic bright points, and light bridges, as well as adjacent large-scale layers in the solar atmosphere (e.g., the photosphere—interface region—corona triad, or the chromosphere—transition region—corona group). In these individual cases, the appropriate dispersion relations are derived and solved. The obtained wave propagation solutions may serve (i) not just as impetus to be confirmed by high-resolution observations but (ii) also to be exploited for further diagnostic purposes by solar magnetoseismology of these frequently studied magnetic structures.

Magneto-acoustic waves in a magnetic slab embedded in an asymmetric magnetic environment II: Thin and wide slabs, hot and cold plasmas

Noémi Kinga **Zsámberger**, Róbert Erdélyi

ApJ **894** 123 **2020**

https://arxiv.org/pdf/2004.05584.pdf

https://doi.org/10.3847/1538-4357/ab8791

Wave propagation in magnetically structured atmospheres is a thoroughly studied, yet practically inexhaustible well of investigations in the field of solar magneto-seismology. A simple but powerful example is the examination of wave behaviour in a magnetic slab. Our previous study (Zsámberger, Allcock and Erdélyi, Astrophys. J., 853, p. 136, 2018) used an analytical approach to derive the general dispersion relation for magneto-acoustic waves in a magnetic slab of homogeneous plasma, which was enclosed in an asymmetric magnetic environment. In the present study, we focus on the analysis of wave propagation in various limiting cases applicable to solar and space plasma or astrophysics. The thin- and wide-slab approximations, as well as the limits of low and high plasma-beta values are considered. Utilising the fact that in a weakly asymmetric slab, the dispersion relation can be decoupled, the behaviour of quasi-sausage and quasi-kink modes is studied in further analytical and numerical detail, and their avoided crossings are described. The results highlight how the asymmetry influences the wave properties, e.g. the phase speed of eigenmodes, depending on the ratios of external-to-internal densities and magnetic fields on the two sides. Notably, the phase speeds of surface modes will converge to different values for quasi-sausage and quasi-kink modes in the wide-slab limit, and cut-off frequencies are introduced with respect to both surface and body modes, in

thin as well as wide slabs, beyond which the solutions become leaky. These obtained properties of MHD wave behaviour could be measured with suitable high-resolution instruments in the future.

Magneto-acoustic Waves in a Magnetic Slab Embedded in an Asymmetric Magnetic Environment: The Effects of Asymmetry

Zsámberger, Noémi Kinga; Allcock, Matthew; Erdélyi, Róbert
2018 ApJ...853..136K
https://ui.adsabs.harvard.edu/link_gateway/2018ApJ...853..136K/PUB_PDF
https://iopscience.iop.org/article/10.3847/1538-4357/aa9ffe/pdf
Modeling the behavior of magnetohydrodynamic waves in a range of magnetic geometries mimicking solar atmospheric waveguides, from photospheric flux tubes to coronal loops, can offer a valuable contribution to the field of solar magneto-seismology. The present study uses an analytical approach to derive the dispersion relation for magneto-acoustic waves in a magnetic slab of homogeneous plasma enclosed on its two sides by semi-infinite plasma of different densities, temperatures, and magnetic field strengths, providing an asymmetric plasma environment. This is a step further in the generalization of the classic magnetic slab model, which is symmetric about the slab, was developed by Roberts, and is an extension of the work by Allcock & Erdélyi where a magnetic slab is sandwiched in an asymmetric nonmagnetic plasma environment. In contrast to the symmetric case, the dispersion relation governing the asymmetric slab cannot be factorized into separate sausage and kink eigenmodes. The solutions obtained resemble these well-known modes; however, their properties are now mixed. Therefore we call these modes quasi-sausage and quasi-kink modes. If conditions on the two sides of the slab do not differ strongly, then a factorization of the dispersion relation can be achieved for the further analytic study of various limiting cases representing a solar environment. In the current paper, we examine the incompressible limit in detail and demonstrate its possible application to photospheric magnetic bright points. After the introduction of a mechanical analogy, we reveal a relationship between the external plasma and magnetic parameters, which allows for the existence of quasi-symmetric modes.

Threshold of non-potential magnetic helicity ratios at the onset of solar eruptions

Francesco P. **Zuccarello**, Etienne Pariat, Gherardo Valori, Luis Linan
ApJ **2018**
https://arxiv.org/pdf/1807.00532.pdf
The relative magnetic helicity is a quantity that is often used to describe the level of entanglement of non-isolated magnetic fields, such as the magnetic field of solar active regions.The aim of this paper is to investigate how different kinds of photospheric boundary flows accumulate relative magnetic helicity in the corona and if and how-well magnetic helicity related quantities identify the onset of an eruption. We use a series of three-dimensional, parametric magnetohydrodynamic simulations of the formation and eruption of magnetic flux ropes. All the simulations are performed on the same grid, using the same parameters, but they are characterized by different driving photospheric flows, i.e., shearing, convergence, stretching, peripheral- and central- dispersion flows. For each of the simulations, the instant of the onset of the eruption is carefully identified by using a series of relaxation runs. We find that magnetic energy and total relative helicity are mostly injected when shearing flows are applied at the boundary, while the magnetic energy and helicity associated with the coronal electric currents increase regardless of the kind of photospheric flows. We also find that, at the onset of the eruptions, the ratio between the non-potential magnetic helicity and the total relative magnetic helicity has the same value for all the simulations, suggesting the existence of a threshold in this quantity. Such threshold is not observed for other quantities as, for example, those related to the magnetic energy.

Solar slow magneto-acoustic-gravity waves: an erratum correction and a revisited scenario

E. **Zurbriggen**, M. V. Sieyra, A. Costa, A. Esquivel, G. Stenborg
MNRAS **2020**
https://arxiv.org/pdf/2004.09609.pdf
Slow waves are commonly observed on the entire solar atmosphere. Assuming a thin flux tube approximation, the cut-off periods of slow-mode magneto-acoustic-gravity waves that travel from the photosphere to the corona were obtained in Costa et al. (2018). In that paper, however, a typo in the specific heat coefficient at constant pressure cp value led to an inconsistency in the cut-off calculation, which is only significant at the transition region. Due to the abrupt temperature change in the region, a change of the mean atomic weight (by a factor of approximately two) also occurs, but is often overlooked in analytical models for simplicity purposes. In this paper, we revisit the calculation of the cut-off periods of magneto-acoustic-gravity waves in Costa et al. (2018) by considering an atmosphere in hydrostatic equilibrium with a temperature profile, with the inclusion of the variation of the mean atomic weight and the correction of the inconsistency aforementioned. In addition, we show that the cut-off periods obtained analytically are consistent with the corresponding periods measured in observations of a particular active region.

MHD simulations of coronal supra-arcade downflows including anisotropic thermal conduction

E. **Zurbriggen**, A. Costa, A. Esquivel, M. Schneiter, M. Cécere
ApJ, 832:74, **2016**
https://arxiv.org/pdf/1703.05802.pdf

Coronal supra-arcade downflows (SADs) are observed as dark trails descending towards hot turbulent fan shaped regions. Due to the large temperature values, and gradients in these fan regions the thermal conduction should be very efficient. While several models have been proposed to explain the triggering and the evolution of SADs, none of these scenarios address a systematic consideration of thermal conduction. Thus, we accomplish this task numerically simulating the evolution of SADs within this framework. That is, SADs are conceived as voided (subdense) cavities formed by non-linear waves triggered by downflowing bursty localized reconnection events in a perturbed hot fan. We generate a properly turbulent fan, obtained by a stirring force that permits control of the energy and vorticity input in the medium where SADs develop. We include anisotropic thermal conduction and consider plasma properties consistent with observations. Our aim is to study if it is possible to prevent SADs to vanish by thermal diffusion. We find that this will be the case, depending on the turbulence parameters. In particular, if the magnetic field lines are able to envelope the voided cavities, thermally isolating them from the hot environment. Velocity shear perturbations that are able to generate instabilities of the Kelvin-Helmholtz type help to produce magnetic islands, extending the life-time of SADs.

Segmentation of Coronal Features to Understand the Solar EUV and UV Irradiance Variability III. Inclusion and Analysis of Bright Points

https://doi.org/10.1007/s11207-021-01863-9

The study of solar irradiance variability is of great importance in heliophysics, Earth's climate, and space weather applications. These studies require careful identifying, tracking and monitoring of features in the solar photosphere, chromosphere, and corona. Do coronal bright points contribute to the solar irradiance or its variability as input to the Earth atmosphere? We studied the variability of solar irradiance for a period of 10 years (May 2010 – June 2020) using the Large Yield Radiometer (LYRA), the Sun Watcher using APS and image Processing (SWAP) on board PROBA2, and the Atmospheric Imaging Assembly (AIA), and applied a linear model between the segmented features identified in the EUV images and the solar irradiance measured by LYRA. Based on EUV images from AIA, a spatial possibilistic clustering algorithm (SPoCA) is applied to identify coronal holes (CHs), and a morphological feature detection algorithm is applied to identify active regions (ARs), coronal bright points (BPs), and the quiet Sun (QS). The resulting segmentation maps were then applied on SWAP images, images of all AIA wavelengths, and parameters such as the intensity, fractional area, and contribution of ARs/CHs/BPs/QS features were computed and compared with LYRA irradiance measurements as a proxy for ultraviolet irradiation incident to the Earth atmosphere. We modeled the relation between the solar disk features (ARs, CHs, BPs, and QS) applied to EUV images against the solar irradiance as measured by LYRA and the F10.7 radio flux. A straightforward linear model was used and corresponding coefficients computed using a Bayesian method, indicating a strong influence of active regions to the EUV irradiance as measured at Earth's atmosphere. It is concluded that the long- and short-term fluctuations of the active regions drive the EUV signal as measured at Earth's atmosphere. A significant contribution from the bright points to the LYRA irradiance could not be found.

О НЕКОРРЕКТНОСТИ ПРАВИЛА ГНЕВЫШЕВА–ОЛЯ В ОБЪЕДИНЕНИИ ЧЕТНО-НЕЧЕТНЫХ ЦИКЛОВ 11-ЛЕТНЕЙ СОЛНЕЧНОЙ АКТИВНОСТИ В ФИЗИЧЕСКИЕ ПАРЫ И ВЫСОТЕ МАКСИМУМА XXV И XXVI ЦИКЛОВ

Абдусаматов *Х.И.*
АЖ Том: 99Номер: 8 Год: **2022** Страницы: 684-693

Гневышев и Оль, используя ряд с достаточно малой статистикой событий, предложили объединять 11-летние циклы солнечной активности (СА) в отдельные физические пары четный-нечетный, где относительная интенсивность нечетного цикла выше, чем предшествующего четного цикла. Однако данное правило может выполняться только на фазе роста продолжительного и более мощного квазидвухвекового цикла (КДВЦ), когда интенсивность каждого последующего 11-летнего цикла больше интенсивности предыдущего, и нарушаться на фазе спада КДВЦ, когда, наоборот, мощность каждого последующего цикла становится меньше предыдущего. Значительно мощный и более чем на порядок длительный квазидвухвековой цикл определяет и управляет физическими параметрами и последовательными вариациями амплитуды интенсивности коротких и слабых квази-11-летних циклов СА в зависимости от фазы его вариаций. В период фазы спада КДВЦ продолжительность 11-летних циклов солнечной активности последовательно увеличивается, а высота уровня их максимума и относительная интегральная мощность последовательно уменьшаются. Противоположные соотношения наблюдаются в фазе его роста. Впервые утверждается, что правило Гневышева–Оля выполняется как следствие последовательного роста интегральной мощности коротких 11-летних циклов только в течение периода фазы роста квазидвухвекового цикла и нарушается последовательным уменьшением их мощности в течение периода фазы его спада. В XXV и XXVI циклах, развивающихся в период фазы спада КДВЦ, сохранится тенденция последовательного уменьшения

высоты максимума солнечной активности до 110 ± 25 и 60 ± 35 (до 65 ± 15 и 35 ± 20 в версии 1.0 системы подсчета) единиц относительного числа пятен соответственно.

Проявления турбулентной составляющей глобального солнечного динамо

ФОРМИРОВАНИЕ УНИФИЦИРОВАННОЙ БАЗЫ ДАННЫХ НАБЛЮДЕНИЙ СОЛНЦА В ЛИНИИ НЕ I 10830 Å, ПОЛУЧЕННЫХ В 1999-2023 ГГ. НА ТЕЛЕСКОПЕ БСТ-2 КРАО
Андреева О.А., Плотников А.А., Малащук В.М.
Изв. КрАО Том: 119Номер: 4 Год: 2023 Страницы: 35-41
На телескопе БСТ-2 накоплен уникальный наблюдательный материал за более чем два солнечных цикла. В период с 1999 г. по настоящее время получено свыше 4500 карт полного диска Солнца в линии Не I 10830 Å , позволяющих исследовать эволюцию и характеристики корональных дыр, волокон и активных областей. В связи с тем, что за этот период процесс наблюдений неоднократно претерпевал модернизацию разной сложности и вносились изменения в программы обработки, мы имеем несколько рядов карт Солнца разного вида. В работе поставлена задача обработать весь наблюдательный материал по единой методике и сформировать унифицированную базу данных наблюдений в линии Не I 10830 Å . Дается краткое описание алгоритма обработки наблюдений, и приводятся фрагменты базы данных.

