High-Speed Solar Wind Streams and Geomagnetic Storms During Solar Cycle 24

M. **Gerontidou**, H. Mavromichalaki, T. Daglis

[Solar Physics](#) September 2018, 293:131

<https://link.springer.com/article/10.1007/s11207-018-1348-8>

An updated catalog is created of 303 well-defined high-speed solar wind streams that occurred in the time period 2009–2016. These streams are identified from solar and interplanetary measurements obtained from the OMNIWeb database as well as from the Solar and Heliospheric Observatory (SOHO) database. This time interval covers the deep minimum observed between the last two Solar Cycles 23 and 24, as well as the ascending, the maximum, and part of the descending phases of the current Solar Cycle 24. The main properties of solar-wind high-speed streams, such as their maximum velocity, their duration, and their possible sources are analyzed in detail. We discuss the relative importance of all those parameters of high-speed solar wind streams and especially of their sources in terms of the different phases of the current cycle. We carry out a comparison between the characteristic parameters of high-speed solar wind streams in the present solar cycle with those of previous solar cycles to understand the dependence of their long-term variation on the cycle phase. Moreover, the present study investigates the varied phenomenology related to the magnetic interactions between these streams and the Earth's magnetosphere. These interactions can initiate geomagnetic disturbances resulting in geomagnetic storms at Earth that may have impact on technology and endanger human activity and health.

we use the timings of different structures/features of **ICMEs and CIRs** detected during solar cycle 23 (1995–2009) from the **catalogue prepared and made available by L. Jian** (http://www-ssc.igpp.ucla.edu/~jlan/ACE/Level3/ICME_List_from_Lan_Jian.pdf) and (http://www-ssc.igpp.ucla.edu/~jlan/ACE/Level3/SIR_List_from_Lan_Jian.pdf).

In addition to light and other wavelengths of electromagnetic radiation the Sun affects our environment through complicated plasma physical processes. The study of these interactions is known as solar–terrestrial physics. Already long before the space era there were indications that solar activity and geomagnetic perturbations must somehow be connected. **A remarkable event was the large flare on the Sun observed, independently, by Carrington [1859] and Hodgson [1859] on September 1, 1859, after which a major magnetic storm commenced only 17 hours later.**

Today we understand that the storm was caused by a magnetic cloud associated with a coronal mass ejection (CME) that reached the Earth exceptionally quickly. The storm was very strong, evidently much stronger than any event recorded during the present era of space weather sensitive equipment in space and on the ground.

Measurements of the Time-Dependent Cosmic-Ray Sun Shadow with Seven Years of IceCube Data -- Comparison with the Solar Cycle and Magnetic Field Models

[M. G. Aartsen](#), [R. Abbasi](#), [M. Ackermann](#), [J. Adams](#), [J. A. Aguilar](#), and many others

2020

<https://arxiv.org/pdf/2006.16298.pdf>

Observations of the time-dependent cosmic-ray Sun shadow have been proven as a valuable diagnostic for the assessment of solar magnetic field models. In this paper, seven years of IceCube data are compared to solar activity and solar magnetic field models. A quantitative comparison of solar magnetic field models with IceCube data on the event rate level is performed for the first time. Additionally, a first energy-dependent analysis is presented and compared to recent predictions. We use seven years of IceCube data for the Moon and the Sun and compare them to simulations on data rate level. The simulations are performed for the geometrical shadow hypothesis for the Moon and the Sun and for a cosmic-ray propagation model governed by the solar magnetic field for the case of the Sun. We find that a linearly decreasing relationship between Sun shadow strength and solar activity is preferred over a constant relationship at the 6.4sigma level. We test two commonly used models of the coronal magnetic field, both combined with a Parker spiral, by modeling cosmic-ray propagation in the solar magnetic field. Both models predict a weakening of the shadow in

times of high solar activity as it is also visible in the data. We find tensions with the data on the order of 3σ for both models, assuming only statistical uncertainties. The magnetic field model CSSS fits the data slightly better than the PFSS model. This is generally consistent with what is found previously by the Tibet AS-gamma Experiment, a deviation of the data from the two models is, however, not significant at this point. Regarding the energy dependence of the Sun shadow, we find indications that the shadowing effect increases with energy during times of high solar activity, in agreement with theoretical predictions.

Slow Solar Wind: Observations and Modeling

Review

L. **Abbo**, L. Ofman, S. K. Antiochos, V. H. Hansteen, L. Harra, Y.-K. Ko, G. Lapenta, B. Li, P. Riley and 3 more

Space Sci. Rev. Volume 201, [Issue 1](#), pp 55–108 2016

While it is certain that the fast solar wind originates from coronal holes, where and how the slow solar wind (SSW) is formed remains an outstanding question in solar physics even in the post-SOHO era. The quest for the SSW origin forms a major objective for the planned future missions such as the Solar Orbiter and Solar Probe Plus. Nonetheless, results from spacecraft data, combined with theoretical modeling, have helped to investigate many aspects of the SSW. Fundamental physical properties of the coronal plasma have been derived from spectroscopic and imaging remote-sensing data and in situ data, and these results have provided crucial insights for a deeper understanding of the origin and acceleration of the SSW. Advanced models of the SSW in coronal streamers and other structures have been developed using 3D MHD and multi-fluid equations.

However, the following questions remain open: What are the source regions and their contributions to the SSW? What is the role of the magnetic topology in the corona for the origin, acceleration and energy deposition of the SSW? What are the possible acceleration and heating mechanisms for the SSW? The aim of this review is to present insights on the SSW origin and formation gathered from the discussions at the International Space Science Institute (ISSI) by the Team entitled “Slow solar wind sources and acceleration mechanisms in the corona” held in Bern (Switzerland) in March 2014 and 2015.

Prediction of the SYM-H Index Using a Bayesian Deep Learning Method With Uncertainty Quantification

Space Weather [Volume22, Issue2](#) February 2024 e2023SW003824

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2023SW003824>

We propose a novel deep learning framework, named SYMHnet, which employs a graph neural network and a bidirectional long short-term memory network to cooperatively learn patterns from solar wind and interplanetary magnetic field parameters for short-term forecasts of the SYM-H index based on 1- and 5-min resolution data. SYMHnet takes, as input, the time series of the parameters' values provided by NASA's Space Science Data Coordinated Archive and predicts, as output, the SYM-H index value at time point $t + w$ hours for a given time point t where w is 1 or 2. By incorporating Bayesian inference into the learning framework, SYMHnet can quantify both aleatoric (data) uncertainty and epistemic (model) uncertainty when predicting future SYM-H indices. Experimental results show that SYMHnet works well at quiet time and storm time, for both 1- and 5-min resolution data. The results also show that SYMHnet generally performs better than related machine learning methods. For example, SYMHnet achieves a forecast skill score (FSS) of 0.343 compared to the FSS of 0.074 of a recent gradient boosting machine (GBM) method when predicting SYM-H indices (1 hr in advance) in a large storm (SYM-H = -393 nT) using 5-min resolution data. When predicting the SYM-H indices (2 hr in advance) in the large storm, SYMHnet achieves an FSS of 0.553 compared to the FSS of 0.087 of the GBM method. In addition, SYMHnet can provide results for both data and model uncertainty quantification, whereas the related methods cannot.

Main Time Characteristics of Cosmic Ray Variations and Related Parameters in Magnetic Clouds.

Abunina, M.A., Belov, A.V., Shlyk, N.S. et al.

Geomagn. Aeron. 64, 24–31 (2024).

<https://doi.org/10.1134/S0016793223600856>

The behavior of the main parameters of the interplanetary medium, cosmic ray variations, and geomagnetic activity as magnetic clouds pass the Earth (466 events from 1967 to 2021) was studied. Time distributions of these parameters during magnetic clouds passage are considered. It is shown that the maximum values of the solar wind velocity, interplanetary magnetic field strength, and geomagnetic activity indices are more often recorded in the front part of the magnetic cloud, while the minimum values of the temperature index, density, and equatorial component of cosmic ray anisotropy can be observed in any part of the studied structure.

Peculiar solar sources and geospace disturbances on 20-26 August 2018

A.A. [Abunin](#), [M.A. Abunina](#), [A.V. Belov](#), [I.M. Chertok](#)

Solar Phys. **295**, 7 (2020)

<https://arxiv.org/ftp/arxiv/papers/1912/1912.08153.pdf>

<https://doi.org/10.1007/s11207-019-1574-8>

<https://link.springer.com/content/pdf/10.1007/s11207-019-1574-8.pdf>

On the approach to minimum of Solar Cycle 24, on 26 August 2018, an unexpectedly strong geomagnetic storm (GMS) suddenly occurred. Its Dst index reached -174 nT, that is the third of the most intense storms during the cycle. The analysis showed that it was initiated by a two-step long filament eruption, which occurred on 20 August in the central sector of the solar disk. The eruptions were accompanied by two large-scale divergent ribbons and dimmings of a considerable size and were followed by relatively weak but evident Earth-directed coronal mass ejections. In the inner corona, their estimated speed was very low of about 200-360 km/s. The respective interplanetary transients apparently propagated between two high-speed solar wind streams originated from a two-component coronal hole and therefore their expansion was limited. The resulting ejecta arrived at the Earth only on 25 August and brought an unexpectedly strong field of $B_t \sim 18.2$ nT with a predominantly negative B_z component of almost the same strength. The geospace storm also manifested itself in the form of a peculiar Forbush decrease (FD). Its magnitude was about 1.5%, which is rather small for the observed G3-class GMS. The main unusual feature of the event is that large positive bursts with an enhancement up to 3% above the pre-event level were recorded on the FD background. We argue that these bursts were mainly caused by an unusually large and changeable cosmic ray anisotropy combined with lowering of the geomagnetic cutoff rigidity in the perturbed Earth's magnetosphere under conditions of the cycle minimum.

Ring of Stations Method in Cosmic Rays Variations Research

<https://link.springer.com/content/pdf/10.1007/s11207-020-01639-7.pdf>

For over 60 years, neutron monitors have been the main standard and high precision detectors for measuring cosmic rays with energy from 400 MeV to hundreds GeV. In order to obtain sufficiently complete information about the distribution of cosmic rays outside the magnetosphere, it is necessary to have a network of detectors spaced evenly around the globe. The ring of stations method is one of the most useful methods for studying the properties of the angular distribution of cosmic rays without expressing the cosmic ray intensity in terms of spherical harmonics. The method allows one to get the hourly longitude distribution of the cosmic ray intensity without modeling. The main objective of this work is to expand the use of the ring of stations method, as it is a convenient and useful method of studying cosmic ray variation. Using the ring of stations method, it is possible to study specific angular distributions of cosmic ray variation that are described poorly by the sum of the first spherical harmonics. The ring of stations method is primarily used to study Forbush decreases. Detailed descriptions of Forbush decrease investigation by the ring of stations method are presented in this study. The application of the method to the study of the precursors of Forbush decreases and cosmic rays behavior inside the solar wind disturbances is shown. **25 September 2001, 1 February 2003, 13 September 2004, 23 June 2013, 15 February 2014, 17 March 2015, 6 November 2015, 25 August 2018**

Forbush-decreases in 19th solar cycle

A [Abunin](#)¹, M [Abunina](#)¹, A [Belov](#)¹, E [Eroshenko](#)¹, V [Oleneva](#)¹ and V [Yanke](#)

2013 J. Phys.: Conf. Ser. 409 012165

The abnormally high solar activity was observed in the late 50's – the early 60's of the 20th century, but not many possibilities was available that time of its observation to which we have got in use during the last years. Ground level cosmic ray observations, along with geomagnetic activity, are one of a few kinds of the continuous measurements, allowing to judge on the events of 19th cycle. The IZMIRAN Database in which all Forbush-decreases are collected since July, 1957 has been used for the analysis. To make the statistics of 19th cycle fuller, the catalogue by Lockwood containing rather big Forbush-decreases (>3 %), picked out from the data of one neutron monitor (Mount Washington),

was involved. Comparison of the events in cosmic rays with solar and geomagnetic activity has shown that the quantity and intensity of geomagnetic storms in 19th cycle correspond to abnormally high number of the sunspots. However in this cycle there is a certain deficiency of Forbush-effects of the large size. Apparently, deficiency of the big Forbush-decreases during this period means that coronal mass ejections (CMEs/ICMEs) in the 19th cycle distinguished from later CMEs and differently affected of the cosmic ray modulation and geomagnetic activity. Probably, the most powerful CMEs of the 19th cycle had, as a whole, the smaller size, than the greatest emissions of solar plasma in later period.