ЦИКЛИЧЕСКИЕ ВАРИАЦИИ ПЛОЩАДЕЙ КОРОНАЛЬНЫХ ДЫР И СОЛНЕЧНЫХ ПЯТЕН В 2010-2021 ГГ
Андреева *О.А., Абраменко В.И., Малащук В.М.*
ГиА Том: 118Номер: 2 Год: **2022** Страницы: 20-27
https://elibrary.ru/item.asp?id=48749026
В работе исследуется циклическая связь корональных дыр с индексами солнечной активности (solar activity - SA). На основе наблюдательных данных, полученных инструментом AIA/SDO в линии железа Fe XII 19.3 нм в период с 13.05.2010 по 13.05.2021, изучены свойства полярных и неполярных корональных дыр (coronal holes - CHs). Подробно рассмотрены особенности каждой группы, установлена связь площадей корональных дыр с фазой солнечного цикла. В исследуемый период обнаружена северо-южная (N - S) асимметрия полушарий как по индексам солнечной активности, так и по локализации максимальных площадей полярных и неполярных CHs. На протяжении всего цикла выявлена определяющая роль полярных CHs южного и неполярных CHs северного полушария, которая проявилась как в динамике SA полушарий, так и всего диска Солнца в целом.

ПРОСТРАНСТВЕННЫЕ СТРУКТУРЫ СЕВЕРО-ЮЖНОЙ АСИММЕТРИИ В ЗЕЛЕНОЙ КОРОНАЛЬНОЙ ЛИНИИ И В МАГНИТНЫХ ПОЛЯХ
БАДАЛЯН О.Г.
ПАЖ Том: 46Номер: 10 Год: **2020** Страницы: 750-760
Исследуется пространственное распределение северо-южной асимметрии за 1977–2001 гг. Сопоставление распределения и временн\'{\cyr\cyrery }х изменений индекса асимметрии A в зеленой корональной линии 530.3 нм Fe XIV, в полном корональном магнитном поле и в полях малых и больших масштабов показало, что на низких широтах распределение A для полей малых масштабов имеет наибольшее сходство с его распределением в яркости зеленой линии. На широтах выше 40◦ наблюдается антикорреляция между поведением A в зеленой линии и в магнитном поле больших масштабов. Ранее было показано, что широтно-долготные области с преобладанием яркости зеленой линии в одном из полушарий через 14–18 оборотов сменяются похожими по форме областями с преобладанием другого полушария, т.е. карта как бы изменяется на “негативную”. В данной работе этот вывод подтверждается рассмотрением поведения северо-южной асимметрии в напряженности магнитного поля. Изменение карты на негативную наиболее выражено для полей больших масштабов. Северо-южная асимметрия является свидетельством и мерой того, что существуют различия (рассинхронизация) в работе двух полушарий Солнца. Этот факт необходимо учитывать при построении современных теорий динамо.

ДИФФЕРЕНЦИАЛЬНОЕ ВРАЩЕНИЕ СОЛНЕЧНОЙ КОРОНЫ ПО ДАННЫМ О МАГНИТНОМ ПОЛЕ

БАДАЛЯН О.Г.1, ОБРИДКО В.Н.1

АЖ Том: 44Номер: 11 Год: **2018** Страницы: 791-798
Предлагается метод исследования дифференциального вращения солнечной короны с использованием корональных магнитного поля как трассера. Поле рассчитывается в потенциальном приближении по

данным наблюдений на уровне фотосферы. Рассматривается временной интервал с 24.06.1976 по 31.12.2004. Поле рассчитывалось для всех широт от экватора до $\pm 75^{\circ}$ с шагом 5° на расстояниях от основания короны 1.0 $R_{\odot}$ до 2.45 $R_{\odot}$ вблизи поверхности источника. Методом периодограммного анализа определены периоды вращения короны на 14 расстояниях от центра Солнца. Показано, что с увеличением гелиоцентрического расстояния вращение короны становится все менее дифференциальным. При этом даже вблизи поверхности источника оно не становится твердотельным. Рассмотрено изменение периодов вращения короны со временем. Получено, что в минимуме цикла вращение является наиболее дифференциальным, особенно на малых расстояниях от центра Солнца. Изменение вращения короны со временем согласуется с наклоном магнитного экватора Солнца. Результаты, полученные по магнитному полю, сопоставлены с результатами, получаемыми при использовании данных о яркости зеленой корональной линии 530.3 nm Fe XIV. Согласованность этих результатов подтверждает надежность предлагаемого метода изучения вращения короны. Изучение вращения магнитного поля короны позволяет надеяться на возможность использовать этот метод для диагностики дифференциального вращения в подфотосферных слоях.

О СВЯЗИ МЕЖДУ КВАЗИ-ДВУХЛЕТНИМИ ВАРИАЦИЯМИ СОЛНЕЧНОЙ АКТИВНОСТИ, ГЕЛИОСФЕРНОГО МАГНИТНОГО ПОЛЯ И КОСМИЧЕСКИХ ЛУЧЕЙ*

Г. А. **Базилевская**, М. С. Калинин, М. Б. Крайнев, В. С. Махмутов,
А. К. Свиржевская, Н. С. Свиржевский, Ю. И. Стожков КОСМИЧЕСКИЕ ИССЛЕДОВАНИЯ, **2016**, том 54, № 3, с. 181–187 **File**

Квази-двухлетние осцилляции солнечной активности (T ≈ 1–4 года) считаются одними из базовых вариаций солнечной активности, связанных с процессом солнечного динамо. Они передаются в межпланетное пространство открытым магнитным потоком Солнца и порождают КДО в интенсивности космических лучей. В статье обсуждаются наблюдательные характеристики КДО в КЛ, их связь с КДО на Солнце и в межпланетной среде. Время запаздывания КДО в КЛ относительно КДО солнечного и гелиосферного магнитного поля позволяет предположить, что формирование КДО открытого магнитного потока Солнца происходит в течение 3–5 мес. Рассматривается вопрос о выделенной периодичности КЛ (T = 1.6 года), которая превалировала в КЛ и гелиосферном магнитном поле на протяжении более 10 лет, но не была стабильной в течение 60 лет наблюдений. Различия характеристик КДО и долговременных вариаций КЛ предполагают особенности в механизме их образования.

ВАРИАЦИИ КОСМИЧЕСКИХ ЛУЧЕЙ В 23-24 ЦИКЛАХ СОЛНЕЧНОЙ АКТИВНОСТИ ПО ДАННЫМ МИРОВОЙ СЕТИ СТАНЦИЙ КОСМИЧЕСКИХ ЛУЧЕЙ

ИНДЕКС ДОЛГОВРЕМЕННОГО ВЛИЯНИЯ СПОРАДИЧЕСКОЙ СОЛНЕЧНОЙ АКТИВНОСТИ НА МОДУЛЯЦИЮ КОСМИЧЕСКИХ ЛУЧЕЙ

Белов А.В., Гущина Р.Т.
Г и А Том: 58Номер: 1 Год: **2018** Страницы: 3-10

Корональные выбросы вещества не только создают Форбуш-эффекты, но вносят вклад и в долговременную модуляцию космических лучей. Это делает корональные выбросы главным спорадическим проявлением солнечной активности, которое следует учитывать в моделях модуляции. В работе предложен новый вариант CME-индекса, полученный на основе сопоставления данных спутниковых коронографов с Форбуш-эффектами и долговременными вариациями космических лучей.

РАЗЛИЧИЕ ХАРАКТЕРИСТИК СОЛНЕЧНЫХ МАКРОСПИКУЛ НА НИЗКИХ И ВЫСОКИХ ШИРОТАХ

Богачёв С. А., Лобода И. П., Рева А. А., Ульянов А. С., Кириченко А. С.
ПАЖ Том: 48Номер: 1 Год: 2022 Страницы: 52-60

Исследованы 49 солнечных макроспикул, наблюдавшихся в 2010 г., на фазе роста солнечного цикла, на высоких (околополярных) и на низких широтах вблизи солнечного экватора. Мы нашли, что темп формирования макроспикул в пределах точности измерения не зависит от широты и составляет ∼0.1 град$^{-2}$ ч$^{-1}$. Одновременно установлено, что средняя высота макроспикул вблизи экватора и полюсов заметно различается. После устранения эффектов проекции нами получено значение 31.7±0.2 тыс. км для макроспикул на низких широтах и 39.1±0.3 тыс. км для высокоширотных макроспикул.

РЕСТРУКТУРИЗАЦИЯ МАГНИТНЫХ ПОЛЕЙ СОЛНЦА И ЦЕНТРЫ ВСПЫШЕЧНОЙ АКТИВНОСТИ В ЦИКЛЕ 24

БОРОВИК А. В.*1, МОРДВИНОВ А. В.*1, ГОЛУБЕВА Е. М.*

1, ЖДАНОВ А. А.

АЖ Том: 97Номер: 6 Год: **2020** Страницы: 521-528

Выполнен анализ развития магнитной активности Солнца в цикле 24. Показано, что значительная северо-южная асимметрия магнитной активности сопровождалась асинхронной реорганизацией магнитных полей Солнца в северном и южном полушариях. Изучено формирование униполярных магнитных областей после распада центров активности. Показано, что меридиональный перенос униполярных магнитных областей приводит к изменениям зональной структуры магнитного поля Солнца. Установлено, что долгоживущие центры вспышечной активности существовали в периоды перестройки магнитных полей. Показано, что пространственно-временной анализ вспышечного ансамбля дает возможность для диагностики нестационарных процессов в атмосфере Солнца.

Исследования солнечной активности в Байкальской астрофизической обсерватории ИСЗФ СО РАН.

Боровик *А.В., Головко А.А., Поляков В.И., Трифонов В.Д., Язев С.А.*

СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том 5. 2019. № 3. **С.** 21–35

https://naukaru.ru/ru/storage/view/40054

В статье приведены основные результаты исследований Солнца в Байкальской астрофизической обсерватории (БАО) Института солнечно-земной физики Сибирского отделения Российской академии наук за 40 лет существования обсерватории. Кратко изложена история развития обсерватории, упомянуты телескопы, находящиеся на ее территории. Основное внимание уделено Большому солнечному вакуумному телескопу (БСВТ) и хромосферному телескопу полного диска Солнца. Рассказывается о научных задачах, которые решаются с помощью этих инструментов. Представлены некоторые результаты исследований, выполненных на БСВТ и хромосферном телескопе. Приведен список основных публикаций, в которых использованы результаты наблюдений в БАО.

ВОЗМОЖНОСТЬ ДИАГНОСТИКИ НАЧАЛА 25-ГО СОЛНЕЧНОГО ЦИКЛА НА ОСНОВЕ ЕГО ПРЕДВЕСТНИКОВ НА СРЕДНИХ ГЕЛИОШИРОТАХ

ГОЛОВКО А. А.*

Г. И А. Том: 60Номер: 6 Год: 2020 Страницы: 695-703

Geomagnetism and Aeronomy, **2020**, Vol. 60, No. 6, pp. 684–692.

https://link.springer.com/epdf/10.1134/S0016793220060055?sharing_token=WLatUoRla9c51Y77BLjv7UckSORA_DxfnEvY7GoQybbtIrX37QvPuAi0IQvb5eaSUEmCsXkvcLDX24OJQLvnTwSCsT13Zei9fp2wWiMJ5e0WKrdIqfH_fBuBsHOUBfGtq_EhkPifd8Jic7QJrxNDQZLF8gO6XJRMP-sKPJswTJM%3D

Исследована возможность диагностики начала солнечного цикла на основании обнаружения мелкомасштабных магнитных образований — магнитных узлов эфемерных активных областей в зоне средних гелиоширот от 40° до 60°. Магнитные узлы выявлялись на стадии их возникновения методом мультифрактальной сегментации, использованном ранее для фиксации новых магнитных потоков активных областей в зоне низких гелиоширот. Проведены статистические оценки числа магнитных узлов, фиксируемых таким методом, по данным магнитографа SOLIS NSO для 24-го цикла солнечной активности, а также для начала 25-го цикла активности. Обнаружен предвестник 24-го солнечного цикла в виде всплеска числа магнитных узлов в 2007–2008 гг., значительно превышающего его фоновое значение, характерное для периода 2011–2015 гг. Спустя два года началось появление первых активных областей на широтах 30° ± 10°. Аналогичная последовательность фаз начала цикла обнаружена для 25-го цикла. В отличие от ситуации 24-го цикла, массовое появление высокоширотных активных областей 25-го цикла произошло позже всплеска числа узлов эфемерных активных областей примерно на 2.5 года.

Вариации фактора различия и корреляции солнечных магнитных полей в линиях Fe I 525.02 нм и Na I 589.59 нм по измерениям обсерватории Маунт-Вилсон в 2000–2012 гг.

Голубева Елена

Солнечно-земная физика (Том 4 № 2, **2018**)

https://naukaru.ru/ru/nauka/article/20754/view

На основе сопоставления одновременных измерений обсерватории Маунт-Вилсон в двух спектральных линиях анализируются 13-летние вариации фактора различия магнитных полей. Фактор различия и коэффициент корреляции вычисляются как в общем случае, так и в различных диапазонах значений магнитного поля. Рассматриваются изменения обоих параметров. Демонстрируются следующие тенденции: 1) в общем случае имеют место изменения обоих коэффициентов с циклом солнечной активности; 2) зависимости коэффициентов от величины магнитного поля представляют собой нелинейные функции времени, что особенно ярко выражено в поведении фактора различия; 3) анализ общей картины поведения фактора различия дает возможность выделить несколько характерных диапазонов величины магнитного поля.

Обсуждаются соответствия между этими диапазонами и известными структурными объектами солнечной атмосферы. Это позволяет прийти к заключению, что зависимости рассматриваемых коэффициентов от величины поля и от времени определяются разнообразием структурных магнитных элементов и их циклическими перестройками. Представленные результаты могут быть полезны при решении проблем интерпретации измерений солнечных магнитных полей и для взаимной калибровки инструментов. Также они представляют интерес для задач формирования однородных продолжительных рядов солнечных магнитных полей по данным из различных источников.