PROPERTIES OF MAGNETIC FIELDS IN CORONAL HOLES AND GEOEFFECTIVE DISTURBANCES IN SOLAR CYCLE 24

The coronal holes (CH) are sources of high-speed flows of solar wind, and, in its turn, are one of the main sources of geomagnetic disturbances. The coronal holes differ very much one from another and their geoeffectivity varies in a wide range. In this paper we implement a study to answer the question how the coronal holes characterized by different location on the Sun and by their polarity influence the geomagnetic activity. We considered 53 coronal holes observed in the period 2011-2012 of solar cycle 24, and separated them into groups by the heliolatitude and their polarity. A conclusion is made that the trans-equatorial group is the most effective one. Less, but yet sufficiently effective, are the holes of negative polarity at north latitudes and those of positive polarity at south latitudes. The much smaller number of coronal holes of opposite polarity (CH of negative polarity in south hemisphere and CH of positive one in north hemisphere) are less effective

Forecasting Geomagnetic Conditions in near-Earth space

<http://iopscience.iop.org/article/10.1088/1742-6596/409/1/012197/pdf>

Geomagnetic conditions in near-Earth space have been a constantly evolving scientific field, especially during the latest years when the dependence of our everyday life on space environment has significantly increased. The scientific community managed to implement centers for the continuous monitoring of the geomagnetic conditions which resulted into short and long term forecasting of the planetary geomagnetic index Ap. In this work, the centers that have been established and are in operational mode in Russia (IZMIRAN), Greece (Athens), Kazakhstan (Almaty) and Bulgaria (Sofia) are presented. The methods that have been used for the forecasting of Ap index are demonstrated and the forecasted results in comparison to the actual Ap measurements are also discussed.

Geoeffectivity of Solar Coronal Holes with Different Magnetic Field Polarity

Abunina, Maria; Abunin, Anatoly; Belov, Anatoly; Gaidash, Sergey; Tassev, Yordan; Velinov, Peter; Mateev, Lachezar; Tonev, Peter

Bulgarian Academy of Sciences. Space Research and Technology Institute. Aerospace Research in Bulgaria. Vol. 25, p. 70-77, 2013

The coronal holes (CH) are sources of high-speed flows of solar wind, and, in its turn, are one of the main sources of geomagnetic disturbances. The coronal holes differ very much one from another and their geoeffectivity varies in a wide range. In this paper we implement a study to answer the question how the coronal holes characterized by different location on the Sun and by their polarity influence the geomagnetic activity. We consider several tens of coronal holes observed in a few recent years, and separate them into groups by the solar latitude and their polarity. A conclusion is made that the transequatorial group is the most effective one, and that almost all coronal holes in this group have a negative polarity. Less, but yet sufficiently effective, are the holes of negative polarity at north latitudes and those of positive polarity at south latitudes. The much smaller number of coronal holes of opposite polarity (CH of negative polarity in south hemisphere and CH of positive one in north hemisphere) are less effective.

A limit for the values of the Dst geomagnetic index

F.J. **Acero**, J.M. **Vaquero**, M.C. **Gallego**, J.A. **García**

2024

<https://arxiv.org/pdf/2402.00437.pdf>

The study of the extreme weather space events is important for a technological dependent society. Extreme Value Theory could be decisive to characterize those extreme events in order to have the knowledge to make decisions in technological, economic and social matters, in all fields with possible impacts. In this work, the hourly values of the Dst geomagnetic index has been studied for the period 1957-2014 using the peaks-over-threshold technique. The shape parameter obtained from the fit of the generalized Pareto distribution to the extreme values of the $|Dst|$ index leads to a negative value implying an upper bound for this time series. This result is relevant, because the estimation of this limit for the extreme values lead to 850 nT as the highest expected value for this geomagnetic index. Thus, from the previous characterization of the Carrington geomagnetic storm and our results, it could be considered the worst case scenario. **13-15 March 1989**

Modeling of Joint Parker Solar Probe–Metis/Solar Orbiter Observations

L. Adhikari¹, G. P. Zank¹, D. Telloni², and L.-L. Zhao¹

2022 ApJL 937 L29

<https://iopscience.iop.org/article/10.3847/2041-8213/ac91c6/pdf>

We present the first theoretical modeling of joint Parker Solar Probe (PSP)–Metis/Solar Orbiter (SolO) quadrature observations. The combined observations describe the evolution of a slow solar wind plasma parcel from the extended solar corona (3.5–6.3 R_{\odot}) to the very inner heliosphere (23.2 R_{\odot}). The Metis/SolO instrument remotely measures the solar wind speed finding a range from 96 to 201 km s⁻¹, and PSP measures the solar wind plasma in situ, observing a radial speed of 219.34 km s⁻¹. We find theoretically and observationally that the solar wind speed accelerates rapidly within 3.3–4 R_{\odot} and then increases more gradually with distance. Similarly, we find that the theoretical solar wind density is consistent with the remotely and in-situ observed solar wind density. The normalized cross helicity and normalized residual energy observed by PSP are 0.96 and -0.07, respectively, indicating that the slow solar wind is very Alfvénic. The theoretical NI/slab results are very similar to PSP measurements, which is a consequence of the highly magnetic field-aligned radial flow ensuring that PSP can measure slab fluctuations and not 2D ones. Finally, we calculate the theoretical 2D and slab turbulence pressure, finding that the theoretical slab pressure is very similar to that observed by PSP.

A Solar Coronal Hole and Fast Solar Wind Turbulence Model and First-orbit Parker Solar Probe (PSP) Observations

L. Adhikari¹, G. P. Zank^{1,2}, and L.-L. Zhao¹

2020 ApJ 901 102

<https://doi.org/10.3847/1538-4357/abb132>

We propose a turbulence-driven solar wind model for a fast solar wind flow in an open coronal hole where the solar wind flow and the magnetic field are highly aligned. We compare the numerical results of our model with Parker Solar Probe measurements of the fast solar wind flow and find good agreement between them. We find that (1) the majority quasi-2D turbulence is mainly responsible for coronal heating, raising the temperature to about $\sim 10^6$ K within a few solar radii, which leads in turn to the acceleration of the solar wind; (2) the heating rate due to quasi-2D turbulence near the coronal base is larger than that due to nearly incompressible/slab turbulence; (3) the quasi-2D energy in forward-propagating modes decreases with increasing distance, while the nearly incompressible/slab energy in forward-propagating modes increases, reaching a peak value at $\sim 11.7 R_{\odot}$ before decreasing with increasing heliocentric distance; (4) the correlation length increases with increasing distance from the coronal base; and (5) the variance of the density fluctuations decreases as a function of heliocentric distance.

Impacts On Proton Fluxes Observed During Different Interplanetary Conditions

Binod Adhikari, Niraj Adhikari, Binil Aryal, Narayan P. Chapagain, and Ildiko Horvath

Solar Phys. 294:61 **2019**

sci-hub.se/10.1007/s11207-019-1450-6

Interplanetary coronal mass ejections (ICMEs) and Corotating Interaction Regions (CIRs) are the major characteristic events of the solar wind. We utilized the proton flux data of different energy level measured by the Low Energy Magnetic Spectrometers (LEMS) 120 system of the Electron, Proton and Alpha Monitor (EPAM) for studying different ICME-driven and CIR-driven storms. Our main aim was to find out from the observational results the nature of proton flux during solar storms driven by different forces, in our cases, ICMEs and CIRs, in the interplanetary regions. We analysed the different parameters provided by the LEMS 120 system and compared them during the different storm types and during the quietest day as well. We studied four events: a geomagnetically quiet day, two ICME-driven storms

and one CIR-driven storm. We also analysed the IMF magnitude (B_{mag}) and the different parameters of the solar wind during all these events. We observed that the prolonged particle precipitations during CIRs and the intense particle precipitations during ICMEs result in the different nature of the proton flux of different energy level in comparison to other parameters such as B_{mag} , and solar wind velocity (V_{sw}). Our results show that there is strong correlation between the higher energy proton fluxes and $B_{\text{mag}}-V_{\text{sw}}$ during the quiet period and weak correlation in the case of lower energy protons during the quiet event. But, when the storm is either driven by ICMEs or CIRs, the lower energy also starts to show positive correlations with B_{mag} and V_{sw} with a 0 min time lag during ICMEs and a ~ 100 min time lag during CIRs. During the quiet day, the proton flux observed was due to the perturbations created by ionization and the higher energy of the protons sufficiently weakened. Whereas, CMEs speed, preceding CMEs, and the presence of pre-existing Solar Energetic Particles (SEPs) in the ambient medium, the makeup of CIRs wind, and the nature of precipitation during both ICMEs and CIRs caused the fluxes of protons of different energy level during storm times. **19 April 2003, 20 November 2003 and 25 July 2004, 8 May 2005**

The Role of Magnetic Reconnection–associated Processes in Local Particle Acceleration in the Solar Wind

L. [Adhikari](#)¹, O. Khabarova², G. P. Zank^{1,3}, and L.-L. Zhao
2019 ApJ 873 72

[sci-hub.se/10.3847/1538-4357/ab05c6](https://doi.org/10.3847/1538-4357/ab05c6)

Recent studies of unusual or atypical energetic particle flux events (AEPEs) observed at 1 au show that another mechanism, different from diffusive shock acceleration, can energize particles locally in the solar wind. The mechanism proposed by Zank et al. is based on the stochastic energization of charged particles in regions filled with numerous small-scale magnetic islands (SMIs) dynamically contracting or merging and experiencing multiple magnetic reconnection in the super-Alfvénic solar wind flow. A first- and second-order Fermi mechanism results from compression-induced changes in the shape of SMIs and their developing dynamics. Charged particles can also be accelerated by the formation of antireconnection electric fields. Observations show that both processes often coexist in the solar wind. The occurrence of SMIs depends on the presence of strong current sheets like the heliospheric current sheet (HCS), and related AEPEs are found to occur within magnetic cavities formed by stream–stream, stream–HCS, or HCS–shock interactions that are filled with SMIs. Previous case studies comparing observations with theoretical predictions were qualitative. Here we present quantitative theoretical predictions of AEPEs based on several events, including a detailed analysis of the corresponding observations. The study illustrates the necessity of accounting for local processes of particle acceleration in the solar wind.

Impacts on Cosmic-Ray Intensity Observed During Geomagnetic Disturbances

Binod [Adhikari](#), Nirakar Sapkota, Prashrit Baruwal, Narayan P. Chapagain, Carlos Roberto Braga
[Solar Physics](#) October **2017**, 292:149

Geomagnetic disturbances are the results of interplanetary causes such as high-speed streamers (HSSs), interplanetary coronal mass ejections (ICMEs), corotating interaction regions (CIRs), and magnetic clouds. During different forms of geomagnetic disturbances, we observed changes in the count rate at neutron monitors that are kept at various locations. We studied the count rates measured by neutron monitors at four stations at various latitudes during different categories of geomagnetic events and compared them. We analysed five events: a geomagnetically quiet event, a non-storm high-intensity long-duration continuous AE activity (HILDCAA) event, a storm-preceded HILDCAA event, a geomagnetic substorm event, and a geomagnetic moderate storm event. We based our analysis on geomagnetic indices, solar wind parameters, and interplanetary magnetic field (IMF) parameters. We found that the strength of the modulation was least during the quiet event and highest during the storm-preceded HILDCAA. By analysing the cause of these geomagnetic disturbances, we related each decrease in the neutron monitor data with the corresponding solar cause. For the ICME-driven storm, we observed a decrease in neutron monitor data ranging from 6% to 12% in all stations. On the other hand, we observed a decrease ranging from 2% to 5% for the HSS-driven storm. For the non-storm HILDCAA, we observed a decrease in neutron monitor data of about 1% to 1.5%. For the quiet event, the neutron monitor data fluctuated such that there was no overall decrease in all stations. **19 – 24 April 2003, 16 November 2003, 21 January 2005, 14 – 19 May 2005, 18 – 21 July 2006,**

Constraints on the Alfvénicity of Switchbacks

O.V. [Agapitov](#) (1), [J. F. Drake](#) (2,3), [M. Swisdak](#) (3), [K.-E. Choi](#) (1), [N. Raouafi](#) (4)
2023

<https://arxiv.org/ftp/arxiv/papers/2312/2312.01011.pdf>

Switchbacks (SBs) are localized structures in the solar wind containing deflections of the magnetic field direction relative to the background solar wind magnetic field. The amplitudes of the magnetic field deflection angles for different SBs vary from ~40 to ~160-170 degrees. Alignment of the perturbations of the magnetic field and the bulk solar wind velocity is observed inside SBs and causes spiky enhancements of the radial bulk velocity inside SBs. We have investigated the deviations of SB perturbations from Alfvénicity by evaluating the distribution of the parameter defined as the ratio of the parallel to ΔB^{\rightarrow} component of ΔV^{\rightarrow} to $\Delta V^{\rightarrow} A = \Delta B^{\rightarrow} / 4\pi n m_i$ inside SBs, i.e. $\alpha = V_{\parallel} / |\Delta V^{\rightarrow}|$ ($\alpha = \Delta V^{\rightarrow} / |\Delta V^{\rightarrow}|$ when $\Delta V^{\rightarrow} \parallel \Delta B^{\rightarrow}$), which quantifies the deviation of the perturbation from an Alfvénic one. Based on Parker Solar Probe (PSP) observations, we show that α inside SBs has systematically lower values than it has in the pristine solar wind: α inside SBs observed during PSP Encounter 1 were distributed in a range of 0.2-0.9. The upper limit on α is constrained by the requirement that the jump in velocity across the switchback boundary be less than the local Alfvén speed. This prevents the onset of shear flow instabilities. The consequence is that the perturbation of the proton bulk velocity in SBs with deflection greater than 60 degrees cannot reach $\alpha=1$ (the Alfvénicity condition) and the highest possible α for a SB with the full reversal of B is 0.5. These results have consequences for the interpretation of switchbacks as large amplitude Alfvén waves. **November 6, 2018**

Flux rope merging and the structure of switchbacks in the solar wind

O. Agapitov, J. F. Drake, M. Swisdak, S. D. Bale, T. S. Horbury, J. C. Kasper, R. J. MacDowall, F. S. Mozer, T. D. Phan, M. Pulupa, N.E. Raouafi, M. Velli

2022 *ApJ* 925 213

<https://arxiv.org/ftp/arxiv/papers/2109/2109.04016.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac4016/pdf>

A major discovery of Parker Solar Probe (PSP) was the presence of large numbers of localized increases in the radial solar wind speed and associated sharp deflections of the magnetic field - switchbacks (SB). A possible generation mechanism of SBs is through magnetic reconnection between open and closed magnetic flux near the solar surface, termed interchange reconnection that leads to the ejection of flux ropes (FR) into the solar wind. Observations also suggest that SBs undergo merging, consistent with a FR picture of these structures. The role of FRs merging in controlling the structure of SB in the solar wind is explored through direct observations, through analytic analysis, and numerical simulations. Analytic analysis reveals key features of the structure of FR and their scaling with the heliocentric distance R that are consistent with observations and that reveal the critical role of merging in controlling the SB structure. FR merging is shown to be energetically favorable to reduce the strength of the wrapping magnetic field and drive the observed elongation of SBs. A further consequence is the resulting dominance of the axial magnetic field within SBs that leads to the characteristic sharp rotation of the magnetic field into the axial direction at the SB boundary that is revealed in observations. Finally, the radial scaling of the SB area in the FR model of SBs suggests that the observational probability of SB identification should be insensitive to R, which is consistent with the most recent statistical analysis of SB observations from PSP. **November 4, 2018**

Sunward propagating whistler waves collocated with localized magnetic field holes in the solar wind: Parker Solar Probe observations at 35.7 Sun radii

O.V. Agapitov, T. Dudok de Wit, F.S. Mozer, J. W. Bonnell, ...

2020 *ApJL* 891 L20

<https://arxiv.org/ftp/arxiv/papers/2002/2002.09837.pdf>

<https://doi.org/10.3847/2041-8213/ab799c>

Observations by the Parker Solar Probe mission of the solar wind at about 35.7 solar radii reveal the existence of whistler wave packets with frequencies below 0.1 f/fce (20-80 Hz in the spacecraft frame). These waves often coincide with local minima of the magnetic field magnitude or with sudden deflections of the magnetic field that are called switchbacks. Their sunward propagation leads to a significant Doppler frequency downshift from 200-300 Hz to 20-80 Hz (from 0.2 f/fce to 0.5 f/fce). The polarization of these waves varies from quasi-parallel to significantly oblique with wave normal angles that are close to the resonance cone. Their peak amplitude can be as large as 2 to 4 nT. Such values represent approximately 10% of the background magnetic field, which is considerably more than what is observed at 1 a.u. Recent numerical studies show that such waves may potentially play a key role in breaking the heat flux and scattering the Strahl population of suprathermal electrons into a halo population. **4-7 Nov 2018**

Non-conventional Approach for Deriving the Radial Sizes of Coronal Mass Ejections at Different Instances: Discrepancies in the Estimates Between Remote and In Situ Observations

Anjali Agarwal, Wageesh Mishra

MNRAS Volume 534, Issue 3, November 2024, Pages 2458–2474,

<https://doi.org/10.1093/mnras/stae2260>

<https://arxiv.org/pdf/2409.18851?>

<https://academic.oup.com/mnras/article-pdf/534/3/2458/59713264/stae2260.pdf>

Understanding the evolution of radial sizes and instantaneous expansion speeds of coronal mass ejections (CMEs) is crucial for assessing their impact duration on Earth's environment. We introduce a non-conventional approach to derive the CME's radial sizes and expansion speeds at different instances during its passage over a single-point in situ spacecraft. We also estimate the CME's radial sizes and expansion speeds during its journey from the Sun to 1 AU using the 3D kinematics of different CME features, including the leading edge (LE), center, and trailing edge (TE). The continuous 3D kinematics of the CME is estimated by employing the GCS and SSSE reconstruction methods on multi-point observations from coronagraphs and heliospheric imagers combined with the drag-based model. We choose the **2010 April 3** CME as a suitable case for our study, promising a more accurate comparison of its remote and in situ observations. We show that the introduced non-conventional approach can provide better accuracy in estimating radial sizes and instantaneous expansion speeds of CMEs at different instances. We examine the aspect ratio of the CME, which influences its expansion behavior and shows the discrepancy between its value in the corona and interplanetary medium. Our study highlights significant inconsistencies in the arrival time, radial size, and expansion speed estimates obtained from remote and in situ observations. We advocate for future studies leveraging multi-spacecraft in situ observations and our non-conventional approach to analyze them to improve the comprehension of CME dynamics in the solar wind.

Forbush decrease on September 6-13, 2017 observed by the Tanca water-Cherenkov detector de **Aguiar**, R ; Fauth, AC

37TH INTERNATIONAL COSMIC RAY CONFERENCE, ICRC2021 Article Number 1267, 2022

<https://pos.sissa.it/395/1267/pdf>

Solar activity was intense in September 2017 and its effects were observed in different detectors placed at the Earth's surface. Three halo Coronal Mass Ejections (CME) hit the planet and caused magnetic storms. The effects of the CMEs on the flux of galactic cosmic rays at ground level were observed by the Tanca detector, which is one of the water-Cherenkov detectors (WCD) that make up the Latin American Giant Observatory (LAGO). In this paper we present the detection of Forbush events observed by Tanca during the month of September 2017. This WCD is installed on the campus of the University of Campinas, in Brazil, having three photomultiplier tubes that detect Cherenkov photons produced by cosmic radiation in 11400 liters of ultra pure water. We present the description and performance of the experimental apparatus and the observation on days 6(th), 8(th) and 13(th) of the Forbush events originated by the CMEs. A decrease in the cosmic rays flux due to a stream interaction region was also observed on 14(th) September. These results were compared with observations made by neutron monitors and indices of the Earth's magnetic activity.

Numerical MHD models of stream interaction regions (SIRs) and corotating interaction regions (CIRs) using sunRunner3D: comparison with observations

E **Aguiar-Rodríguez**, J J González-Avilés, P Riley, M Ben-Nun, M Rodríguez-Martínez, R F González, M A Pérez-Rivera, A C Raga-Rasmussen

MNRAS Volume 529, Issue 2, April 2024, Pages 1250–1257,

<https://doi.org/10.1093/mnras/stae640>

<https://academic.oup.com/mnras/article-pdf/doi/10.1093/mnras/stae640/56916491/stae640.pdf>

In this work, we present numerical simulations of Stream Interaction Regions (SIRs) and Corotating Interaction Regions (CIRs) using the SUNRUNNER3D tool that employs as a coronal model the boundary conditions obtained by CORHEL/MAS with the PLUTO code that describes the global 3D structure of the solar wind using the magnetohydrodynamics (MHD) approach in the inner heliosphere. Specifically, we selected a set of SIRs and CIRs observed by the Parker Solar Probe (PSP) and STEREO-A (STA) missions during the Carrington rotations (CRs) 2207 to 2210 and CRs from 2020 to 2022. In order to describe the dynamics of the plasma that constitutes the solar wind background conditions for the selected CRs, we solve the ideal MHD equations in an inertial frame of reference, managing the solar rotation by rotating the boundary values in ϕ (longitude) at a rate corresponding to the sidereal rotation rate of the solar equator. We show that our results using SUNRUNNER3D can globally reproduce the plasma parameters, such as radial velocity, number proton density, and radial magnetic field strength of these large-scale structures, observed by PSP and STA at distances near the Sun and around 1 au, respectively. These results allow exploring the global evolution of SIRs/CIRs in the inner heliosphere using SUNRUNNER3D.