Активные долготы и структура крупномасштабного магнитного поля в минимуме солнечной активности.

Григорьев В.М., Ермакова Л.В.

СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том 9 № 4 , **2023** С. 30–37.

https://naukaru.ru/ru/storage/viewWindow/138047

По данным каталогов групп солнечных пятен RGO и USAF/NOAA рассмотрены глубокие минимумы 11-летних циклов солнечной активности 13-14, 14-15, 22-23, 23-24, 24-25. Все они имеют большое количество беспятенных дней. Несмотря на это, активные долготы как предпочтительные зоны, где возникают солнечные пятна, проявляются на этой стадии цикла. Анализ синоптических карт и отдельных ежедневных магнитограмм WSO (Wilcox Solar Observatory), отражающих структуру слабого крупномасштабного поля, обнаруживает неосесимметричную компоненту магнитного поля Солнца. В минимуме активности в структуре крупномасштабного магнитного поля наблюдаются вытянутые вдоль меридиана области положительной и отрицательной полярностей, пересекающие экватор. Наиболее заметные из них находятся в зоне активных долгот и часто связаны с полярными магнитными полями. Обсуждается возможная природа меридиональных структур крупномасштабного поля в период минимума активности. Возможно, это связано с гигантскими ячейками конвекции, имеющими структуру банановых ячеек.

Появление активных областей в период завершения 24-го и начала 25-го циклов активности.

Григорьев *В.М., Ермакова Л.В., Хлыстова А.И.*

Солн.-земн. Физика Том 8. **2022**. № 4 С. 29–37.

https://naukaru.ru/ru/storage/viewWindow/105299

Изучение пространственно-временной картины появления активных областей и связи их возникновения со структурой и развитием крупномасштабного магнитного поля (КМП) проводилось в период смены 24-го и 25-го циклов солнечной активности. В этот период не отмечается бурного развития активности и поэтому динамика КМП в процессе появления новых активных областей наиболее заметна. Использовались данные SDO/HMI о продольном магнитном поле для определения времени и гелиографических координат места возникновения активной области и ежедневные карты WSO (Wilcox Solar Observatory) для сравнения со структурой КМП. Получены следующие результаты. В переходный период от одного цикла к другому новые активные области возникали в половине случаев на границе раздела полярностей КМП, причем почти исключительно на хейловских границах в соответствующих полусферах и циклах активности. В остальных случаях местом возникновения были униполярные области КМП без видимого преимущества в расположении областей поля по правилу Хейла. Образование активных областей предваряется или сопровождается изменениями в структуре КМП, при этом в тонкой структуре магнитного поля в фотосфере может наблюдаться усиление сетки магнитного поля на пространственном масштабе размера супергранул и более, а также появление малых областей нового магнитного поля обеих полярностей. Возникающие активные области концентрировались в двух узких долготных зонах, которые покрывали обе полусферы Солнца. Новый цикл начинался в тех же долготных зонах, где затухала активность старого цикла.

КРУПНОМАСШТАБНЫЕ МАГНИТНЫЕ ПОЛЯ СОЛНЦА ПО НАБЛЮДЕНИЯМ В ВИДИМЫХ И ИНФРАКРАСНЫХ ЛИНИЯХ И НЕКОТОРЫЕ ПРОБЛЕМЫ КОСМИЧЕСКОЙ ПОГОДЫ

Демидов М.Л., Ханаока И., Сакураи Т.

Изв. КрАО Том: **119** Номер: **2** Год: **2023**

Одним из наиболее актуальных направлений современной науки, имеющим к тому же важный прикладной аспект, является космическая погода (КП) - исследование и прогноз физических условий в межпланетном космическом пространстве, обусловленных процессами на Солнце. В настоящее время достигнут значительный прогресс в прогнозировании таких важных параметров КП, как скорость и плотность солнечного ветра. Но некоторые проблемы по-прежнему далеки от решения. Одна из таких проблем - противоречие в рассчитанных по различным моделям и наблюдаемых значениях напряженности межпланетного магнитного поля (ММП). Попытки устранить такое различие, например посредством корректировки магнитограмм, носят довольно искусственный характер и не дают стабильного результата. Основной целью настоящей работы, наряду с задачей сопоставления солнечных полнодисковых магнитограмм, получаемых в различных обсерваториях, является попытка разрешения данного противоречия посредством использования новых наблюдений,

выполненных в инфракрасных линиях. Такие линии, как известно, отличаются более высокой чувствительностью к слабым магнитным полям (а именно слабые крупномасштабные магнитные поля определяют параметры ММП), чем линии видимого диапазона. Измерения в инфракрасных линиях Fe i 1564.8 нм, Si i 1082.7 нм, He i 1083.0 нм выполняются на инструменте IRmag (Infrared Stokes spectro-polarimeter) Национальной астрономической обсерватории Японии (NAOJ). Использованные наблюдения в линиях видимого диапазона выполнены на инструментах GONG, SDO/HMI, Wilcox Solar Observatory (WSO), Солнечном телескопе оперативных прогнозов Саянской солнечной обсерватории (СТОП ССО). Обнаружено, что систематические различия в магнитограммах, выполненных в различных линиях, могут быть очень значительными и достигать фактора 2-5. Показано, что при использовании в расчетах ММП наблюдений в линии Si i 1082.7 нм удается в значительной степени устранить противоречие между модельными расчетами и экспериментальными результатами.

О ВОЗМОЖНОСТЯХ И ПРОБЛЕМАХ НАБЛЮДЕНИЙ МАГНИТНЫХ ПОЛЕЙ СОЛНЦА ДЛЯ ПРОГНОЗА КОСМИЧЕСКОЙ ПОГОДЫ

ДЕМИДОВ М.Л.

СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том: 3Номер: 1 Год: **2017** Страницы: 22-33

Важной составной частью актуальной в последние десятилетия проблемы космической погоды является прогноз параметров околоземного космического пространства, состояния ионосферы и геомагнитной активности на основе наблюдений различных явлений на Солнце. Особо значимы измерения магнитных полей, поскольку именно они определяют пространственную структуру внешних слоев солнечной атмосферы и в значительной степени параметры солнечного ветра. Ввиду отсутствия в настоящее время возможностей наблюдений магнитных полей непосредственно в короне практически единственным источником разнообразных моделей количественного расчета параметров гелиосферы являются измеряемые в фотосферных линиях ежедневные магнитограммы и получаемые на их основе синоптические карты. При этом оказывается, что результаты прогноза, в частности, скорости солнечного ветра на орбите Земли и положения гелиосферного токового слоя сильно зависят не только от выбранной модели расчетов, но и от исходного материала, поскольку магнитограммы различных инструментов (а зачастую и наблюдения в разных линиях на одном и том же телескопе) хотя и похожи морфологически, но могут значительно различаться при подробном количественном анализе. Детальному рассмотрению именно этого аспекта проблемы космической погоды посвящена значительная часть настоящей работы.

ИНДЕКСЫ СОЛНЕЧНОЙ АКТИВНОСТИ ДЛЯ ИОНОСФЕРЫ В ЦИКЛАХ 23 И 24: ФОРМА ЦИКЛОВ

Деминов М.Г., Деминов Р.Г., Непомнящая Е.В.

ГиА Том: 62Номер: 1 Год: 2022 Страницы: 75-80

Проведен анализ особенностей формы низких солнечных циклов 23 и 24 для индексов солнечной активности (*F* – потока солнечного радиоизлучения на длине волны 10.7 см, *Rz* и *Ri* – относительного числа солнечных пятен, прежняя и новая версии) и ионосферного индекса этой активности *T*. Для этого анализируемые индексы приведены к шкале *Rz* и рассмотрены сглаженные (с помощью 24-месячного гауссова фильтра) значения этих индексов. Получено, что для циклов 23 и 24 и предыдущих солнечных циклов по индексу *Rz* форма циклов сохранялась, т.е. выполнялась определенная связь между амплитудой цикла и временем наступления максимума цикла. Эта же связь соблюдалась для индекса *Ri*, за исключением цикла 23, когда наблюдаемое время наступления максимума цикла произошло на 7 месяцев позже времени, ожидаемого на основе предыдущих циклов. Для индексов *F* и *T* форма циклов также сохранялась вплоть до цикла 22, но в циклах 23 и 24 наблюдаемые максимумы циклов произошли почти на год позже ожидаемых, что является одним из свойств нового режима продолжительной низкой солнечной активности. В этом режиме нарушается связь между индексами *Ri* и *F*, что и приводит к разным формам циклов для этих индексов.

ИНДЕКСЫ СОЛНЕЧНОЙ АКТИВНОСТИ ДЛЯ ПАРАМЕТРОВ ИОНОСФЕРЫ В ЦИКЛАХ 23 И 24

Деминов М.Г., Непомнящая Е.В., Обридко В.Н.

ГиА Том: 60Номер: 1 Год: **2020**

Проведен анализ особенностей изменений индексов солнечной активности (F – потока солнечного радиоизлучения на длине волны 10.7 см, Ri – относительного числа солнечных пятен, новая версия) и ионосферного индекса этой активности T в солнечных циклах 23 и 24, которые были низкими по амплитуде солнечной и геомагнитной активности. Для этого рассмотрены скользящие средние за 12 мес. и сглаженные (с помощью 24-месячного фильтра) значения этих индексов. Получено, что в среднем связь между индексами T и F оставалась стабильной для этих циклов и не отличалась от предыдущих солнечных циклов. Связь между индексами T и Ri изменялась со временем в циклах 23 и 24 и отличалась от предыдущих циклов. Кроме того, для цикла 24 наблюдался отчетливый эффект гистерезиса в зависимости сглаженных значений T от Ri, когда на фазах роста и спада солнечного цикла фиксированному значению Ri соответствовали разные значения T. Этот эффект отсутствовал в зависимости T от F. Тем самым подтверждено, что индекс F является более точным, чем Ri, индикатором солнечной активности для ионосферы.

ОБ ОДНОМ ИЗ ВОЗМОЖНЫХ МЕХАНИЗМОВ ОБРАЗОВАНИЯ СПИКУЛ В СПОКОЙНЫХ ОБЛАСТЯХ НА СОЛНЦЕ

ДУНИН-БАРКОВСКАЯ О. В.*✉1, СОМОВ Б. В.*✉

ПАЖ ом: 47Номер: 10 Год: **2021** Страницы: 728-732
В качестве источника энергии для образования спикул в хромосфере Солнца рассмотрена гравитационная энергия падающего из короны вещества. Показано, что в спокойном переходном слое между хромосферой и короной направленный вниз поток вещества может порождать ударную волну, которая движется вверх. При этом часть энергии падающего вещества возвращается в корону и дает вклад в ее нагрев. Рассчитаны необходимые для этого скорости падающего вещества. Соответствующий диапазон скоростей хорошо согласуется с современными наблюдениями.

ОБ ЭФФЕКТИВНОМ МЕХАНИЗМЕ ГЕНЕРАЦИИ УДАРНЫХ ВОЛН В СПОКОЙНОМ ПЕРЕХОДНОМ СЛОЕ СОЛНЦА

ДУНИН-БАРКОВСКАЯ О.В.1, СОМОВ Б.В.

ПАЖ Том: 43Номер: 8 Год: **2016** Страницы: 624-630

В проблеме нагрева короны Солнца обычно постулируются две конкурирующие фундаментальные гипотезы: нагрев нановспышками и нагрев волнами. В рамках второй из них предполагается, что из конвективной зоны приходят акустические и магнитогидродинамические возмущения, амплитуда которых нарастает при распространении в среде с падающей плотностью. Формирующиеся при этом ударные волны нагревают корону. В данной работе мы обращаем внимание на еще один весьма эффективный процесс генерации ударных волн, который может реализоваться при определенных условиях, характерных для спокойных областей на Солнце. В приближении стационарной диссипативной гидродинамики нами показано, что в спокойном переходном слое между короной и хромосферой ударная волна может возникать за счет падения вещества из короны в хромосферу. Такая ударная волна направлена вверх, и ее диссипация в короне возвращает часть кинетической энергии падающего вещества в тепловую энергию короны. Обсуждаются перспективы разработки количественной нестационарной модели явления.

ФИЗИЧЕСКИЕ СВОЙСТВА СПОКОЙНОГО ПЕРЕХОДНОГО СЛОЯ МЕЖДУ КОРОНОЙ И ХРОМОСФЕРОЙ СОЛНЦА

ДУНИН-БАРКОВСКАЯ О.В.1, СОМОВ Б.В.

ПАЖ Том: 42Номер: 12 Год: **2016** Страницы: 908
Представлены результаты исследований физических свойств переходного слоя между короной и хромосферой Солнца в спокойных областях. Здесь структура атмосферы Солнца определяется взаимодействием магнитных полей над фотосферой. Они концентрируются в тонкие трубки, внутри которых велика напряженность поля. Исследовано, как в зависимости от скорости плазмы на хромосферной границе переходного слоя меняются распределения температуры, концентрации и скорости плазмы вдоль магнитной трубки, один конец которой находится в хромосфере, а другой - в короне. Рассмотрены два предельных случая: горизонтально и вертикально расположенная магнитная трубка. Для различных концентраций плазмы определены диапазоны скоростей на хромосферной границе переходного слоя, для которых в переходном слое не должны возбуждаться ударные волны. Показано, что наиболее благоприятными для возбуждения ударных волн в переходном слое являются направленные вниз течения плазмы в его основании. Для всех рассчитанных вариантов переходного слоя показано, что перенос тепловой энергии вдоль магнитных трубок может быть хорошо описан в приближении классической электронной столкновительной теплопроводности вплоть до очень больших скоростей в основании переходного слоя. Рассчитанное жесткое ультрафиолетовое (EUV) излучение хорошо согласуется с современными космическими наблюдениями Солнца.