Comparison of Solar Wind Speeds Using Wavelet Transform and Fourier Analysis in IPS Data

E. [Aguilar-Rodriguez](#), J. C. Mejia-Ambriz, B. V. Jackson, A. Buffington, E. Romero-Hernandez, J. A. Gonzalez-Esparza, M. Rodriguez-Martinez, P. Hick, M. Tokumaru and 1 more
Solar Phys. **2015**

The power spectra of intensity fluctuations in interplanetary scintillation (IPS) observations can be used to estimate solar-wind speeds in the inner heliosphere. We obtain and then compare IPS spectra from both wavelet and Fourier analyses for 12 time series of the radio source 3C48; these observations were carried out at Japan's Solar-Terrestrial Environment Laboratory (STEL) facility, at 327 MHz. We show that wavelet and Fourier analyses yield very similar power spectra. Thus, when fitting a model to spectra to determine solar-wind speeds, both yield comparable results. Although spectra from wavelet and Fourier closely match each other for solar-wind speed purposes, those from the wavelet analysis are slightly cleaner, which is reflected in an apparent level of intensity fluctuations that is enhanced, being $\approx 13\%$ higher. This is potentially useful for records that show a low signal-to-noise ratio.

Interplanetary Scintillation (IPS) of the Radio Source 3C48 During Periods of Low and High Solar Activity

E. [Aguilar-Rodriguez](#), S. A. Tyul'bashev, I. V. Chashei, E. Romero-Hernandez
[Solar Physics](#) September **2015**, Volume 290, Issue 9, pp 2567-2575

We present a comparative study of three techniques used to estimate the scintillation index using interplanetary scintillation (IPS) observations carried out by the Big Scanning Array (BSA), which operates at a frequency of 111 MHz. These techniques are based on: rms analysis on-source and off-source (classic), Fourier, and wavelet transforms. IPS data are analyzed separately for the period of low solar activity (2007 – 2009), and for the year 2013, near the solar-activity maximum. Our results show that, in general, these methods are equivalent. We analyze the radial dependence of the scintillation index at meter wavelengths during these two periods. It is found that the observed radial dependence of the scintillation index during both periods of U.C. cycle 24 is flatter than the theoretical dependence expected for the case of solar-wind spherical symmetry. This flattening can be explained in terms of the influence of the heliospheric current sheet during the low solar-activity period, and the influence of solar disturbances, such as coronal mass ejections (CMEs), for the high solar-activity period.

May 2005 Halo CMEs and Galactic Cosmic Ray Flux Changes at Earth's Orbit

Solar Physics, May **2014**, Volume 289, Issue 5, pp 1763-1782

The pressure corrected hourly data from the global network of cosmic ray detectors, measurements of the interplanetary magnetic field (IMF) intensity (B) at Earth's orbit and its components B_x , B_y , B_z (in the geocentric solar ecliptic coordinates) are used to conduct a comprehensive study of the galactic cosmic ray (GCR) intensity fluctuations caused by the halo coronal mass ejection of **13 May 2005**. Distinct differences exist in GCR timelines recorded by neutron monitors (NMs) and multidirectional muon telescopes (MTs), the latter respond to the high rigidity portion of the GCR differential rigidity spectrum. The Forbush decrease (FD) onset in MTs is delayed (~ 5 h) with respect to the onset of a geomagnetic storm sudden commencement (SSC) and a large pre-increase is present in MT data before, during, and after the SSC onset, of unknown origin. The rigidity spectrum, for a range of GCR rigidities (≤ 200 GV), is a power law in rigidity (R) with a negative exponent ($\gamma = -1.05$) at GCR minimum intensity, leading us to infer that the quasi-linear theory of modulation is inconsistent with observations at high rigidities (> 1 GV); the results support the force field theory of modulation. At present, we do not have a comprehensive model for the FD explaining quantitatively all the observational features but we present a preliminary model listing physical processes that may contribute to a FD timeline. We explored the connections between different phases of the FD and the power spectra of IMF components but did not find a sustained relationship.

Characteristics and development of the main phase disturbance in geomagnetic storms ($Dst \leq -50$ nT)

Osman M. [Ahmed](#), [Badruudin Zaheer Ahmad](#), [Moncef Derouich](#)

Advances in Space Research **2024**

<https://arxiv.org/pdf/2402.03261.pdf>

We present geomagnetic storms (GSs) selected from three solar cycles, spanning the years 1995 to 2022. We studied the development of the main phase of storms within disturbance storm time (Dst) amplitudes ranging from $Dst = -64$ nT to $Dst = -422$ nT. In order to determine the solar wind (SW) parameters that mainly influence the main phase development of a GS, which can best describe the SW-magnetosphere coupling, we divided our selected GSs into four groups based on main phase duration. Superposed epoch analysis was performed on the selected geomagnetic indices, SW plasma and field parameters, and their derivatives separately for each group. To that end, the dynamics of GS main phase development is mainly guided by interplanetary driver magnetic field southward component, (-Bz). It has been determined that there is a temporal difference between the peak values of Bz and Dst. As a result, Dst is delayed from Bz by 1-4 hours, which is crucial for space weather forecasting. The peak of Dst has a direct relationship with the amplitude of storm sudden commencement (SSC) and an inverse relationship with the duration of SSC. The inter-relationship between the peaks of the three indices (Dst, AE, and ap) during GS, is also obtained. Dst is found to be more closely related to ap than AE. To determine the best fit SW parameter to the geomagnetic activity indices, we used a linear correlation between the peak values of individual geomagnetic indices and SW plasma and field parameters and their derivatives. An electric field related function involving speed and IMF ($v_4/3Bz$) when coupled with a viscous term ($\rho^{1/2}$) correlates very well with the intensity of the GS (Dst_{min} or ΔDst) and the magnitude of (ap_{max}) and (AE_{max}) during storms. However, a related function ($v_4/3B\rho^{1/2}$) represents slightly better the peak of AE_{max} during the storms.

Magnetic Interaction of a Super-CME with the Earth's Magnetosphere: Scenario for Young Earth

Vladimir S. [Airapetian](#), Alex Gloer, William Danchi

Proceedings of 18th Cambridge Workshop on Cool Stars, Stellar Systems, and the Sun

Proceedings of Lowell Observatory (9-13 June **2014**) Edited by G. van Belle & H. Harris

<http://arxiv.org/pdf/1410.7355v2.pdf>

Solar eruptions, known as Coronal Mass Ejections (CMEs), are frequently observed on our Sun. Recent Kepler observations of superflares on G-type stars have implied that so called super-CMEs, possessing kinetic energies 10 times of the most powerful CME event ever observed on the Sun, could be produced with a frequency of 1 event per 800-2000 yr on solar-like slowly rotating stars. We have performed a 3D time-dependent global magnetohydrodynamic simulation of the magnetic interaction of such a CME cloud with the Earth's magnetosphere. We calculated the global structure of the perturbed magnetosphere and derive the latitude of the open-closed magnetic field boundary. We also estimated energy fluxes penetrating the Earth's ionosphere and discuss the consequences of energetic particle fluxes on biological systems on early Earth.

Solar Origins of 26th August 2018 Geomagnetic Storm: Responses of the Interplanetary Medium and Equatorial/low-latitude Ionosphere to the Storm

A. O. [Akala](#), [O. J. Oyedokun](#), [P. O. Amaechi](#), [K. G. Simi](#), [A. Ogwala](#), [O.A. Arowolo](#),

Space Weather **Volume 19, Issue 10** e2021SW002734 **2021**

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2021SW002734>

<https://doi.org/10.1029/2021SW002734>

This geomagnetic storm was initiated by a solar filament eruption of **20th August, 2018**, and driven by an aggregation of weak CME transients and CIR/HSSs. The weak PPEF during the storm, which is associated with the extreme quietness of year 2018 caused plasma densities to localize at locations that are not up to the EIA crests. A clear hemispherical asymmetry, with higher TEC in the northern hemisphere was observed. The determining factors for ionospheric responses to this storm are; local time of the storm's onset, local time of storm's minimum SYM-H, and changes in thermospheric O/N₂. Furthermore, one major factor that is hindering our progress in developing robust prediction capabilities for geomagnetic storm is the characteristic peculiarity of each storm. **26th August 2018** geomagnetic storm is peculiar due to the intertwined physical processes that led to its occurrence. To develop future forecasting capabilities for this type of a complex storm, a comprehensive understanding of the intertwined physical processes is required, which this study provided.

A Review of Studies of Geomagnetic Storms and Auroral/Magnetospheric Substorms Based on the Electric Current Approach **Review**

Syun-Ichi **Akasofu**

Front. Astron. Space Sci. 7:604750. 2021 |

<https://www.frontiersin.org/articles/10.3389/fspas.2020.604750/full>

<https://doi.org/10.3389/fspas.2020.604750>

The progress of space physics is reviewed from my personal point of view, particularly how I have reached my present understanding of auroral substorms and geomagnetic storms from the time of the earliest days of space physics. This review is somewhat unique in two ways. First of all, instead of taking the magnetic field line approach (including magnetic reconnection), I have taken the electric current approach; it consists of power supply (dynamo), transmission (currents/circuits), and dissipation (auroral/magnetospheric substorms). This is the basic way to study electromagnetic phenomena and it is much more instructive in understanding the physics involved in the chain processes. Secondly, this is not a textbook-like review, but it is hoped that my humble experience may be useful to see how a new science of space physics has evolved with a number of controversies. On the other hand, it can be seen that the electric current approach is still in a very rudiment stage. Thus, new generations of researchers are most welcome in taking this new way of studying auroral/magnetospheric substorms and geomagnetic storms.

Electric Current Approach Studying Both Auroral Substorms and Solar Flares Together **Review***

Syun-Ichi **Akasofu***

Front. Astron. Space Sci., 7:4 2020 | <https://doi.org/10.3389/fspas.2020.00004>

<https://www.frontiersin.org/articles/10.3389/fspas.2020.00004/pdf>

Auroral substorms and solar flares are basically various manifestations of electromagnetic energy dissipation processes, so it is useful to consider both phenomena in terms of a chain of processes, consisting of power supply (dynamo), transmission (currents/circuits), and dissipation (auroral substorms, solar flares), the electric current approach. In this short review, we briefly describe both phenomena together on the basis of the chain process. It is shown that the introduction of a dynamo process in this consideration provides a step-by-step way of studying both phenomena. It is shown that (a) both the solar wind–magnetosphere dynamo and a photospheric dynamo proposed by [Lee et al. \(1995\)](#) have enough power to accumulate enough energy for the explosive features of both phenomena, respectively. (b) For substorms, the power is accumulated in the inner magnetosphere and inflates it, and for flares, the power is likely to be accumulated in a loop current along and above two-ribbon flares. (c) For substorms, the energy release (unloading) process deflates the inner magnetosphere, resulting in an earthward electric field, and for flares, the disruption of the loop current suggested by [Alfvén \(1950\)](#) may be responsible for the energy release.

A Historical Review of the Geomagnetic Storm-Producing Plasma Flows from the Sun

Syun-Ichi **Akasofu**

Space Science Reviews, Volume 164, Numbers 1-4, 85-132, 2012; **File**

The concept of geomagnetic storm-producing solar plasma flows has evolved and advanced considerably over the last 100 years or so. This particular field of study began in an effort to understand geomagnetic disturbances and the aurora. The purpose of this paper is try to follow the ways in which early concepts evolved to later ones, not to review each concept in detail. It is fascinating to see a step-by-step buildup of these concepts, from the earliest idea of flow of solar electrons to coronal mass ejections (CMEs). The time line, though tentative, of the studies of geomagnetic storm-producing plasma flows is presented. The author hopes that this paper will serve young researchers in particular to consider how they plan to advance further this scientific field. There is still much uncertainty about geomagnetic storm-producing solar plasma flows. Some of the major questions are listed from the point of view of a geophysicist in the summary sections by grouping them in terms of the quiet-time solar wind, solar streams from corona holes and CMEs associated with solar flares.

Space Weather Investigation Frontier (SWIFT)

Mojtaba **Akhavan-Tafti**, Les Johnson, Rohan Sood, +++

Front. Astron. Space Sci. 10: 1185603. 2023

doi: 10.3389/fspas.2023.1185603

<https://www.frontiersin.org/articles/10.3389/fspas.2023.1185603/pdf>

The Space Weather Investigation Frontier (SWIFT) mission will aim at making major discoveries on the three-dimensional structure and dynamics of heliospheric structures that drive space weather. The focus will be on

Interplanetary Coronal Mass Ejections (ICMEs) that originate from massive expulsions of plasma and magnetic flux from the solar corona. They cause the largest geomagnetic storms and solar energetic particle events, threatening to endanger life and disrupt technology on Earth and in space. A big current problem, both regarding fundamental solar-terrestrial physics and space weather, is that we do not yet understand spatial characteristics and temporal evolution of ICMEs and that the existing remote-sensing and in-situ observatories are not suited for resolving multi-layered and evolutionary structures in these massive storm drivers. Here, we propose a groundbreaking mission concept study using solar sail technology that, for the first time, will make continuous, in-situ multi-point observations along the Sun-Earth line beyond the Lagrange point L1 (sub-L1). This unique position, in combination with L1 assets, will allow distinguishing between local and global processes, spatial characteristics, temporal evolution, and particle energization mechanisms related to ICMEs. In addition, measurements of the magnetic field in earthbound ICMEs and their sub-structures from the SWIFT location will double the current forecasting lead-times from L1. This concept also paves the way for missions with increasingly longer forecasting lead-times, addressing NASA and NOAA's space weather goals, as set forth by the Decadal Survey. The objective of this communication is to inform the community of the ongoing effort, including plans to further develop the mission concept, supported by the Heliophysics Flight Opportunities Studies (HFOS) program under NASA's Research Opportunities in Space and Earth Sciences (ROSES). **20-21 Apr 2020**

Interplanetary Magnetic Flux Rope Observed at Ground Level by HAWC

S. **Akiyama**, R. Alfaro, C. Alvarez, J. R. Angeles Camacho, +++

2020 ApJ 905 73

<https://doi.org/10.3847/1538-4357/abc344>

<https://arxiv.org/pdf/2101.03243.pdf>

We report the ground-level detection of a Galactic cosmic-ray (GCR) flux enhancement lasting ~17 hr and associated with the passage of a magnetic flux rope (MFR) over the Earth. The MFR was associated with a slow coronal mass ejection (CME) caused by the eruption of a filament on **2016 October 9**. Due to the quiet conditions during the eruption and the lack of interactions during the interplanetary CME transport to the Earth, the associated MFR preserved its configuration and reached the Earth with a strong magnetic field, low density, and a very low turbulence level compared to local background, thus generating the ideal conditions to redirect and guide GCRs (in the ~8–60 GV rigidity range) along the magnetic field of the MFR. An important negative B Z component inside the MFR caused large disturbances in the geomagnetic field and a relatively strong geomagnetic storm. However, these disturbances are not the main factors behind the GCR enhancement. Instead, we found that the major factor was the alignment between the MFR axis and the asymptotic direction of the observer.

A Study of Coronal Holes Observed by SoHO/EIT and the Nobeyama Radioheliograph

S. **Akiyama**, N. Gopalswamy, S. Yashiro, and P. Mäkelä

Publ. Astron. Soc. Japan 65, No SP1, S15 [10 pages] (**2013**)

<http://pasj.asj.or.jp/v65/sp1/65S015/65S015.pdf>

Coronal holes (CHs) are areas of reduced emission in EUV and X-ray images that show bright patches of microwave enhancements (MEs) related to magnetic network junctions inside the CHs. A clear correlation between the CH size and the solar wind (SW) speed is well known, but we have less information about the relationship between MEs and other CH and SW properties. We studied the characteristics of 21 equatorial CHs associated with corotating interaction regions (CIRs) during 1996 to 2005. Our CHs were divided into two groups according to the intensity of the associated geomagnetic storms: $Dst \leq -100$ nT (10 events) and $Dst > -100$ nT (11 events). Using EUV 284 Å images obtained by SOHO/EIT and 17 GHz microwave images obtained by the Nobeyama Radioheliograph (NoRH), we found a linear correlation not only between the maximum SW speed and the area of EUV CH ($r = 0.62$), but also between the maximum SW speed and the area of the ME ($r = 0.79$). We also compared the EUVCH areas with and without an overlapping ME. The area of the CHs with an ME is better correlated with the SW speed ($r = 0.71$) than the area of those without an ME ($r = 0.36$). Therefore, the radio ME may play an important role in understanding the origin of SW. **Tables of geomagnetic storms from CHs.**

Deriving the Topological Properties of the Magnetic Field of Coronal Mass Ejections from In Situ Measurements: Techniques

Nada **Al-Haddad**, [Mitchell Berger](#)

ApJ **2024**

<https://arxiv.org/pdf/2408.04608>

Coronal mass ejections (CMEs) are magnetized plasma systems with highly complex magnetic topology and evolution. Methods developed to assess their magnetic configuration have primarily focused on reconstructing three-dimensional representations from one-dimensional time series measurements taken in situ using techniques based on the "highly twisted magnetic flux rope" approximations. However, the magnetic fields of CMEs is known to have more complicated geometries. Their structure can be quantified using measures of field line topology, which have been primarily used for solar physics research. In this work, we introduce a novel technique of directly quantifying the various forms of magnetic helicity within a CME in the interplanetary space using synthetic in situ measurements. We use a relatively simple three-dimensional simulation of a CME initiated with a highly-twisted flux rope. We find that a significant portion of the magnetic helicity near 1 AU is contained in writhe and mutual helicity rather than just in twist. We discuss the implications of this finding for fitting and reconstruction techniques.

Multipoint Observations of the Dynamics at an ICME Sheath–Ejecta Boundary

Matti [Ala-Lahti](#)^{1,2}, Tuija I. [Pulkkinen](#)¹, Julia [Ruohotie](#)², Mojtaba [Akhavan-Tafti](#)¹, Simon W. [Good](#)², and Emilia K. J. [Kilpua](#)²

2023 ApJ 956 131

<https://iopscience.iop.org/article/10.3847/1538-4357/acf99e/pdf>

The radial evolution of interplanetary coronal mass ejections (ICMEs) is dependent on their interaction with the ambient medium, which causes ICME erosion and affects their geoefficiency. Here, an ICME front boundary, which separates the confined ejecta from the mixed, interacted sheath–ejecta plasma upstream, is analyzed in a multipoint study examining the ICME at 1 au on **2020 April 20**. A bifurcated current sheet, highly filamented currents, and a two-sided jet were observed at the boundary. The two-sided jet, which was recorded for the first time for a magnetic shear angle $<40^\circ$, implies multiple (patchy) reconnection sites associated with the ICME erosion. The reconnection exhaust exhibited fine structure, including multistep magnetic field rotation and localized structures that were measured only by separate Cluster spacecraft with the mission inter-spacecraft separation of 0.4–1.6 RE. The mixed plasma upstream of the boundary with a precursor at 0.8 au lacked coherency at 1 au and exhibited substantial variations of southward magnetic fields over radial (transverse) distances of 41–237 RE (114 RE). This incoherence demonstrates the need for continuous (sub)second-resolution plasma and field measurements at multiple locations in the solar wind to adequately address the spatiotemporal structure of ICMEs and to produce accurate space weather predictions.

Spatial Coherence of Interplanetary Coronal Mass Ejection Sheaths at 1 AU

Matti [Ala-Lahti](#), Julia [Ruohotie](#), [Simon Good](#), Emilia K. J. [Kilpua](#), [Noé Lugaz](#)

JGR [Volume 125, Issue 9](#) September 2020 e2020JA028002

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2020JA028002>

<https://doi.org/10.1029/2020JA028002>

The longitudinal spatial coherence near 1 AU of the magnetic field in sheath regions driven by interplanetary coronal mass ejection (ICME) is studied by investigating ACE and Wind spacecraft measurements of 29 sheaths. During 2000–2002 Wind performed prograde orbits, and the non-radial spacecraft separation varied from 0.001 to 0.012 AU between the studied events. We compare the measurements by computing the Pearson correlation coefficients for the magnetic field magnitude and components and estimate the magnetic field coherence by evaluating the scale lengths that give the extrapolated distance of zero correlation between the measurements. The correlation is also separately examined for low- and high-pass filtered data. We discover magnetic fields in ICME sheaths have scale lengths that are larger than those reported in the solar wind but that, in general, are smaller than the ones of the ICME ejecta. Our results imply that magnetic fields in the sheath are more coherently structured and well correlated compared to the solar wind. The largest sheath coherence is reported in the GSE y-direction that has the scale length of 0.149 AU while the lengths for B_x , B_z , and $|B|$ vary between 0.024 and 0.035 AU. The same sheath magnitude ordering of scale lengths also apply for the low-pass filtered magnetic field data. We discuss field line draping and the alignment of preexisting discontinuities by the shock passage giving reasoning for the observed results. **15 May 2005**

Alfvén Ion Cyclotron Waves in Sheath Regions Driven by Interplanetary Coronal Mass Ejections

Matti [Ala-Lahti](#), Emilia K. J. [Kilpua](#), [Jan Souček](#), Tuija I. [Pulkkinen](#), [Andrew P. Dimmock](#)

JGR [Volume 124, Issue 6](#) June 2019 Pages 3893–3909

[sci-hub.se/10.1029/2019JA026579](https://doi.org/10.1029/2019JA026579)

We report on a statistical analysis of the occurrence and properties of Alfvén ion cyclotron (AIC) waves in sheath regions driven by interplanetary coronal mass ejections (ICMEs). We have developed an automated algorithm to identify AIC wave events from magnetic field data and apply it to investigate 91 ICME sheath regions recorded by the Wind

spacecraft. Our analysis focuses on waves generated by the ion cyclotron instability. AIC waves are observed to be frequent structures in ICME-driven sheaths, and their occurrence is the highest in the vicinity of the shock. Together with previous studies, our results imply that the shock compression has a crucial role in generating wave activity in ICME sheaths. AIC waves tend to have their frequency below the ion cyclotron frequency, and, in general, occur in plasma that is stable with respect to the ion cyclotron instability and has lower ion β_{\parallel} than mirror modes. The results suggest that the ion beta anisotropy $\beta_{\perp}/\beta_{\parallel} > 1$ appearing in ICME sheaths is regulated by both ion cyclotron and mirror instabilities.