Квазипериодические колебания мелкомасштабных магнитных структур и специальный метод измерения дифференциального вращения Солнца

Живанович И., Риехокайнен А., Соловьев А.А., Ефремов В.И.
СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том 5. **2019**. № 1., 4–12
https://naukaru.ru/upload/7fd3f86c299d8e1ce467f949bdfec858/files/f851f9b299792a475c14162a4da81b56.pdf
Для изучения дифференциального вращения Солнца с помощью эффекта p2p на основе движений мелкомасштабных магнитных структур в фотосфере были использованы данные SDO/HMI с угловым разрешением 1". Показано, что стабильный p2p-артефакт, присущий данным ПЗС-матрицы SDO/HMI, может быть эффективным средством для измерения скорости различных трассеров на Солнце. В частности, в сочетании с анализом Фурье он позволяет исследовать дифференциальное вращение Солнца на различных широтах. Скорости дифференциального вращения, полученные по магнитограммам SDO/HMI с помощью данного метода, хорошо совпадают с полученными ранее из наземных наблюдений.

ПОВЕРХНОСТНЫЕ И ФУНДАМЕНТАЛЬНЫЕ МОДЫ КОЛЕБАНИЙ В ТОНКИХ КОРОНАЛЬНЫХ АРКАХ

ЖУГЖДА Ю. Д.1

ПАЖ ом: 46Номер: 4 Год: **2020** Страницы: 285-291

Рассмотрены колебания в тонких магнитных трубках в солнечной короне. Показано, что основными модами быстрых и медленных колебаний являются поверхностная и фундаментальная моды колебаний. Медленные поверхностная и фундаментальная моды являются волноводными модами. Быстрая поверхностная мода является излучающей модой, в то время как быстрая фундаментальная мода - это волноводная мода. Рассмотренные нами фундаментальные моды существуют только в магнитных трубках, подверженных влиянию окружающей среды. Наше определение фундаментальных мод не совпадает с общепринятым. Современные наблюдения колебаний в корональных арках вряд ли могут зафиксировать медленные сосисочные моды, первая из которых рассматривается как фундаментальная. Быстрые сосисочные моды также не должны наблюдаться при плохом пространственном разрешении. Исключением является первая быстрая сосисочная мода, обычно рассматриваемая как фундаментальная. Однако эта мода отсутствует в тонких магнитных трубках.

ЦИКЛИЧЕСКИЕ ВАРИАЦИИ, МАГНИТНАЯ МОРФОЛОГИЯ И СЛОЖНОСТЬ АКТИВНЫХ ОБЛАСТЕЙ В 23-М И 24-М СОЛНЕЧНЫХ ЦИКЛАХ

ЖУКОВА А. В.[*][1], **СОКОЛОВ Д. Д.**[*][2], **АБРАМЕНКО В. И.**[1], **ХЛЫСТОВА А. И.**[*]

Г. И А. Том: 60Номер: 6 Год: 2020 Страницы: 683-694

Изучены 2046 активных областей 23-го и 1507 – 24-го солнечных циклов с мая 1996 по декабрь 2018 гг. Группы солнечных пятен распределены в соответствии с недавно предложенной магнито-морфологической классификацией. Выделены регулярные активные области, которые подчиняются закону полярностей Хейла, закону Джоя, с лидирующим пятном, преобладающим над основным хвостовым пятном, а также нерегулярные группы солнечных пятен и одиночные пятна. Показано, что основной вклад в развитие цикла вносят регулярные активные области, что согласуется с моделями магнитного цикла. Вклад нерегулярных групп солнечных пятен примерно в 2–5 раз меньше (в максимумах цикла) и сопоставим с вкладом регулярных активных областей в минимумах цикла, что может свидетельствовать о совместном действии глобального динамо среднего поля и флуктуационного динамо. Увеличение количества нерегулярных активных областей в южном полушарии во втором максимуме каждого из исследованных циклов можно объяснить ослаблением тороидального поля (произведенного глобальным динамо) и увеличением вклада флуктуационного динамо в их конкурентном взаимодействии...

СРАВНИТЕЛЬНЫЙ АНАЛИЗ КВАЗИПЕРИОДИЧЕСКИХ ПРОЦЕССОВ В МАГНИТОСФЕРНОМ ТОКОВОМ СЛОЕ И В ТОКОВЫХ СЛОЯХ СОЛНЕЧНОЙ КОРОНЫ

Зимовец И.В., Лукин А.С., Артемьев А.В.

Косм. Исслед. Том: 60Номер: 6 Год: **2022** Страницы: 454-470

Пересоединение магнитных силовых линий представляет собой универсальный процесс высвобождения запасенной энергии магнитного поля и ее трансформации в тепловую энергию плазмы и энергию ускоренных заряженных частиц. Инициализация и протекание процесса магнитного пересоединения существенным образом связана с динамикой пространственно локализованной области сильных плазменных токов – токового слоя. Две наиболее изученные космические магнитоплазменные системы, содержащие токовые слои, – это хвостовая область земной магнитосферы и области с близко расположенными вытянутыми силовыми линиями магнитного поля противоположной полярности в солнечной короне (в частности, лучи корональных стримеров и эруптивные вспышки). Однако, если для земной магнитосферы основным источником информации о структуре и динамике токовых слоев являются многочисленные прямые измерения спутниковых миссий, то для солнечной короны некоторые характеристики токового слоя могут восстанавливаться на основе удаленных наблюдений квазипериодических осцилляций. Как следствие, для прояснения возможных механизмов, ответственных за данные осцилляции, представляется актуальным сопоставление свойств осцилляций токового слоя земной магнитосферы и токовых слоев солнечной короны. Именно такому сравнительному анализу и посвящена данная работа, в которой приводится небольшой обзор имеющейся информации о квазипериодической динамике магнитосферного токового слоя и обсуждается вероятная интерпретация данной динамики в терминах и параметрах наблюдений квазипериодических процессов в токовых слоях солнечной короны.

ИТОГИ И УРОКИ 24 ЦИКЛА – ПЕРВОГО ЦИКЛА ВТОРОЙ ЭПОХИ ПОНИЖЕННОЙ СОЛНЕЧНОЙ АКТИВНОСТИ

Ишков В. Н.

АЖ Том: 99Номер: 1 Год: 2022 Страницы: 54-69

Прошедший 24 цикл солнечной активности реализовался в условиях, когда после переходного 23 цикла фоновые значения общего магнитного поля Солнца уменьшились более чем в два раза, что привело к полной перестройке физических условий на Солнце, и, как следствие, в гелиосфере, и отразилось на состоянии околоземного космического пространства. Он реализовался как цикл низкой величины, пятнообразовательная и вспышечная активность которого существенно ниже всех предыдущих солнечных циклов космической эры, и впервые на достоверном ряде наблюдений солнечных пятен предоставил возможность детально исследовать ход его развития как начального цикла эпохи пониженной солнечной активности.

ЭКСТРЕМАЛЬНЫЕ СОБЫТИЯ КОСМИЧЕСКОЙ ПОГОДЫ В ПЕРВЫЕ ЦИКЛЫ ЭПОХ ПОНИЖЕННОЙ СОЛНЕЧНОЙ АКТИВНОСТИ

Ишков В. Н.

Г и А Том: 61Номер: 6 Год: 2021 Страницы: 704-712

DOI: 10.31857/S0016794021060080
По однородному ряду геомагнитного индекса *Aa* с учетом современной шкалы интенсивности возмущений в околоземном космическом пространстве и сценария солнечной цикличности рассмотрен вопрос о распределении экстремальных и очень больших магнитных бурь, интенсивности (G5, G4), в первых циклах (12 и 24) эпох пониженной солнечной активности. Значительное уменьшение количества таких событий и солнечных активных явлений в последнем цикле может свидетельствовать о том, что пятнообразовательная и вспышечная активность в солнечном цикле 12 была значимо выше, чем в цикле 24, но значительно уступала солнечным циклам эпохи повышенной солнечной активности.

ТЕКУЩИЙ 24 ЦИКЛ СОЛНЕЧНОЙ АКТИВНОСТИ В ФАЗЕ МИНИМУМА: ПРЕДВАРИТЕЛЬНЫЕ ИТОГИ И ОСОБЕННОСТИ РАЗВИТИЯ

ИШКОВ В.Н.

Косм. Исслед. Том: 58Номер: 6 Год: 2020 Страницы: 471-478

Характеристики и ход развития текущего 24 цикла солнечной активности (СА) позволяют отнести его к циклам эпох пониженной СА. Сравнение эволюционных изменений циклов различных эпох в фазах минимума позволило выделить две группы по темпу спада. Первая группа с относительно быстрым спадом (~15 мес.) включает в себя все циклы эпох повышенной СА, переходных периодов и цикл 16 из эпохи пониженной СА. Вторая, с медленным спадом (~40 мес.), остальные циклы эпох пониженной СА, в том числе и текущий 24, минимум которого можно ожидать уже в первой половине 2020.

КОСМИЧЕСКАЯ ПОГОДА И ОСОБЕННОСТИ РАЗВИТИЯ ТЕКУЩЕГО 24-ГО ЦИКЛА СОЛНЕЧНОЙ АКТИВНОСТИ

ИШКОВ В.Н.*

ГиА Том: 58Номер: 6 Год: **2018** Страницы: 785-800

Согласно сценарию цикличности достоверного ряда относительных чисел солнечных пятен 24-й цикл открывает вторую эпоху пониженной солнечной активности (СА). Основной особенностью этой эпохи (5 циклов) – запрет на осуществление высоких солнечных циклов и непременное выполнение основных наблюдательных правил в развитии отдельных циклов. Уменьшение более чем в два раза фоновых значений общего магнитного поля Солнца к концу 23-го цикла привело к полной перестройке физических условий как на Солнце, так и во внутренней гелиосфере, и отразилось на состоянии околоземного космического пространства (ОКП). Текущий 24-й солнечный цикл после 9.2 лет развития стал циклом низкой величины (W* = 81.9) с пониженной вспышечной активностью, с более низкой геоэффективностью солнечных активных явлений, с практическим отсутствием самых мощных солнечных вспышечных явлений, солнечных протонных событий, проявлений геомагнитной активности и ионосферных возмущений.

МОГУТ ЛИ СУПЕРВСПЫШКИ ПРОИСХОДИТЬ НА СОЛНЦЕ? ВЗГЛЯД С ТОЧКИ ЗРЕНИЯ ТЕОРИИ ДИНАМО

Кацова М.М., Кичатинов Л.Л., Лившиц М.А., Мосс Д.Л., Соколов Д.Д., Усоскин И.Г.

АЖ Том: 95Номер: 1 Год: **2018** Страницы: 78-87

Недавние результаты миссии "Kepler" показали, что на звездах, подобных Солнцу, могут происходить супервспышки, которые существенно превосходят по энерговыделению все когда-либо наблюдавшиеся солнечные вспышки. Данные по радионуклидам не дают оснований предполагать наличие супервспышек на Солнце в течение последних 11 тыс. лет. Естественно считать, что механизм динамо на звездах с супервспышками в некотором отношении отличается от солнечного. В работе выявляются управляющие параметры динамо, которые могут описывать различие между Солнцем и звездами с супервспышками. Наша цель состоит в том, чтобы предложить механизм динамо, максимально близкий к обычному солнечному (звездному) динамо, но способный создать существенно больший запас магнитной энергии. Механизм динамо, основанный на совместном действии дифференциального вращения и зеркально асимметричных движений среды, в принципе может приводить к генерации двух типов магнитных конфигураций. Это хорошо известные в физике Солнца волны магнитного поля (динамо-волны). Однако возможен и другой тип решений, при которых магнитное поле сначала растет, а затем стабилизируется. При сопоставимых условиях напряженность магнитных полей второго типа решений существенно больше, чем первого, просто потому, что возможности динамо не тратятся на периодические изменения знака магнитного поля, а целиком расходуются на его усиление. Мы проанализировали имеющиеся результаты наблюдений миссии "Kepler" озвездах с супервспышками, чтобы найти индикаторы аномальной магнитной активности. Отталкиваясь от недавней работы [1], мы приходим к выводу, что антисолнечное дифференциальное вращение или антисолнечный знак зеркальной асимметрии как раз и являются факторами, способными обеспечить необходимую величину магнитного поля в моделях звездного динамо. Мы подтверждаем это представление численными моделями звездного динамо с подобными параметрами. Мы полагаем, что такой механизм может объяснить феномен супервспышек, по крайней мере, для некоторых звезд поздних спектральных классов, включая двойные звезды, субгиганты, маломассивные звезды и молодые быстро вращающиеся звезды.

ПРОИСХОЖДЕНИЕ ПРИПОВЕРХНОСТНОГО СЛОЯ НЕОДНОРОДНОГО ВРАЩЕНИЯ СОЛНЦА

Кичатинов Л.Л.

ПАЖ Том: 49Номер: 11 Год: 2023 Страницы: 829-836

Гелиосейсмология обнаружила возрастание скорости вращения с глубиной в тонком (~30 Мм) приповерхностном слое. Относительная величина неоднородности вращения в этом слое не зависит от широты. Показано, что такое состояние вращения является следствием малого характерного времени приповерхностной конвекции по сравнению с периодом вращения и радиальной анизотропии конвективной турбулентности. Аналитические расчеты в рамках гидродинамики средних полей воспроизводят наблюдаемую величину относительной неоднородности вращения и согласуются с численными экспериментами по радиационной гидродинамике солнечной конвекции. Приповерхностный слой является источником глобального меридионального течения, важного для солнечного динамо.