Temporal Changes in the Rigidity Spectrum of Forbush Decreases Based on Neutron Monitor Data

M. V. [Alania](#), A. Wawrzynczak, V. E. Sdobnov, M. V. Kravtsova
Solar Physics, September 2013, Volume 286, Issue 2, pp 561-576,

The Forbush decrease (Fd) of the Galactic cosmic ray (GCR) intensity and disturbances in the Earth's magnetic field generally take place simultaneously and are caused by the same phenomenon, namely a coronal mass ejection (CME) or a shock wave created after violent processes in the solar atmosphere. The magnetic cut-off rigidity of the Earth's magnetic field changes because of the disturbances, leading to additional changes in the GCR intensity observed by neutron monitors and muon telescopes. Therefore, one may expect distortion in the temporal changes in the power-law exponent of the rigidity spectrum calculated from neutron monitor data without correcting for the changes in the cut-off rigidity of the Earth's magnetic field. We compare temporal changes in the rigidity spectrum of Fds calculated from neutron monitor data corrected and uncorrected for the geomagnetic disturbances. We show some differences in the power-law exponent of the rigidity spectrum of Fds, particularly during large disturbances of the cut-off rigidity of the Earth's magnetic field. However, the general features of the temporal changes in the rigidity spectrum of Fds remain valid as they were found in our previous study. Namely, at the initial phase of the Fd, the rigidity spectrum is relatively soft and it gradually becomes hard up to the time of the minimum level of the GCR intensity. Then during the recovery phase of the Fd, the rigidity spectrum gradually becomes soft. This confirms that the structural changes of the interplanetary magnetic field turbulence in the range of frequencies of $10^{-6} - 10^{-5}$ Hz are generally responsible for the time variations in the rigidity spectrum we found during the Fds.

Rigidity spectrum of Forbush decrease calculated by neutron monitors data corrected and uncorrected for geomagnetic disturbances

M V [Alania](#)^{1,2}, A Wawrzynczak³, V E Sdobnov⁴ and M V Kravtsova
2013 J. Phys.: Conf. Ser. 409 012184

Forbush decreases (Fd) of the galactic cosmic ray (GCR) intensity and geomagnetic storms are observed almost at the same time. Geomagnetic storm is a reason of significant disturbances of the magnetic cut off rigidity causing the distortion of the time profile of the Fd of the GCR intensity. We show some differences in the temporal changes of the rigidity spectra of Fd calculated by neutron monitors experimental data corrected and uncorrected for the changes of the geomagnetic cut off rigidity. Nevertheless, the general features of the temporal changes of the rigidity spectrum of Fd maintain as it was found in our previous investigations. Namely, at the beginning phase of Fd rigidity spectrum is relatively soft and gradually becomes hard up to reaching the minimum level of the GCR intensity; then the rigidity spectrum gradually becomes soft during the recovery phase of Fd. We also confirm that for the established temporal profiles of the rigidity spectrum of Fd a structural changes of the interplanetary magnetic field turbulence in the range of frequencies, $10^{-6} - 10^{-5}$ Hz are responsible.

Editorial: Interplanetary Medium Variability as Observed in the New Era of Spacecraft Missions

Tommaso [Alberti](#), Lina Hadid, Valeria Mangano, and Beatriz Sánchez-Cano
Front. Astron. Space Sci. 9:1002727 2022

<https://doi.org/10.3389/fspas.2022.1002727>

<https://www.frontiersin.org/articles/10.3389/fspas.2022.1002727/full>

Since 1970s an increasing number of heliospheric and planetary space missions have been launched as Helios ([Porsche, 1981](#)), Ulysses ([Carvell, 1986](#)), Wind ([Acuña et al., 1995](#)), ACE ([Garrard et al., 1997](#)), MAVEN ([Jakosky and MAVEN Science Team, 2008](#)), Rosetta ([Wood, 1987](#)), Cassini ([Prange, 1985](#)) collected a huge amount of data to characterize the interplanetary medium variability through the Heliosphere. Nowadays, the recently launched space missions BepiColombo ([Benkhoff et al., 2021](#)), Parker Solar Probe ([Bale et al., 2016](#)), and Solar Orbiter ([Müller et al., 2020](#)) provide more accurate in situ measurements through high-resolution instruments for monitoring the evolution of solar

wind parameters at different heliocentric distances ranging from ~ 0.05 A.U. to ~ 10 A.U., and for providing new insights into the physics of various plasma processes related to the Sun and the interplanetary medium.

Tracking of magnetic helicity evolution in the inner heliosphere

A radial alignment study

T. **Alberti**¹, Y. Narita², L. Z. Hadid³, D. Heyner⁴, A. Milillo¹, C. Plainaki⁵, H.-U. Auster⁴ and I. Richter⁴
A&A 664, L8 (2022)

<https://www.aanda.org/articles/aa/pdf/2022/08/aa44314-22.pdf>

Context. Magnetic helicity is one of the invariants in ideal magnetohydrodynamics, and its spectral evolution has a substantial amount of information to reveal the mechanism that are behind turbulence in space and astrophysical plasmas.

Aims. The goal of our study is to observationally characterize the magnetic helicity evolution in the inner heliosphere by resolving the helicity transport in a scale-wise fashion in the spectral domain.

Methods. The evolution of the magnetic helicity spectrum in the inner heliosphere was tracked using a radial alignment event achieved by Parker Solar Probe at a distance of 0.17 astronomical units (AU) from the Sun and BepiColombo at 0.58 AU with a delay of about 3.5 days.

Results. The reduced magnetic helicity resolved in the frequency domain shows three main features: (1) a coherent major peak of a highly helical component at the lowest frequency at about 5×10^{-4} Hz, (2) a damping of helicity oscillation at the intermediate frequencies from 10^{-3} to 10^{-2} Hz when observed at 0.58 AU, and (3) a coherent nonhelical component in the ion-kinetic range at frequencies of about 0.1 – 1 Hz.

Conclusions. Though limited in the frequency range, the main message from this work is that the solar wind develops into turbulence by convecting large-scale helicity components on the one hand and creating and annihilating helical wave components on the other hand. Excitation of waves can overwrite the helicity profile in the inner heliosphere. By comparing this with the typical helicity spectra at a distance of 1 AU (that is, a randomly oscillating helicity sign in the intermediate frequency range up to about 1 Hz), the helicity evolution reaches a nearly asymptotic state at the Venus orbit (about 0.7 AU) and beyond. **25 Sep 2020**

Observations of Forbush Decreases of Cosmic-Ray Electrons and Positrons with the Dark Matter Particle Explorer

<https://doi.org/10.3847/2041-8213/ac2de6>

The Forbush decrease (FD) represents the rapid decrease of the intensities of charged particles accompanied with the coronal mass ejections or high-speed streams from coronal holes. It has been mainly explored with the ground-based neutron monitor network, which indirectly measures the integrated intensities of all species of cosmic rays by counting secondary neutrons produced from interaction between atmospheric atoms and cosmic rays. The space-based experiments can resolve the species of particles but the energy ranges are limited by the relatively small acceptances except for the most abundant particles like protons and helium. Therefore, the FD of cosmic-ray electrons and positrons have just been investigated by the PAMELA experiment in the low-energy range (<5 GeV) with limited statistics. In this paper, we study the FD event that occurred in **2017 September** with the electron and positron data recorded by the Dark Matter Particle Explorer. The evolution of the FDs from 2 GeV to 20 GeV with a time resolution of 6 hr are given. We observe two solar energetic particle events in the time profile of the intensity of cosmic rays, the earlier, and weaker, one has not been shown in the neutron monitor data. Furthermore, both the amplitude and recovery time of fluxes of electrons and positrons show clear energy dependence, which is important in probing the disturbances of the interplanetary environment by the coronal mass ejections.

Geomagnetic signatures during the intense geomagnetic storms of 29 October and 20 November 2003

S. **Alex**, S. Mukherjee, G.S. Lakhina

Journal of Atmospheric and Solar-Terrestrial Physics, Volume 68, Issue 7, April 2006, Pages 769-780

Solar cycle 23 in its declining phase witnessed the most pronounced space weather events during October–November 2003. A series of powerful solar flares and associated geoeffective Coronal Mass Ejections (CMEs) travelling at 2000 km/s drove shock fronts that impacted the Earth's magnetic field consecutively on 29 and 30 October, resulting in intense geomagnetic disturbances during 29–31 October. Another intense geomagnetic storm activity occurred during 20–21 November, resulting from a solar flare that had an associated geoeffective CME travelling at a speed of 1100 km/s. Digital ground magnetic field measurements from the equatorial and low-latitude locations in the Indian longitude zone, in conjunction with the interplanetary solar wind and magnetic field parameters, are used to study the characteristics of these storms. Maximum magnitude of the total magnetospheric energy injected into the magnetosphere during the mainphase of the three major storm amounts to approximately 4.5×10^{13} , 3.6×10^{13} , 2.8×10^{13} W. Another salient feature brought out is the close correspondence between the magnitude of the peak of the southward component of the interplanetary magnetic field B_z and the strength of the storm intensity as inferred from the Dst and low-latitude digital magnetic records.

Exploring the Coronal Magnetic Field with Galactic Cosmic Rays: The Sun Shadow Observed by HAWC

Galactic cosmic rays (GCRs) are charged particles that reach the heliosphere almost isotropically in a wide energy range. In the inner heliosphere, the GCR flux is modulated by solar activity so that only energetic GCRs reach the lower layers of the solar atmosphere. In this work, we propose that high-energy GCRs can be used to explore the solar magnetic fields at low coronal altitudes. We used GCR data collected by the High-Altitude Water Cherenkov observatory to construct maps of GCR flux coming from the Sun's sky direction and studied the observed GCR deficit, known as Sun shadow (SS), over a 6 yr period (2016–2021) with a time cadence of 27.3 days. We confirm that the SS is correlated with sunspot number, but we focus on the relationship between the photospheric solar magnetic field measured at different heliolatitudes and the relative GCR deficit at different energies. We found a linear relationship between the relative deficit of GCRs represented by the depth of the SS and the solar magnetic field. This relationship is evident in the observed energy range of 2.5–226 TeV, but is strongest in the range of 12.4–33.4 TeV, which implies that this is the best energy range to study the evolution of magnetic fields in the low solar atmosphere.

Investigating The Cross-section of Coronal Mass Ejections Through the Study of Non-Radial Flows with STEREO/PLASTIC

N. Al-Haddad, A. B. Galvin, N. Lugaz, C. J. Farrugia, W. Yu
ApJ 927 68 2022

<https://arxiv.org/pdf/2110.10682.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac32e1/pdf>

The solar wind, when measured close to 1 au, is found to flow mostly radially outward. There are, however, periods when the flow makes angles up to 15° away from the radial direction, both in the east-west and north-south directions. Stream interaction regions (SIRs) are a common cause of east-west flow deflections. Coronal mass ejections (CMEs) may be associated with non-radial flows in at least two different ways: 1) the deflection of the solar wind in the sheath region, especially close to the magnetic ejecta front boundary, may result in large non-radial flows, 2) the expansion of the magnetic ejecta may include a non-radial component which should be easily measured when the ejecta is crossed away from its central axis.

In this work, we first present general statistics of non-radial solar wind flows as measured by STEREO/PLASTIC throughout the first 13 years of the mission, focusing on solar cycle variation. We then focus on the larger deflection flow angles and determine that most of these are associated with SIRs near solar minimum and with CMEs near solar maximum. However, we find no clear evidence of strongly deflected flows, as would be expected if large deflections around the magnetic ejecta or ejecta with elliptical cross-sections with large eccentricities are common. We use these results to develop a better understanding of CME expansion and the nature of magnetic ejecta, and point to shortcomings in our understanding of CMEs. **2010 September 11, 2012 July 11, 24-25 Jul 2017**

The Magnetic Morphology of Magnetic Clouds: Multi-spacecraft Investigation of Twisted and Writhed Coronal Mass Ejections

N. Al-Haddad¹, S. Poedts², I. Roussev², C. J. Farrugia³, W. Yu³, and N. Lugaz

2019 ApJ 870 100

sci-hub.tw/10.3847/1538-4357/aaf38d

We present a study about the structure of the magnetic field inside coronal mass ejections (CMEs) with consideration of the helicity property of the magnetic field lines. We perform reconstructions and fittings of the magnetic field of two simulated CMEs: (1) a CME with writhed magnetic field lines and minimum twist, and (2) a CME with a twisted flux rope structure. Our aim is to gain insight into the structure of the CMEs' magnetic field through comparing the outcome of the fitting techniques with the actual structure of the simulated CMEs. Reconstructions are performed at 12 different locations using the Grad–Shafranov reconstruction technique and a force-free fitting technique. These locations correspond to different impact parameters, as well as different longitudinal planes in the CME "legs." We find that a flux rope CME and a writhed CME cannot be distinguished by comparing the best-fit orientation at different locations. We also find that the reconstructed shapes and impact parameters may provide some clues about the presence of substantial writhe. Because of the difficulty for present codes to detect writhe, we conclude that reconstruction codes and fitting techniques have to be significantly improved, by taking into consideration the writhe of the magnetic field lines.

Fitting and Reconstruction of Thirteen Simple Coronal Mass Ejections

[Nada Al-Haddad](#), [Teresa Nieves-Chinchilla](#), [Neel P. Savani](#), [Noe Lugaz](#), [Ilia I. Roussev](#)

Solar Phys. **2018**

<https://arxiv.org/pdf/1804.02359.pdf>

Coronal mass ejections (CMEs) are the main drivers of geomagnetic disturbances, but the effects of their interaction with Earth's magnetic field depend on their magnetic configuration and orientation. Fitting and reconstruction techniques have been developed to determine the important geometrical and physical CME properties. In many instances, there is disagreement between such different methods but also between fitting from in situ measurements and reconstruction based on remote imaging. Here, we compare three methods based on different assumptions for measurements of thirteen CMEs by the Wind spacecraft from 1997 to 2015. These CMEs are selected from the interplanetary coronal mass ejections catalog on [this https URL](#) due to their simplicity in terms of 1) small expansion speed throughout the CME and 2) little asymmetry in the magnetic field profile. This makes these thirteen events ideal candidates to compare codes that do not include expansion nor distortion. We find that, for these simple events, the codes are in relatively good agreement in terms of the CME axis orientation for six out of the 13 events. Using the Grad-Shafranov technique, we can determine the shape of the cross-section, which is assumed to be circular for the other two models, a force-free fitting and a circular-cylindrical non-force-free fitting. Five of the events are found to have a clear circular cross-section, even when this is not a pre-condition of the reconstruction. We make an initial attempt at evaluating the adequacy of the different assumptions for these simple CMEs. The conclusion of this work strongly suggests that attempts at reconciling in situ and remote-sensing views of CMEs must take in consideration the compatibility of the different models with specific CME structures to better reproduce flux ropes. **1997-01-10, 1998-08-19, 2000-07-01, 2001-04-21, 2002-09-29, 2008-05-23, 2009-09-30, 2012-05-16, 2012-11-12, 2013-06-27, 2013-12-24, 2014-04-11, 2015-05-06**

Magnetic Field Configuration Models and Reconstruction Methods for Interplanetary Coronal Mass Ejections

N. [Al-Haddad](#), T. Nieves-Chinchilla, N. P. Savani, C. Möstl, K. Marubashi, M. A. Hidalgo, I. I. Roussev, S. Poedts, C. J. Farrugia

Solar Phys. Volume 284, Issue 1, pp 129-149, **2013**; **File**

This study aims to provide a reference for different magnetic field models and reconstruction methods for interplanetary coronal mass ejections (ICMEs). To understand the differences in the outputs of these models and codes, we analyzed 59 events from the Coordinated Data Analysis Workshop (CDAW) list, using four different magnetic field models and reconstruction techniques; force-free fitting, magnetostatic reconstruction using a numerical solution to the Grad–Shafranov equation, fitting to a self-similarly expanding cylindrical configuration and elliptical, non-force-free fitting. The resulting parameters of the reconstructions for the 59 events are compared statistically and in selected case studies. The ability of a method to fit or reconstruct an event is found to vary greatly; this depends on whether the event is a magnetic cloud or not. We find that the magnitude of the axial field is relatively consistent across models, but that the axis orientation of the ejecta is not. We also find that there are a few cases with different signs of the magnetic helicity for the same event when we leave the boundaries free to vary, which illustrates that this simplest of parameters is not necessarily always clearly constrained by fitting and reconstruction models. Finally, we examine three unique cases in depth to provide a comprehensive idea of the different aspects of how the fitting and reconstruction codes work.

ON THE INTERNAL STRUCTURE OF THE MAGNETIC FIELD IN MAGNETIC CLOUDS AND INTERPLANETARY CORONAL MASS EJECTIONS: WRITHE VERSUS TWIST

N. **Al-Haddad**^{1,2}, I. I. Roussev¹, C. Möstl^{3,4}, C. Jacobs², N. Lugaz¹, S. Poedts² and C. J. Farrugia
2011 ApJ 738 L18

In this study, we test the flux rope paradigm by performing a "blind" reconstruction of the magnetic field structure of a simulated interplanetary coronal mass ejection (ICME). The ICME is the result of a magnetohydrodynamic numerical simulation and does not exhibit much magnetic twist, but appears to have some characteristics of a magnetic cloud, due to a writhe in the magnetic field lines. We use the Grad-Shafranov technique with simulated spacecraft measurements at two different distances and compare the reconstructed magnetic field with that of the ICME in the simulation. While the reconstructed magnetic field is similar to the simulated one as seen in two dimensions, it yields a helically twisted magnetic field in three dimensions. To further verify the results, we perform the reconstruction at three different position angles at every distance point, and all results are found to be in agreement. This work demonstrates that the current paradigm of associating magnetic clouds with flux ropes may have to be revised.

Testing the empirical relationship between Forbush decreases and cosmic ray diurnal anisotropy

Jibrin Adejoh **Alhassan**, [Ogbonnaya Okike](#), [Augustine Ejikeme Chukwude](#)

Research in Astronomy and Astrophysics (RAA) 2022

<https://arxiv.org/pdf/2203.08883.pdf>

The abrupt aperiodic modulation of cosmic ray (CR) flux intensity, often referred to as Forbush decrease (FD), plays a significant role in our understanding of the Sun-Earth electrodynamics. Accurate and precise determination of FD magnitude and timing are among the intractable problems in FD-based analysis. FD identification is complicated by CR diurnal anisotropy. CR anisotropy can increase or reduce the number and amplitude of FDs. It is therefore important to remove its contributions from CR raw data before FD identification. Recently, an attempt was made, using a combination of Fourier transformed technique and FD-location machine to address this. Thus, two FD catalogs and amplitude diurnal variation (ADV) were calculated from filtered (FD1 and ADV) and raw (FD2) CR data. In the current work, we test the empirical relationship between FD1, FD2, ADV, and solar-geophysical characteristics. Our analysis shows that two types of magnetic fields-interplanetary (IMF) and geomagnetic (Dst) govern the evolution of CR flux intensity reductions. 30 Oct 2003

<https://arxiv.org/pdf/2111.05332.pdf>

Accurate detection and precise timing of transient events such as X-ray photons, $\{\gamma\}$ -ray burst, coronal mass ejections (CMEs), ground level enhancements (GLEs) and Forbush decreases (FDs) frequently raise issues that remain on the cutting edge of research in astrophysics. In an attempt to automate FD event selection, a combination of Fast Fourier transform as well as FD detection algorithms implemented in the statistical computing software R was developed and recently used to calculate the magnitude and FD event timing. The R-FD code implemented in the present study includes several different calculations. Some subroutines detect both small and large transient intensity reductions (minima/pits) as well as increases (maxima/peaks) in cosmic ray (CR) data. Others calculate event amplitude, timing and cataloging of the events identified. As the current work focuses on reductions in CR flux (FDs), the subroutine that identifies increases was disabled. Totals of 229 FDs at Magadan neutron monitor (NM), 230 (Oulu NM) and 224 (Inuvick NM) were identified with daily averaged data, while 4032 (Magadan), 4144 (Oulu) and 4055 (Inuvick) were detected with hourly averages. FDs identified as simultaneous at the three stations totaled 99 for the daily and 261 for the hourly CR averages respectively. 12-13 Feb 2000, 23 May 2002

Investigation of the Relation between Space-Weather Parameters and Forbush Decreases Automatically Selected from Moscow and Apatity Cosmic Ray Stations during Solar Cycle 23

Jibrin A. **Alhassan**, [Ogbonnaya Okike](#), [Augustine E. Chukwude](#)

Research in Astronomy and Astrophysics (RAA) 2021

<https://arxiv.org/pdf/2108.09371.pdf>

We present the results of an investigation of the relation between space-weather parameters and cosmic ray (CR) intensity modulation using algorithm-selected Forbush decreases (FDs) from Moscow (MOSC) and Apatity (APTY) neutron monitor (NM) stations during solar cycle 23. Our FD location program detected 408 and 383 FDs from MOSC and APTY NM stations respectively. A coincident computer code employed in this work, detected 229 FDs that were observed at the same universal Time (UT) at the two stations. Out of the 229 simultaneous FDs, we formed a subset of 139 large FDs ($\Delta I \leq -4$) at Moscow station. We performed a two dimensional regression analysis between the FD magnitudes and the space-weather data on the two samples. We find that there were significant space-weather disturbances at the time of the CR flux depressions. The correlation between the space-weather parameters and galactic cosmic ray (GCR) intensity decreases at the two NM stations are statistically significant. The implications of the present space-weather data on cosmic ray (CR) intensity depressions are highlighted.

Table 1: Selected FDs at MOSC and APTY Stations from 1996-2005

Testing the Effect of Solar Wind Parameters and Geomagnetic Storm Indices on Galactic Cosmic Ray Flux Variation with Automated-Selected Forbush Decreases

Jibrin A. Alhassan, Ogbonnaya Okike, Augustine E. Chukwude

Research in Astronomy and Astrophysics Volume: 21. Issue: 9. 2021

<https://arxiv.org/pdf/2108.09066.pdf>

<https://iopscience.iop.org/article/10.1088/1674-4527/21/9/234/pdf>

Forbush decrease (FD), discovered by Scott E. Forbush about 80 years ago, is referred to as the non-repetitive short-term depression in galactic cosmic ray (GCR) flux, presumed to be associated with large-scale perturbations in solar wind and interplanetary magnetic field (IMF). It is the most spectacular variability in the GCR intensity which appear to be the compass for investigators seeking solar-terrestrial relationships. The method of selection and validation of FD events are very important to cosmic ray scientists. We have deployed a new computer software to determine the amplitude and timing of FDs from daily-averaged cosmic ray (CR) data at OULU neutron monitor station. The code selected 230 FDs between 1998 and 2002. In an attempt to validate the new FD automated catalog, the relationship between the amplitude of FDs, and IMF, solar wind speed (SWS) and geomagnetic storm indices (Dst, kp, ap) is tested here. A two-dimensional regression analysis indicates significant linear relationship between large FDs ($\Delta I \leq -3$) and solar wind data and geomagnetic storm indices in the present sample. The implications of the relationship among these parameters are discussed.