РАСПАД КРУПНОМАСШТАБНОГО МАГНИТНОГО ПОЛЯ НА ТРУБКИ У ОСНОВАНИЯ КОНВЕКТИВНОЙ ЗОНЫ СОЛНЦА

КИЧАТИНОВ Л.Л.

АЖ Том: 45Номер: 1 Год: **2019** Страницы: 45-54

Подавление турбулентной теплопроводности магнитным полем приводит к неустойчивости крупномасштабного поля с образованием изолированных в пространстве областей усиленного поля. К такому выводу приводит линейный анализ устойчивости в рамках магнитной гидродинамики средних полей с учетом зависимости теплопроводности от напряженности поля. Характерное время развития неустойчивости мало по сравнению с 11-летним периодом солнечной активности. Размер областей усиленного поля составляет десятки тысяч километров. Данная неустойчивость может создавать магнитные неоднородности, всплывание которых на солнечную поверхность создает активные области Солнца. Магнитная энергия образующихся сгустков поля совпадает по порядку величины с энергией активных областей.

АСИММЕТРИЯ СОЛНЕЧНЫХ ЦИКЛОВ КАК СЛЕДСТВИЕ ФЛУКТУАЦИЙ ПАРАМЕТРОВ ДИНАМО

КИЧАТИНОВ Л.Л.1, НЕПОМНЯЩИХ А.А.1

АЖ: Том: 44Номер: 10 Год: **2018** Страницы: 705-712

Длительность ветви роста активности в солнечных циклах в среднем короче длительности ветви спада. Показано, что к такой асимметрии могут приводить флуктуации параметров динамо. Модель солнечного динамо с флуктуациями α -эффекта показывает среднестатистическую асимметрию, которая увеличивается с возрастанием как амплитуды, так и длительности флуктуаций. Предложено объяснение вызванной флуктуациями асимметрии, которое предсказывает корреляцию между величиной асимметрии и временем запаздывания обращений знака полярного поля относительно максимума активности. Такая корреляция подтверждается данными о двенадцати последних солнечных циклах.

К ПОИСКУ НАБЛЮДАТЕЛЬНЫХ ПРОЯВЛЕНИЙ АЛЬВЕНОВСКИХ ВОЛН В СОЛНЕЧНЫХ ФАКЕЛАХ

КОБАНОВ Н.И.1, ЧУПИН С.А.1, ЧЕЛПАНОВ А.А.1

АЖ Том: 43Номер: 12 Год: **2017** Страницы: 925-934

С целью обнаружения крутильных колебаний выполнены исследования периодических вариаций полуширины нескольких спектральных линий в солнечных факелах. Длительность анализируемых серий составляла от 40 до 150 мин. Были определены доминирующие частоты и амплитуды колебаний полуширины, рассмотрены их фазовые связи с колебаниями интенсивности и лучевой скорости. В линии верхней фотосферы Si I 10827 А в факелах уверенно регистрируются пятиминутные колебания полуширины профиля около 10 мЛ (peak-to-peak). Профили хромосферных линий He I 10830 Л и Na показывают вариации величиной около 40-60 мЛ в двух частотных диапазонах 2.5-4 мГц и 1 - 1.9 мГц. В поведении амплитуд этих колебаний не выявлено зависимости центр-лимб, которая, согласно теории, должна сопровождать крутильные колебания. В рамках современных представлений эти вариации не могут быть вызваны периодическими изменениями температуры и магнитного поля. Наши наблюдения также не позволяют объяснить эти вариации и действием "сосисочной" моды (sausage mode), которое должно проявляться на удвоенной частоте.

О ВЕРОЯТНОЙ СМЕНЕ СТАТУСА ТЕКУЩЕГО НЕОРДИНАРНОГО СБОЯ 11-ЛЕТНЕЙ ЦИКЛИЧНОСТИ СОЛНЦА С ЛОКАЛЬНОГО НА ГЛОБАЛЬНЫЙ

КОЗЛОВ В.И.*

КОСМИЧЕСКИЕ ИССЛЕДОВАНИЯ Том: 59Номер: 2 Год: 2021 Страницы: 92-101

Обнаруженное по галактическим космическим лучам (ГКЛ) аномальное увеличение площади солнечного цикла 23 явилось предвестником сбоя 11-летней цикличности: в соответствии с гипотезой автора об инварианте 22-летнего цикла, вслед за увеличением площади 23 цикла последовало уменьшение площади (энергоемкости) следующего 24 цикла. Уменьшение энергоемкости сопровождается уменьшением (относительной вариации) светимости Солнца, которая в 24-цикле уменьшилась до уровня среднего значения трех предыдущих циклов, т.е. практически вдвое. При сохранении инварианта 22-летнего цикла следует ожидать восстановления 11-летней цикличности в 25-м цикле. При нарушении инварианта 22-летнего цикла, уровень радиационного фона ГКЛ в максимуме предстоящего 25 цикла (с 2024 на 2025 гг.) должен быть не ниже уровня фонового излучения в максимуме 24 цикла (2014 г.). В этом случае, состояние неординарного сбоя 23-24-25 циклов изменится с локального на глобальный.

ГЛАВНЫЙ АРГУМЕНТ ПРОТИВ ПУЛЬСАЦИЙ СОЛНЦА

Котов В.А.

Изв. КрАО Том: 119Номер: 4 Год: 2023 Страницы: 27-34

Близость периода колебаний Солнца, 0.111 сут, к 9-й гармонике среднесолнечных суток представляется оппонентами в качестве основного аргумента против колебаний. Мы показываем, что на деле он, наоборот, доказывает реальность явления, поскольку суточный период Земли, повидимому, является фундаментальной временн´ой шкалой Солнечной системы, тесно связанной с движениями Солнца, Меркурия, Венеры и Земли. Однако истинная природа солнечных колебаний остается неизвестной.

МАГНИТНЫЕ ЦИКЛЫ СОЛНЦА И РЕЗОНАНСЫ СОЛНЕЧНОЙ СИСТЕМЫ

Котов В.А.

Изв. КрАО Том: 119 Номер: 1 Год: 2023 Страницы: 42-47

Общее магнитное поле Солнца в КрАО, Стэнфорде и пяти других обсерваториях измерялось с 1968 по 2021 гг. (в сумме более 28 тыс. суточных значений). Из этих данных следует, что поле изменяется с циклом Хейла PH ≈ 22 г. и периодом P7 ≈ 7 лет, отношение которых совпадает с приближением Архимеда, 22:7, для числа п. Показано, что в пределах ошибок измеряемых величин (а) орбитальный период Земли PE = (1 - 3/п)PH = (п - 3)P7 = P2$_\odot$/2PD, где P$_\odot$ ≈ 27 сут - синодический период вращения Солнца, а PD - среднесолнечные сутки; (б) связь PE-PH следует также из измерений полярного поля Солнца; (в) шкала PE тесно связана с движением Венеры. Выдвинута гипотеза, что годовой и суточный периоды движения нашей планеты, скорость вращения Солнца и цикл Хейла, объединенные числами 2, 3 и п, имеют космологический смысл и фундаментальное значение для Солнца, Земли и Солнечной системы. Истинная природа связи движений Солнца и Земли с циклом Хейла неизвестна.

ПЯТЬДЕСЯТ ЛЕТ ИССЛЕДОВАНИЯ ПОВЕДЕНИЯ ИНТЕНСИВНОСТИ ГКЛ В ПЕРИОДЫ ИНВЕРСИИ ГЕЛИОСФЕРНОГО МАГНИТНОГО ПОЛЯ. II. ИНВЕРСИЯ ГМП НА ВНУТРЕННЕЙ ГРАНИЦЕ ГЕЛИОСФЕРЫ

КРАЙНЕВ М.Б.[1], **КАЛИНИН М.С.**[1]

СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том: 10 Номер: 3 Год: 2024 Страницы: 40-52

Явления в наружном слое солнечной атмосферы, гелиосфере, включающие сверхзвуковой солнечный ветер, переносимое им гелиосферное магнитное поле (ГМП) и распространяющиеся в гелиосфере космические лучи, важны для многих процессов, происходящих в этом слое. Для некоторых, например геомагнитной активности или распространения космических лучей, важны не только напряженность, но и направление поля. Но если в этом отношении ситуация в периоды низкой пятенной солнечной активности вполне ясна - гелиосфера разделена на два полушария с противоположной полярностью (к Солнцу/от Солнца) - в периоды высокой активности Солнца, когда происходит инверсия ГМП, простой модели этого явления нет. В статье продолжается исследование явления инверсии ГМП и связанных с ним эффектов в интенсивности галактических космических лучей (ГКЛ). Ранее были сформулированы общие представления о 22-летней цикличности в характеристиках Солнца, гелиосферы и космических лучей и подробно обсуждались наблюдаемые эффекты в интенсивности ГКЛ, связываемые нами с

инверсией ГМП. В данной работе рассмотрена модель инверсии ГМП, связанной лишь с эволюцией магнитного поля в слое между фотосферой и основанием гелиосферы из-за изменения распределения фотосферных полей от оборота к обороту Солнца, и показано, что этого недостаточно для объяснения основных эффектов в интенсивности ГКЛ. В указанном слое магнитное поле является основным энергетическим фактором. Более полная модель инверсии ГМП, включающая преобразование его характеристик из-за взаимодействия разноскоростных потоков солнечного ветра в самой гелиосфере, где солнечный ветер является основным энергетическим фактором, будет обсуждаться в следующей статье.

Пятьдесят лет исследования поведения интенсивности ГКЛ в периоды инверсии гелиосферного магнитного поля. I. Наблюдаемые эффекты.

https://naukaru.ru/ru/storage/viewWindow/138045

Впервые эффекты 22-летней цикличности солнечных магнитных полей в интенсивности галактических космических лучей (ГКЛ) были замечены группой ФИАН в 1973 г. и интерпретированы как проявления инверсии высокоширотного магнитного поля Солнца в свойствах гелиосферных магнитных полей. С тех пор эти эффекты исследуются уже в течение пятидесяти лет. Для периодов средней и низкой пятенной активности ситуация с гелиосферным магнитным полем (ГМП) понятна: гелиосфера состоит из двух униполярных «полушарий», разделенных волнистым глобальным гелиосферным токовым слоем и характеризующихся общей полярностью A (единичная величина со знаком радиальной компоненты поля в северном полушарии). Однако нет единого мнения, в чем заключается инверсия ГМП и какие явления в ГКЛ с ней связаны. В статье кратко формулируются общие представления о 22-летней цикличности в характеристиках Солнца, гелиосферы и ГКЛ и обсуждаются наблюдаемые эффекты в интенсивности ГКЛ, связываемые нами с инверсией ГМП. Модели этого явления, а также результаты расчетов интенсивности ГКЛ, использующих эти модели, будут обсуждаться в следующей статье.

ПРОЯВЛЕНИЯ В ГЕЛИОСФЕРЕ И В ИНТЕНСИВНОСТИ ГКЛ ДВУХ ВЕТВЕЙ СОЛНЕЧНОЙ АКТИВНОСТИ

Крайнев М.Б.

СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том 5 № 4 ,2019 С 12-25

https://naukaru.ru/ru/storage/viewWindow/43510

Дается представление о процессах в гелиосфере и модуляции галактических космических лучей (ГКЛ) в ней как результатах действия в этом слое Солнца двух ветвей солнечной активности, называемых по топологии солнечных магнитных полей внутри Солнца тороидальной ветвью (активные области, пятна, вспышки, корональные выбросы массы и т. д.) и полоидальной ветвью (высокоширотные магнитные поля, полярные корональные дыры, зональные униполярные магнитные области и т. д.). Формулируется основная причина различного проявления обеих ветвей на поверхности Солнца и в гелиосфере — наличие в основании гелиосферы слоя, в котором основным энергетическим фактором является магнитное поле. При этом преимущество при проникновении в гелиосферу получают более крупномасштабные, хотя и менее интенсивные солнечные магнитные поля полоидальной ветви. Показана связь с полоидальной ветвью солнечной активности гелиосферных характеристик (поле скорости солнечного ветра, размер гелиосферы, форма гелиосферного токового слоя, регулярное гелиосферное магнитное поле и его флуктуации), которые, согласно современным представлениям, определяют распространение в гелиосфере ГКЛ.

НЕЛИНЕЙНАЯ ЗАВИСИМОСТЬ ПОТОКА ИЗЛУЧЕНИЯ СОЛНЦА ОТ ЧИСЕЛ ВОЛЬФА И ЕЕ РАЗЛИЧИЕ ДЛЯ РАЗНЫХ 11-ЛЕТНИХ ЦИКЛОВ

Лаптухов А.И., Лаптухов В.А.

Г и А Том: 61Номер: 5 Год: 2021 Страницы: 547-554

DOI: 10.31857/S0016794021050084

Установлена статистическая нелинейная немонотонная зависимость среднесуточных величин солнечной “постоянной” от суточных чисел Вольфа. Предложен физический механизм этой нелинейной зависимости. Показано, что поток излучения Солнца для 11-летних циклов с высокой и низкой активностью существенно разный и, кроме того, он выше на фазе роста, чем на фазе спада цикла. Эти особенности надо учитывать при восстановлении солнечной “постоянной” на основе суточных чисел Вольфа.

СВЯЗЬ СЕВЕРО-ЮЖНОЙ АСИММЕТРИИ ПЯТНООБРАЗОВАНИЯ С АМПЛИТУДОЙ 11-ЛЕТНИХ ЦИКЛОВ СОЛНЕЧНОЙ АКТИВНОСТИ

ЛАТЫШЕВ С.В.1, ОЛЕМСКОЙ С.В.

ПАЖ Том: 42Номер: 7 Год: **2016** Страницы: 540
По данным о солнечных пятнах RGO/USAF/NOAA установлена связь северо-южной асимметрии пятнообразования с амплитудой 11-летних циклов. Показано, что чем выше амплитуда солнечного цикла, тем меньше абсолютное значение северо-южной асимметрии. Выявленная закономерность исследована в численной модели динамо с нерегулярными изменениями альфа-эффекта.

ФОРМИРОВАНИЕ ВЕКОВОГО РЯДА ДАННЫХ ПО СОЛНЕЧНОЙ ХРОМОСФЕРЕ ДЛЯ ИССЛЕДОВАНИЙ, СВЯЗАННЫХ С СОЛНЕЧНОЙ АКТИВНОСТЬЮ

СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том: 3Номер: 2 Год: **2017** Страницы: 5-9
В статье представлен наш действующий проект «Формирование векового ряда данных по солнечной хромосфере для исследований, связанных с солнечной активностью». Солнечная активность является главным фактором космической погоды, влияющим на жизнь человечества. Некоторые серьезные последствия воздействия космической погоды, например, нарушение космической связи и навигации, угроза безопасности астронавтов и спутников, повреждение электрических систем. Поэтому исследование солнечной активности имеет и научный, и социальный аспекты. Основная база данных формируется из оцифрованных и нормированных данных, полученных в нескольких обсерваториях по всему земному шару, и покрывает более чем 100-летний временной интервал. После тщательной калибровки мы сможем извлечь и получить данные и вместе с полной базой данных предоставить их астрономическому сообществу. Нашей конечной целью является привлечение внимания к нескольким физическим проблемам: поведение волокон в солнечном цикле, аномальный ход 24 цикла, крупномасштабные солнечные эрупции и дистанционно-индуцированные уярчения. Существенный прогресс ожидается в разработке алгоритмов получения данных и программного обеспечения, что поможет научному анализу и в итоге будет способствовать пониманию солнечных циклов.

ПОДТВЕРЖДЕНИЕ "ПОТЕРЯННОГО" ЦИКЛА И ПРАВИЛА ГНЕВЫШЕВА-ОЛЯ В РЯДЕ ПЛОЩАДЕЙ СОЛНЕЧНЫХ ПЯТЕН ЗА 410 ЛЕТ

НАГОВИЦЫН Ю.А.

ПАЖ Том: 50 Номер: 8 Год: 2024 Страницы: 561-566
Правило Гневышева-Оля рассмотрено для нового ряда площадей солнечных пятен на четырехвековой шкале Наговицына и Осиповой (MNRAS 505, 1206, 2021). Принята гипотеза Усоскина и др. (Astron. Astrophys. 370, L31, 2001) о существовании на ветви спада цикла № 4 цюрихской нумерации дополнительного малого цикла. Это приводит к изменению четности циклов ранее № 5. Выделены 11-летние циклы в XVII в. Их средняя продолжительность - от минимума до минимума - составляет T = 8.9 ± 1.4 года. Новые данные и подходы позволили заключить, что правило Гневышева-Оля выполняется для 410-летнего интервала в целом без исключения пары циклов №№ 4-5 цюрихской нумерации, принимаемого в правиле ранее.

ПРАВИЛО ГНЕВЫШЕВА-ОЛЯ: СОВРЕМЕННЫЙ СТАТУС

НАГОВИЦЫН Ю.А.[1,2], **ОСИПОВА А.А.**[1], **ИВАНОВ В.Г.**[1]

АЖ Том: 101Номер: 1 Год: 2024 Страницы: 56-64
Проведено статистическое исследование утверждений, содержащихся в Правиле Гневышева-Оля (ПГО) и в некоторых его толкованиях. Показано, что ПГО в его оригинальной формулировке для индекса суммарной активности за 11-летний цикл SW, фиксирующее тесную связь в паре четный-последующий нечетный цикл (ЧН) и ее отсутствие в противоположной паре (НЧ), строго выполняется для современных наблюдательных данных - версии 2.0 чисел пятен (чисел Вольфа) - при уровне значимости a=0.01. При этом за четным 11-летним циклом следует нечетный с большим S W. Для амплитуд циклов ПГО существует лишь как тенденция, и различие зависимостей пар циклов ЧН и НЧ статистически незначимо. Статистически не подтверждается также чередование величины циклов как для параметра S W, так и для амплитуд. Получено, что различные аспекты ПГО статистически лучше выполняются для новой версии 2.0 относительных чисел пятен - чисел Вольфа, что говорит в пользу ее дальнейшего успешного использования для исследований в солнечной физике.

ЭКСТРЕМАЛЬНЫЕ ЗНАЧЕНИЯ СОЛНЕЧНОЙ ПЯТНООБРАЗОВАТЕЛЬНОЙ ДЕЯТЕЛЬНОСТИ НА ДЛИТЕЛЬНОЙ ВРЕМЕННОЙ ШКАЛЕ

***Наговицын** Ю.А., Осипова А.А.*
ПАЖ Том: 49Номер: 7 Год: **2023** Страницы: 506-514
Рассмотрены экстремальные уровни солнечной активности на временных шкалах 300–400 и 9000 лет. Суммарная площадь солнечных пятен AR — физический индекс активности Солнца — оценена с помощью реконструкции числа солнечных пятен, полученной в работе By и др. (Astron. Astrophys. 615, A93, 2018). Основное исследование проведено именно в терминах этого индекса. Изменения солнечной активности в эпоху последних 300–400 лет достаточно хорошо представляют ее изменения на временах порядка девяти тысячелетий. Максимальный уровень солнечной активности для среднегодовых значений составил AR_M=2930±400 м.д.п. (миллионных долей полусферы). Верхний предел для суточных значений составил AR_M=7500±2200 м.д.п. для традиционных площадей пятен, скорректированных за перспективное искажение, и AR_{OM}=11400±3300 м.д.д. (миллионных долей диска Солнца) для так называемых "наблюдаемых" площадей —

проекций пятен на видимый диск Солнца. Оценены также максимальные среднегодовые значения чисел пятен SN_M=258±38 и чисел групп пятен GN_M=12.3±2.4; 11.3% времени солнечная активность находится на экстремально высоком уровне; 8.5% времени ее уровень соответствует минимуму Дальтона и ниже и 4.5% — крайне низкому. Таким образом, для солнечной активности более вероятны экстремально высокие уровни, чем экстремально низкие.

ДВЕ ПОПУЛЯЦИИ СОЛНЕЧНЫХ ПЯТЕН И ВЕКОВЫЕ ИЗМЕНЕНИЯ ИХ ХАРАКТЕРИСТИК

Ю. А. **Наговицын**1, 2*, А. А. Певцов3, А. А. Осипова1,
А. Г. Тлатов1, Е. В. Милецкий1, Е. Ю. Наговицына1
ПИСЬМА В АСТРОНОМИЧЕСКИЙЖУРНАЛ, **2016**, том 42,№10, с. 773–782
Исследуются магнитные поля и полные площади средне- и низкоширотных солнечных пятен на основе наблюдений в обсерваториях Гринвич, Кисловодск (площади пятен); Маунт-Вилсон, КрАО, Пулково, Урал,ИМИС, Уссурийск,ИЗМИРАН,Шемаха (магнитные поля). Показано, что в линейной форме зависимости логарифма полной площади пятна S от его центрального магнитного поля H коэффициенты изменяются со временем. На двумерной гистограмме встречаемости в осях H − log S выявляются две популяции пятен: мелкие и крупные, разделенные границами log S = 1.6 (S = 40 мдп) и H = 2050 Гс. Рассмотрение пятенного магнитного потока выявляет с высокой степенью достоверности существование двух логнормально распределенных популяций со средней границей между ними Ф = 1021 Мх. В то же время положения максимумов встречаемости значений потока у популяций изменяются на вековой шкале: у мелких пятен в 4.5 раза, у крупных — в 1.15 раза. Подтверждено, что пятна образуют две физически различающиеся популяции, и показано, что свойства этих популяций заметно изменяются со временем. Это согласуется с гипотезой о существовании двух зон генерации пятенного магнитного поля на Солнце в свете пространственно-распределенного динамо.

СТРУКТУРА СОЛНЕЧНОГО ЦИКЛА И ЦИКЛОВ АКТИВНОСТИ ЗВЕЗД ПОЗДНИХ СПЕКТРАЛЬНЫХ ТИПОВ

Обридко В.Н., Соколов Д.Д., Кацова М.М.
АЖ Том: 100Номер: 12 Год: 2023 Страницы: 1311-1321
DOI: 10.31857/S000462992312006X
Показано, что использование описания солнечного цикла, учитывающего нечетную зональную гармонику магнитного поля Солнца, позволяет углубить наши знания о двух важных аспектах солнечной активности: во-первых, уточнить и расширить предсказания на ближайшее будущее эволюции циклической активности Солнца; во-вторых, сформулировать программу мониторинга спектрофотометрических характеристик излучения звезд, подобных Солнцу, нацеленную на получение новой информации об их магнитных полях.

МЕРИДИОНАЛЬНАЯ СОСТАВЛЯЮЩАЯ КРУПНОМАСШТАБНОГО ПОЛЯ В МИНИМУМЕ И ХАРАКТЕРИСТИКИ ПОСЛЕДУЮЩЕГО ЦИКЛА СОЛНЕЧНОЙ АКТИВНОСТИ

ОБРИДКО В.Н.1, ШЕЛЬТИНГ Б.Д.1
ПАЖ Том: 43Номер: 10 Год: **2017** Страницы: 770
Известно, что полярное поле вблизи минимума цикла коррелирует с высотой следующего максимума числа солнечных пятен. Есть основание полагать, что в формировании следующего цикла важную роль может играть взаимодействие полушарий. Одним из индексов связи полушарий может быть меридиональная составляющая крупномасштабного магнитного поля. Для анализа были использованы реконструированные данные о крупномасштабном магнитном поле за 1915□1986 гг. Показано, что в нескольких циклах удается таким образом описать не только высоту, но и общий ход цикла с заблаговременностью около 6 лет. По современным данным с 1976 по 2016 г. такая связь подтвердилась, однако более перспективным оказался параметр отношения меридионального поля к полной абсолютной величине вектора поля. В данной работе он вычислялся на высоте около 70 Мм над фотосферой. Оценка даты предстоящего минимума с использованием этого параметра - середина 2018 г., использование глобального поля в качестве прогностического параметра дает более позднюю дату минимума - начало 2020 г.

ВЛИЯНИЕ ЦИКЛА ГЛЕЙСБЕРГА НА ВАРИАЦИИ ПЕРИОДА 11-ЛЕТНЕГО ЦИКЛА СОЛНЕЧНОЙ АКТИВНОСТИ В 1700–2021 ГГ.

ПТИЦЫНА Н.Г.*[1], **ДЕМИНА И.М.**[1]
ГиА Том: 63Номер: 3 Год: 2023 Страницы: 284-297
При помощи вейвлет-анализа проведено исследование спектрального состава числа солнечных пятен *SN* в течение 1700–2021 гг. Кроме доминирующей 11-летней составляющей, в спектре прослеживаются две мощные составляющие цикла Глейсберга: до 1880 г. ветвь с периодом ~60 лет, с 1850 г. ~115 лет. Найдено, что ряды длины и амплитуды солнечного

цикла в целом находятся в обратной зависимости (коэффициент корреляции $k = -0.5...-0.63$). Лаг между рядами, при котором достигается максимум антикорреляции, зависит от времени. В XVIII–начале XIX века лаг равен одному циклу, в XIX в. – двум циклам, а начиная с 1950 г. и до нашего времени лаг уменьшается до 2 лет. Выделены квазипериодические структуры, которые характерны для длительных периодов пониженной солнечной активности. Такая спектральная особенность в ~1800 г. (минимум Дальтона) вызвана влиянием 60-летней ветви, а формирующаяся с начала XXI в. – более слабым влиянием околостолетней. Поэтому следует ожидать, что ближайшие солнечные циклы будут более высокими и менее длинными, чем в период минимума Дальтона. Показано, что вариации длины солнечного цикла за последние 321 год могут быть описаны в рамках модели, представляющей собой 11-летнее колебание, которое подвергается частотной модуляции ветвями цикла Глейсберга (60 и 115 лет) с изменяющимся во времени влиянием модулятора.

ЧАСТОТНАЯ МОДУЛЯЦИЯ КАК ПРИЧИНА ВОЗНИКНОВЕНИЯ ДОПОЛНИТЕЛЬНЫХ ВЕТВЕЙ ВЕКОВОГО ЦИКЛА ГЛЕЙСБЕРГА В СОЛНЕЧНОЙ АКТИВНОСТИ

Птицына Н.Г., Демина И.М.

ГиА Том: 62Номер: 1 Год: 2022 Страницы: 52-66

Среди цикличностей солнечной активности с периодом более 22 лет вековой цикл, или цикл Глейсберга, привлекает наибольшее внимание исследователей. В данной работе методами Фурье и вейвлет-анализа проведено изучение цикличности солнечной активности, выраженной числом солнечных пятен *SN*, реконструированных из разных источников (длина рядов до ~12 000 лет), в диапазоне периодов цикла Глейсберга. Найдено, что цикл Глейсберга состоит из трех выделенных ветвей со средними периодами 60, 88 и 140 лет. Характер амплитудной вариации всех трех ветвей идентичен, что указывает на то, что они являются частью одного квазипериодического процесса. Анализ показал, что 88-летний цикл является основным. Его источником является солнечное динамо. А 60- и 140-летние циклы являются результатом частотной модуляции основного цикла процессом с периодом 224 года (цикл Зюсса). Построена модель, которая подтверждает и объясняет этот результат. Цикл Зюсса, являющийся частотным модулятором цикла Глейсберга, скорее всего, имеет внесолнечное происхождение. Наши результаты не поддерживают гипотезу о хаотическом Солнце, свидетельствуя о более регулярном квазиопериодическом поведении солнечного динамо.

НЕВИДИМОЕ ДИНАМО В МОДЕЛЯХ СРЕДНЕГО ПОЛЯ

РЕШЕТНЯК М.Ю.

ПАЖ Том: 42Номер: 7 Год: **2016** Страницы: 533

Решена обратная задача в сферической оболочке по нахождению двумерных пространственных распределений -эффекта и дифференциального вращения в модели динамо среднего поля. Полученные распределения приводят к генерации магнитного поля, сконцентрированного внутри конвективной зоны. Показано, что за счет магнитной диффузии магнитное поле за время смены полярности не успевает выйти из области максимальной генерации, расположенной в нижних слоях, к поверхности. Отношение максимальной магнитной энергии в конвективной зоне к ее значению на внешней границе достигает двух порядков и более. Полученный результат важен при интерпретации наблюдаемых звездных и планетарных магнитных полей. Предложенный метод решения обратной задачи нелинейного динамо легко адаптируется для широкого класса задач математической физики.

ФАЗОВОЕ ПРОСТРАНСТВО ДВУМЕРНОЙ МОДЕЛИ ДИНАМО ПАРКЕРА

РЕШЕТНЯК М. Ю.1

АЖ Том: 93 Номер: 2 Год: **2016** Страницы: 254

На примере двумерной модели Паркера в сферическом слое рассмотрены зависимости интенсивности магнитного поля, его вариаций, уровня мультипольности от амплитуд - и -эффектов. Расчеты приведены как для традиционных в астрофизике пространственных распределений и , так и для геострофических режимов, полученных из трехмерного моделирования тепловой конвекции. Приведены двумерные распределения скоростей динамо-волн в зоне генерации магнитного поля. Предложены сопоставления с солнечным и планетарным динамо.

ОСОБЕННОСТИ ДОЛГОТНОГО РАСПРЕДЕЛЕНИЯ ГРУПП СОЛНЕЧНЫХ ПЯТЕН ЗА ПОСЛЕДНИЕ ЧЕТЫРЕ ОДИННАДЦАТИЛЕТНИХ ЦИКЛА

РЫБАК А.Л.

СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том: 2Номер: 2 **2016** Страницы: 22-28

Рассматривается долготное распределение групп солнечных пятен за период 1982-2013 гг. по данным Национального центра геофизических данных (Боулдер, США). Анализируется пространственно-временное распределение групп солнечных пятен по координатным секторам, полученным на основе гелиографических долгот групп. Долготная протяженность координатного сектора сопоставляется со средним размером одной активной области (30-40°). Далее в каждом координатном секторе за все время наблюдения суммируется эволюционная активность групп пятен по классификационной оценке Малдэ. Построенное таким образом долготное распределение групп крупных пятен не показывает отрицательной корреляции между северным и южным полушариями

Солнца в 23-м цикле пятнообразования.

РЕЗУЛЬТАТЫ НАБЛЮДЕНИЙ СОЛНЕЧНОЙ АКТИВНОСТИ В МИРОВОМ ЦЕНТРЕ ДАННЫХ ПО СОЛНЕЧНО-ЗЕМНОЙ ФИЗИКЕ

СЕРГЕЕВА Н.А. 1, ЗАБАРИНСКАЯ Л.П.1, ИШКОВ В.Н.2, КРЫЛОВА Т.А.1

Косм. Исслед. Том: 57Номер: 1 Год: **2019** Страницы: 12-16

В настоящее время экспериментальные данные о солнечной активности находят самое широкое применение в области фундаментальных и прикладных научных исследований – изучении явлений, происходящих на Солнце и в межпланетном пространстве, и их влияния на процессы во внешних и внутренних оболочках Земли. Наиболее ценными являются данные многолетних наблюдений. Мировой центр данных по солнечно-земной физике в Москве обладает представительной коллекцией результатов наблюдений, полученных мировой сетью солнечных и астрономических обсерваторий и на приборах, установленных на космических аппаратах. В статье приводится описание данных о солнечной активности, находящихся в хранилище и опубликованных на веб-сайте Центра в открытом доступе. Центр постоянно совершенствуется, использует новые информационные технологии, обеспечивающие свободный, удобный доступ к данным и возможность цитирования данных, увеличивает информационные ресурсы, доступные в сети Интернет.

НЕКОТОРЫЕ НЕРЕШЕННЫЕ ПРОБЛЕМЫ СОЛНЕЧНОГО ДИНАМО Review

СОКОЛОВ Д.Д.[1,2,3]

Изв. КрАО Том: 118Номер: 1 Год: 2022 Страницы: 12-17
https://www.elibrary.ru/download/elibrary_48073410_55559976.pdf

В изучении работы солнечного динамо сейчас намечается переход к задачам прогноза солнечной активности. При этом важно сохранить тематику изучения основ солнечного динамо. В этой связи дается обзор некоторых задач по выяснению основ работы солнечного динамо, которые остаются до настоящего времени недостаточно исследованными. Эти задачи важны для понимания не только природы магнитной активности Солнца, но и ее эволюционного статуса среди подобных звезд.

ДИНАМО – МЕХАНИЗМ ГЕНЕРАЦИИ МАГНИТНОГО ПОЛЯ В РАЗЛИЧНЫХ ТИПАХ НЕБЕСНЫХ ТЕЛ

Соколов Д.Д.

Астрономия-2018 Том 1 Современная звездная астрономия **2018** Стр. 43

ВЫСШИЕ ИНВАРИАНТЫ СПИРАЛЬНОСТИ И СОЛНЕЧНОЕ ДИНАМО

СОКОЛОВ Д.Д.1,2, ИЛЛАРИОНОВ Е.А.1, АХМЕТЬЕВ П.М.2

ГиА Том: 57Номер: 1 Год: **2017** Страницы: 123-128

Современные модели нелинейного насыщения динамо в небесных телах и, в частности, на Солнце во многом основаны на рассмотрении баланса магнитной спиральности. Эта физическая величина имеет и топологический смысл: она связана с коэффициентом зацепления магнитных трубок. Кроме магнитной спиральности, в магнитной гидродинамике имеется еще ряд топологических интегралов движения, так называемые высшие моменты спиральности. Мы сравнили свойства этих инвариантов со свойствами магнитной спиральности и пришли к выводу, что они вряд ли могут служить в качестве нелинейных ограничений действия динамо.

УЕДИНЕННЫЙ ФАКЕЛЬНЫЙ УЗЕЛ: ФОНТАННАЯ МАГНИТНАЯ СТРУКТУРА И ТЕМПЕРАТУРНЫЙ ПРОФИЛЬ

СОЛОВЬЕВ А. А.1

ПАЖ Том: 46Номер: 11 Год: **2020** Страницы: 792-801

На основе предложенной ранее стационарной 3D-модели солнечного факельного узла развит ее модифицированный вариант, в котором отражен уединенный характер факельного объекта: его магнитное поле резко ограничено в радиальном направлении. Температурный профиль факела, рассчитанный для стационарного состояния такой магнитной структуры, сопоставляется с фильтрограммой высокого разрешения, полученной в фотосферной линии TiO 7057 Å на Big Bear Solar Observatory 19 июня 2017 г. на New Solar Telescope (с апертурой 1.6 м). Снимок изображает две близко расположенных очень темных микропоры с поперечником около 300 км каждая. Микропоры окружены веером тонких, светлых, радиально вытянутых волоконец, напоминающим полутень солнечного пятна. Теоретически рассчитанный T-профиль факельного узла полностью воспроизводит эти морфологические особенности моделируемого объекта.

КОРРЕЛЯЦИЯ ВРЕМЕННЫ́Х РЯДОВ ЧИСЕЛ ВОЛЬФА И ИХ ПРОИЗВОДНЫХ

Старченко С.В., Яковлева С.В.

Г и А Том: 62Номер: 6 Год: 2022 Страницы: 693-701
DOI: 10.31857/S0016794022050169

Приведены результаты исследования корреляции среднегодовых чисел Вольфа W и их временны́х производных W' при сдвигах во времени фрагментов рядов W и W' относительно друг друга. Наиболее значимые (до 0.88 и –0.85) коэффициенты корреляции и антикорреляции получаются при сдвигах на два-три года для фрагментов, охватывающих два 11-летних цикла. Для более длительных фрагментов коэффициенты остаются значимыми (на уровнях около ±0.8) при тех же сдвигах. Поэтому сдвиг по фазе между W и W' составляет примерно четверть солнечного цикла, что физически соответствует преимущественной связи пятен с магнитной энергией. При этом также значим сдвиг на 8–9 лет, которому соответствуют коэффициенты корреляции на уровнях около ±0.75. Обсуждаются прогностические потенциалы полученных корреляционных зависимостей.

ПРОСТЕЙШЕЕ ДИНАМО СОЛНЦА И НОВЫЙ МЕХАНИЗМ СТАБИЛИЗАЦИИ

Старченко С.В.

Г и А Том: 62Номер: 2 Год: 2022 139-143

Показано, что для гидромагнитного динамо Солнца и подобных ему динамо, возможно, значимой является стабилизирующая нелинейность, обратно пропорциональная величине электрического тока. Соответствующая простейшая локальная гидромагнитная модель для магнитной энергии состоит из одного неоднородного линейного обыкновенного дифференциального уравнения, которое детализируется для солнечных пятен. Простейшее же глобальное солнечное динамо может достоверно определяться двумя однородными линейными обыкновенными дифференциальными уравнениями, имитирующими известные альфа-эффект и омега-эффект.

СОЛНЕЧНАЯ АКТИВНОСТЬ ЗА ПОСЛЕДНИЕ 20 ЛЕТ И ЕЕ ПРОГНОЗ НА 25-Й СОЛНЕЧНЫЙ ЦИКЛ

СТОЖКОВ Ю.И.✉1, ХЛОПКОВ В.П.

КОСМИЧЕСКИЕ ИССЛЕДОВАНИЯ Том: 62Номер: 4 Год**: 2024** Страницы: 329-333

Экспериментальные данные о солнечной активности (числе солнечных пятен Rz, индукции полоидального магнитного поля Солнца в полярных шапках Вп и другие), характеристики межпланетной среды и потоки космических лучей свидетельствуют о том, что Солнце вступило в глубокий минимум своей активности, подобный минимуму Дальтона. Обнаружена почти функциональная связь максимальной величины Впmax, наблюдаемой в минимумах солнечной активности, с предстоящим максимумом солнечных пятен. На основе этой связи разработан метод прогнозирования максимального числа солнечных пятен Rzmax и временного хода значений Rz в текущем (в настоящее время 25-ом) цикле солнечной активности.

Сделан обзор проведенных в последнее время экспериментальных и теоретических исследований источников колебаний и волн в атмосфере солнечных пятен. Представлены результаты наблюдений на наземных и космических инструментах. Показана важная роль механизма частотного обрезания в формировании пространственного распределения узкополосных источников колебаний в атмосфере пятен. Обсуждаются альтернативные методы исследования структуры магнитного поля с использованием полученных гелиосейсмологических результатов. Исследована динамика распространяющихся волновых фронтов с использованием метода попиксельной вейвлет-фильтрации. Проведен анализ параметров колебаний с высотой. Рассмотрена возможность инициации вспышечного энерговыделения МГД-волнами, проникающими из области пятен в область вспышки вдоль магнитных волноводов. Уделено внимание процессам усиления волновой активности в пятнах перед началом вспышки. Дано краткое описание теоретической модели на основе подфотосферного низкочастотного резонатора.

НАПРАВЛЕННАЯ ФИЛЬТРАЦИЯ ДЛЯ ОБРАБОТКИ ИЗОБРАЖЕНИЙ/ВИДЕОИЗОБРАЖЕНИЙ СОЛНЦА

ЛУН **СЮЙ**1, ЙИХУА ЯН1, ЦЗЮНЬ ЧЭН1

Солнечно-земная физика Том: 3Номер: 2 Год: **2017** Страницы: 10-17

В данной работе предлагается новый алгоритм повышения четкости изображений, использующий направленную фильтрацию для улучшения изображений и видеоизображений Солнца, который позволит легко выделять существенные мелкие структуры. Предлагаемый алгоритм может эффективно устранять шумы на изображениях, в том числе гауссовы и импульсные шумы. Кроме того, он может выделять волокнистые структуры на/за солнечным диском. Такие структуры наглядно демонстрируют развитие солнечной вспышки, протуберанца, выброса корональной массы, магнитного поля и т. д. Полученные

экспериментальные результаты показывают, что предложенный алгоритм значительно повышает качество изображений Солнца по сравнению с первоначальными и несколькими классическими алгоритмами улучшения изображений, что облегчит определение **всплесков солнечного радиоизлучения по изображениям/ видеоизображениям Солнца**

Пространственные и временные вариации формы контуров линии K Ca II в различных структурных образованиях солнечной хромосферы. II. Методика определения и корреляционные соотношения между параметрами линии для участков K1 и K2.

Турова И.П., Григорьева С.А., Ожогина О.А.
СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том 6. **2020**. № 4. С. 10–17.
http://ru.iszf.irk.ru/images/3/3f/756238_10-17.pdf
Исследовались две области в атмосфере Солнца, находящиеся в основании корональной дыры. Вычислен ряд параметров линии K Ca II для минимумов интенсивности K_1 и пиков K_2, которые образуются на высотах между верхней фотосферой и нижней хромосферой, и в нижней хромосфере, соответственно. Уточнена методика определения сдвигов контура $\Delta\lambda_{K_{1v}}$ и $\Delta\lambda_{K_{1r}}$, $\Delta\lambda_{K_{2v}}$ и $\Delta\lambda_{K_{2r}}$, включая случаи, когда их прямое нахождение затруднено. Вычислены интенсивности $I_{K_{1v}}$, $I_{K_{1r}}$, $I_{K_{2v}}$, $I_{K_{2r}}$, разделения минимумов K_1 и пиков K_2: $SEP_{K_1}=\Delta\lambda_{K_{1r}}-\Delta\lambda_{K_{1v}}$, $SEP_{K_2}=\Delta\lambda_{K_{2r}}-\Delta\lambda_{K_{2v}}$ соответственно. Построены графики рассеяния и определены корреляционные соотношения между параметрами, относящимися к разным уровням атмосферы. Получены следующие результаты. Интенсивности, которые наблюдаются в нижней и средней хромосфере связаны между собой сильнее, чем интенсивности, относящиеся к верхней фотосфере и средней хромосфере. Структуры с усиленным магнитным полем более яркие на уровне верхней фотосферы и нижней хромосферы по отношению к структурам с более слабым полем. Разделения минимумов K_1 имеют большую величину для структур с усиленным магнитным полем по отношению к структурам с более слабым полем, тогда как для разделения пиков K_2 картина обратная — они меньше для структур с усиленным магнитным полем. Такая зависимость имеет место не только для выбранных структур спокойной области, но и для флоккулов, хотя по флоккулам требуется дополнительная статистика. Зависимость между сдвигами интенсивности минимумов K_1 и пиков K_2 для фиолетового и красного крыльев оказалась слабой. Это может быть связано как с существенным вкладом случайных движений в поле скоростей на уровнях верхней фотосферы и нижней хромосферы, так и с разностью высот образования фиолетового и красного крыльев.

ХАРАКТЕРИСТИКИ ПЕРЕНОСА ЭНЕРГИИ АЛЬВЕНОВСКИХ ВОЛН В АТМОСФЕРЕ СОЛНЦА

Цап Ю.Т., Степанов А.В., Копылова Ю.Г., Ханейчук О.В.
Г и А Том: 60Номер: 4 Год: **2020** Страницы: 463-468
В условиях изотермической атмосферы с учетом амплитудно-фазовых соотношений рассмотрены особенности распространения линейных альвеновских волн с периодами 10–200 с из фотосферы в хромосферу Солнца. Установлено, что с увеличением высоты амплитуда возмущения скорости волн растет, а возмущения магнитного поля – падает, тогда как разность фаз между возмущениями стремится к $\pi/2$. Так называемые точки поворота не могут адекватно характеризовать поток энергии альвеновских волн. Этот вывод свидетельствует о необходимости пересмотра результатов, следующих из анализа осциляционных теорем. Показано, что в пренебрежении диссипативными процессами эффективность переноса волновой энергии с ростом частоты альвеновских мод увеличивается.

МЕЖПЛАНЕТНЫЕ МЕРЦАНИЯ АНСАМБЛЯ РАДИОИСТОЧНИКОВ В МАКСИМУМЕ 24 ЦИКЛА СОЛНЕЧНОЙ АКТИВНОСТИ

ЧАШЕЙ И.В.1, ШИШОВ В.И.1, ТЮЛЬБАШЕВ С.А.1, СУБАЕВ И.А.1
КОСМИЧЕСКИЕ ИССЛЕДОВАНИЯ Том: 54 Номер: 3 Год: **2016** Страницы: 188-194
Представлены результаты наблюдений межпланетных мерцаний, выполненных в период максимума солнечной активности с апреля 2013 г. по апрель 2014 г. на радиотелескопе БСА ФИАН на частоте 111 МГц. Круглосуточно регистрировались флуктуации потока радиоизлучения всех источников с мерцающим потоком более 0.2 Ян, попадающих в полоску неба шириной 50° по склонениям, соответствующую 96-лучевой диаграмме направленности радиотелескопа. Полное число источников, наблюдавшихся в течение суток, достигало 5000. Обработка данных наблюдений проводилась в предположении, что совокупность мерцающих источников представляет собой однородный статистический ансамбль. Ежедневно строились двумерные карты распределения уровня мерцаний, анализ которых показывает сильную нестационарность и крупномасштабную неоднородность пространственного распределения параметров солнечного ветра. По картам распределения уровня мерцаний, усредненным по месячным интервалам, исследована глобальная структура распределения солнечного ветра в период максимума солнечной активности, которая оказалась в среднем близкой к сферически симметричной. Полученные данные показывают, что на сферически

симметричном фоне наблюдается восточно-западная асимметрия, которая свидетельствует о присутствии в солнечном ветре крупномасштабных структур спирального типа.

Обзор и сравнение особенностей МГД-волн на Солнце и в магнитосфере Земли. Review

Челпанов *М.А., Анфиногентов С.А., Костарев Д.В., Михайлова О.С., Рубцов А.В., Феденёв В.В., Челпанов А.А.*

Магнитогидродинамические (МГД) волны играют ключевую роль в процессах, протекающих в плазменных образованиях в атмосфере Солнца и звезд, а также в магнитосфере Земли и других планет. В настоящий момент известно, что в этих системах имеют место как схожие волновые явления, так и уникальные для каждой из сред. Изучение МГД-волн и сопутствующих явлений в магнитосферной физике и физике Солнца происходит в основном независимо, несмотря на то, что свойства этих сред во многом схожи, а физические основы генерации и распространения волн в них одинаковы. Создание единого подхода к изучению этих явлений на Солнце и в земной магнитосфере открывает перспективы дальнейшего развития и интеграции этих научных направлений. В обзоре рассмотрено текущее состояние исследований МГД-волн в атмосфере Солнца и магнитосфере Земли. Приведены особенности сред, в которых распространяются колебания, их структура, масштабы и типичные параметры. Дано описание основных теоретических моделей, в рамках которых принято изучать поведение волн, их преимущества и ограничения. Сравниваются характеристики различных типов МГД-волн применительно к солнечной атмосфере и земной магнитосфере. Кроме того, представлена информация о методах наблюдений и инструментах, используемых для получения информации о волнах в различных средах.

СОЛНЕЧНЫЙ КВАДРУПОЛЬ В ТЕНЗОРНОМ ОПИСАНИИ

ШИБАЛОВА А. С.*1, ОБРИДКО В. Н.1, СОКОЛОВ Д. Д.1, ПИПИН В. В.2

АЖ Том: 97Номер: 10 Год: **2020** Страницы: 849-857

В работе исследуются циклические вариации квадрупольного компонента магнитного поля Солнца в рамках тензорного описания. Результаты согласуются с классическим описанием квадруполя с помощью сферических функций, а математический аппарат тензорной алгебры позволяет сравнивать наблюдаемые изменения магнитного квадруполя и изменения, предсказываемые теориями магнитного динамо. Мы пришли к выводу, что свойства квадруполя могут быть достаточно хорошо описаны моделями солнечного динамо, предполагающими отклонения от дипольной симметрии без независимого возбуждения мод квадрупольной симметрии.

ФАЗОВЫЙ СДВИГ МЕЖДУ ПОЛУШАРИЯМИ В ЦИКЛЕ СОЛНЕЧНОЙ АКТИВНОСТИ

ШИБАЛОВА А.С.1, ОБРИДКО В.Н.2, СОКОЛОВ Д.Д.

АЖ Том: 93Номер: 10 Год: **2016** Страницы: 918

Исследован сдвиг солнечных циклов активности в северном и южном полушариях Солнца по данным о числе и площадях солнечных пятен. Полученные данные сопоставлены с архивными сведениями об эпизодах существенной асимметрии солнечных циклов. Небольшой фазовый сдвиг между современными циклами активности в северном и южном полушариях Солнца существенно отличается от эпизодов заметных отклонений от дипольной симметрии распределения солнечных пятен, которые с разной степенью достоверности фиксируются по архивным данным об астрономических наблюдениях XVII□XIX вв. В настоящее время временной сдвиг между полушариями невелик и составляет около 6□7 месяцев. В недавней истории солнечной активности этот сдвиг дважды менял знак, что, по-видимому, соответствует его более-менее периодическим изменениям с характерным временем, близким к длительности цикла Гляйсберга.

25-Й ЦИКЛ СОЛНЕЧНОЙ АКТИВНОСТИ: ПЕРВЫЕ ТРИ ГОДА

Язев *С.А., Исаева Е.С., Хос-Эрдэнэ Б.*

СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том: 9Номер: 3 Год: **2023** Страницы: 5-11

Выполнен анализ особенностей текущего 25-го цикла солнечной активности на протяжении первых трех лет развития (2020-2022 гг.). Показано, что по сравнению с предыдущим 24-м циклом текущий превышает его по количеству групп пятен (в 1.5 раза), числу вспышек (в 1.8 раза), суммарному вспышечному индексу (в 1.5 раза). Выявлены различия в распределениях групп пятен в 24-м и 25-м циклах по максимальной достигаемой площади. Показано, что в 25-м цикле наиболее значимо превышение числа групп пятен с площадями до 30

м.д.п. (1 м.д.п.=3.04·106 км^2), а также в интервале от 570 до 1000 м.д.п. В отличие от 24-го цикла, степень северо-южной асимметрии в 25-м цикле существенно понижена. Это позволяет прогнозировать повышенную высоту 25-го цикла (на 20-50 %) в соответствии с правилом Гневышева-Оля, а также возможный одновершинный характер цикла.

Комплексы активности на Солнце в 21-м цикле солнечной активности.

Язев С.А., Ульянова М.М., Исаева Е.С.
СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том 7. **2021**. № 4. С. 3–9
https://naukaru.ru/ru/storage/viewWindow/80807
В работе приведены статистические данные о комплексах активности (КА) на Солнце, наблюдавшихся в 21-м цикле солнечной активности. По синоптическим картам пятенной активности за 1976–1986 гг. выделены области, где пятнообразование наблюдалось как минимум на протяжении трех кэррингтоновских оборотов (CR), — эти области идентифицировались как ядра КА. Составлен каталог КА. Показано, что КА развивались квазипериодично импульсами продолжительностью 15–20 оборотов. Выполнен анализ северо-южной асимметрии расположения КА. Показано, что в 21-м цикле 90 % про-тонных вспышек, влияющих на природную среду, произошли в КА. Для 21–24-го циклов отмечена тенденция к уменьшению активности КА от цикла к циклу, а также проявление правила Гневышева—Оля в свойствах КА.

КОРОНА ВО ВРЕМЯ ПОЛНОГО СОЛНЕЧНОГО ЗАТМЕНИЯ 20 МАРТА 2015 Г.И РАЗВИТИЕ 24-ГО ЦИКЛА

ЯЗЕВ С.А.1,2, МОРДВИНОВ А.В.2, ДВОРКИНА-САМАРСКАЯ А.А.1
СОЛНЕЧНО-ЗЕМНАЯ ФИЗИКА Том: 2Номер: 2 Год: **2016** Страницы: 3-11
Выполнен анализ структуры корональных образований по данным наблюдений полного солнечного затмения **20 марта 2015** г. Индекс Людендорфа, характеризующий форму короны, равен 0.09. Структура короны в северном полушарии соответствует фазе максимума цикла солнечной активности, в южном полушарии - постмаксимальной стадии. Асинхронное развитие магнитной активности в северном и южном полушариях Солнца привело к существенной асимметрии корональных структур, наблюдаемых в период смены знака полярных магнитных полей в текущем цикле. Полярные лучевые структуры в южном полушарии связаны с присутствием полярной корональной дыры, в то время как в северном полушарии полярная дыра еще не сформировалась. Выполнен анализ связи крупномасштабных магнитных полей с расположением высоких корональных структур.

КОМПЛЕКСЫ АКТИВНОСТИ НА СОЛНЦЕ В 24-М ЦИКЛЕ СОЛНЕЧНОЙ АКТИВНОСТИ

ЯЗЕВ С.А.
АЖ Том: 92 Номер: 3 Год: **2015** Страницы: 260
Представлены результаты исследования комплексов активности на Солнце в период с 2009 г. по июль 2014 г. Обсуждается определение комплекса активности, рассмотрены закономерности изменения индексов, описывающих мощность комплексов активности, и закономерности пространственно-временного распределения комплексов активности на солнечной поверхности. Показано, что развитие комплексов активности в 24-м цикле отличается высокой степенью северо-южной асимметрии. Новые комплексы активности имеют тенденцию к возникновению вблизи уже существующих структур (в пределах), формируясь одновременно с последними либо вскоре после их исчезновения (спустя 1 4 кэррингтоновских оборота). Приведены аргументы в пользу того, что именно динамика комплексов активности определяет особенности развития цикла, выраженные в индексах чисел Вольфа.

СТАТИСТИЧЕСКИ-ВЕРОЯТНОСТНЫЕ ХАРАКТЕРИСТИКИ ЧИСЕЛ ВОЛЬФА И ИХ ВРЕМЕННЫ́Х ПРОИЗВОДНЫХ

Яковлева С.В., Старченко С.В.
Г и А Том: 62Номер: 2 Год: 2022 144-154
Предложен результат статистически-вероятностного исследования среднегодовых чисел Вольфа W и их временны́х производных W '. Он состоит в том, что вероятностное распределение W преимущественно экспоненциальное с наиболее вероятным значением, равным 18, при среднеквадратичном 100, медианном 65 и среднем 79. Меньше от нормального распределения отклоняются W ' с наиболее вероятным значением –12/год, медианным –6.1/год, средним –0.02/год, среднеквадратичным 33/год, минимумом –74/год и потенциально недостоверным максимумом 112/год. Отношения средних величин согласуются с характерными временами роста/падения активности в 2.6/3.7 лет и 11-летней цикличностью. Даны оценки полувековой периодичности и скорости течений (~1 м/с), поддерживающих динамо.