Table 2: 129 Oulu NM station FDs (All FDs) and Associated Solar Wind Data and Geomagnetic Activity Indices from 1998-2002

Properties of the HPS-ICME-CIR Interaction Event of 9–10 September 2011

Duraid A. Al-Shakarchi, Huw Morgan

JGR **Volume 123, Issue 4** Pages 2535-2556 **2018**

<https://agupubs.onlinelibrary.wiley.com/doi/full/10.1002/2017JA024849>

During 9–10 September 2011 the ACE, Wind, and SOHO spacecraft measured the complex interaction between an interplanetary coronal mass ejection (ICME) and a corotating interaction region (CIR) associated with the heliospheric sector boundary. Except for a few short periods, the suprathermal electrons are unidirectional, suggesting that the ICME magnetic field has opened through interchange reconnection. Signatures of interaction are distributed throughout the event suggesting that the structures have become entangled or embedded. Since the ICME speed is relatively low, the strong forward shock must be caused by the ICME-CIR interaction. Other interesting features are the upstream heating flux discontinuity, the very high proton density in the frontal boundary of the heliospheric plasma sheet and the forward shock, the significant speed elevation within the sheath, the distortion of Bz in the magnetic cloud, the indistinct location of the stream interface, the unidirectional domination of the suprathermal electrons, and the reverse shock at the CIR rear boundary. There is an unusual delay between the proton density and temperature profiles. Furthermore, large differences in proton speed and forward shock density measured between L1 spacecraft indicate high variation at small spatial scales. A few days earlier, STEREO B recorded the undisturbed CIR, which shows that (i) some general features of the CIR are preserved, (ii) the CIR is compressed by a factor of ~ 4 by the ICME, and (iii) a magnetic exhausted region at the front of the CIR is a continuous feature and is not formed due to the ICME interaction

Study of the Coronal Mass Ejections for the Down Phase of the Solar Cycle 24, the Events, Verifications and Simulation of the Plasma speed in the Sheath and ICME

Hamza A Ali, Alaa F Ahmed, Wafaa Zaki

Indian Journal of Natural Sciences Vol.8 / Issue 49 / August /2018

Coronal mass ejections CMEs are large amount ejections of plasma and magnetic field from solar corona which propagate through interplanetary space, and usually it affects Earth and other planets of solar system , In our study, we've identified all the events and sun activities through the global Labs, SOHO LASCO, (2014-2015), then we've filtered all the events that could reach the earth, the events that have more the 500 km/s as a speed of the coronal mass ejections, after identifying the events in SOHO LASCO and filtering the events, we did compare the results of the proposed events with other Lab (ERNE) in order to figure out if these events are clear showed with ERNE or not, for the clear event, will be considered as real events, other events will be neglected, once comparing done, we worked on mathematical methods for tripled check and verifications, between the times evaluated and the times assumed, and this was the last method to identify where the events are earth reaching or not, using lognormal model to study the probability of the speed distributions in the sheath and ICME.

Studying the Characteristics of Shock waves associated with CMEs using solar radio bursts.

CESRA 2016, p.89

http://cesra2016.sciencesconf.org/conference/cesra2016/pages/CESRA2016_prog_abs_book_v3.pdf

Fast CME/shocks propagating in the Corona and the interplanetary medium can generate metric and kilometric Type II radio emissions at the local plasma frequency and/or its harmonic, respectively. So these radio emissions provide a means of remotely tracking CME/shocks. We apply analysis technique, using the frequency drift of metric spectrum obtained by ground station e-Callisto (Compound Astronomical Low cost Low frequency Instrument for Spectroscopy and Transportable Observatory) in Space Weather Monitoring Center (SWMC) { Helwan University, and estimated by using electron density model the propagation speed of CME/shocks in the corona, and the km-TII spectrum obtained by the WIND/WAVES experiment, to infer, at some adequate intervals, the propagation speed of CME/shocks in the interplanetary medium. We applied this technique on _ve CME/shocks. We combine these results with previously reported speeds from coronagraph white light and interplanetary scintillation observations, and in-situ measurements, to study the temporal speed evolution of the _ve events. The speed values obtained by the metric and km-TII analysis are in a reasonable agreement with the speed measurements obtained by other techniques at di_ erent heliocentric distance ranges. The combination of all the speed measurements show a gradual deceleration of the CME/shocks as they propagate to 1 AU. This technique can be useful in studying the evolution and characteristics of fast CME/shocks when adequate intervals of km-TII emissions are available.

Predictive capabilities and limitations of stream interaction region observations at different solar longitudes

Space Weather [Volume18, Issue4](#) 2020 e2019SW002437

sci-hub.si/10.1029/2019SW002437

<https://doi.org/10.1029/2019SW002437>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2019SW002437>

Advanced warning of a Stream Interaction Region (SIR) or Co-rotating Interaction Region (CIR) impinging upon the magnetosphere of Earth is important for space weather forecasting, due to the ability of SIRs/CIRs to trigger geomagnetic storms and affect ionospheric composition and winds. However, a focused investigation of the likelihood that either an L5 monitor or Earth-trailing “string-of-pearl” constellation of satellites would be able to serve as an effective warning buoy for SIRs/CIRs that will affect the near-Earth space environment has yet to be extensively performed. Through comparing 10 years of SIRs/CIRs observed at L1 and at STEREO, we have investigated the probability of sequentially detecting SIRs/CIRs at two locations as a function of the difference in heliospheric longitude and latitudinal separation between the two spacecraft. By examining the probability of repeat detection of SIRs/CIRs using variable separation distances between two observing points, we explore the utility of an Earth trailing monitor for SIR/CIR predictability (i.e., 74.6% of SIRs observed at L5 reach L1 within ± 3 days of rigid co-rotation). While the

probability of predicting the occurrence of SIRs/CIRs at another spacecraft decreases with longitudinal separation, there is not a significant dependence on latitude. The primary source of error in reliably predicting the arrival time of an SIR/CIR is uncertainty in the rotational speed of the structure. While an L5 monitor would be an advancement in our operational warning ability, an Earth-trailing “string-of-pearls” constellation utilizing multiple point of measurements would engender much more certainty in predicting the arrival time of SIRs/CIRs.

Prediction of Geoeffective CMEs Using SOHO Images and Deep Learning.

Alobaid, K.A., Wang, J.T.L., Wang, H. et al.

Sol Phys 299, 159 (2024).

<https://doi.org/10.1007/s11207-024-02385-w>

<https://link.springer.com/content/pdf/10.1007/s11207-024-02385-w.pdf> **File**

The application of machine learning to the study of coronal mass ejections (CMEs) and their impacts on Earth has seen significant growth recently. Understanding and forecasting CME geoeffectiveness are crucial for protecting infrastructure in space and ensuring the resilience of technological systems on Earth. Here we present GeoCME, a deep-learning framework designed to predict, deterministically or probabilistically, whether a CME event that arrives at Earth will cause a geomagnetic storm. A geomagnetic storm is defined as a disturbance of the Earth’s magnetosphere during which the minimum Dst index value is less than -50 nT. GeoCME is trained on observations from the instruments including LASCO C2, EIT, and MDI on board the Solar and Heliospheric Observatory (SOHO), focusing on a dataset that includes 136 halo/partial halo CMEs in Solar Cycle 23. Using ensemble and transfer learning techniques, GeoCME is capable of extracting features hidden in the SOHO observations and making predictions based on the learned features. Our experimental results demonstrate the good performance of GeoCME, achieving a Matthew’s correlation coefficient of 0.807 and a true skill statistics score of 0.714 when the tool is used as a deterministic prediction model. When the tool is used as a probabilistic forecasting model, it achieves a Brier score of 0.094 and a Brier skill score of 0.493. These results are promising, showing that the proposed GeoCME can help enhance our understanding of CME-triggered solar-terrestrial interactions. **17 September 2022**

Ensemble Learning for CME Arrival Time Prediction

Khalid A. **Alobaid**, [Jason T. L. Wang](#)

2023

<https://arxiv.org/pdf/2305.00258.pdf>

The Sun constantly releases radiation and plasma into the heliosphere. Sporadically, the Sun launches solar eruptions such as flares and coronal mass ejections (CMEs). CMEs carry away a huge amount of mass and magnetic flux with them. An Earth-directed CME can cause serious consequences to the human system. It can destroy power grids/pipelines, satellites, and communications. Therefore, accurately monitoring and predicting CMEs is important to minimize damages to the human system. In this study we propose an ensemble learning approach, named CMETNet, for predicting the arrival time of CMEs from the Sun to the Earth. We collect and integrate eruptive events from two solar cycles, #23 and #24, from 1996 to 2021 with a total of 363 geoeffective CMEs. The data used for making predictions include CME features, solar wind parameters and CME images obtained from the SOHO/LASCO C2 coronagraph. Our ensemble learning framework comprises regression algorithms for numerical data analysis and a convolutional neural network for image processing. Experimental results show that CMETNet performs better than existing machine learning methods reported in the literature, with a Pearson product-moment correlation coefficient of 0.83 and a mean absolute error of 9.75 hours.

Plasma Data Sources in the OMNI Database

B. L. Alterman

2022 Res. Notes AAS 6 135

<https://iopscience.iop.org/article/10.3847/2515-5172/ac7a2f>

The OMNI data set is a tool well situated for analysis with advanced machine learning (ML) and artificial intelligence (AI) techniques. Because OMNI incorporates data from multiple instruments and spacecraft, care must be taken when interpreting these results. We discuss the OMNI/Lo plasma data sources and one potential challenge with interpreting the results of ML and AI techniques when applied to it.

Geoeffectiveness of solar wind interplanetary magnetic structures

M.V. **Alves**, a, , , E. Echer and W.D. Gonzalez

Journal of Atmospheric and Solar-Terrestrial Physics, Volume 73, Issues 11-12, 2011, Pages 1380-1384

We address the geoeffectiveness of three interplanetary structures in the interplanetary space: magnetic clouds (MCs), interplanetary shocks (IPs), and corotating interaction regions (CIRs). The geoeffectiveness is evaluated using the geomagnetic indices K_p , AE, and Dst. We find that MCs are more geoeffective than IPs, or CIRs. The average values of magnetic indices are significantly enhanced during disturbed periods associated with MCs, IPs and CIRs, compared to the whole interval. The highest effect is noted for MC disturbed periods.

Results obtained for the three data sets are used to derive a theoretical (continuous) probability distribution function (PDF) by fitting the histograms representing the percentage of events against the intervals of magnetic index. PDFs allow estimation of the probability of a given level of geomagnetic activity to be reached after the detection, by in situ solar wind observations, of a given interplanetary structure approaching the Earth.

Empirical forecasting models for peak intensities of energetic storm particles at 1 AU

Dheyaa **Ameri** a b, Rami Vainio b, Eino Valtonen b

Advances in Space Research Volume 73, Issue 1, 1 January 2024, Pages 1050-1063

<https://doi.org/10.1016/j.asr.2023.11.021>

<https://www.sciencedirect.com/science/article/pii/S0273117723009067>

We have investigated the dependence of the peak intensities of energetic storm particles (ESPs) on various parameters characterising the coronal mass ejections (CMEs) and associated phenomena. The aim of this study is to suggest empirical models for forecasting the peak intensities of ESP events at 1 AU based on solar and interplanetary (IP) space observations.

For this study we searched for the associations of front-side full and partial halo CMEs with linear speeds >400 km s^{-1} during the years 1996–2015 with IP shocks at 1 AU and ESP events observed near the time when the shock passes the observer. We found 88 CME-driven IP shocks associated with ESP events at proton energy range 5.0–7.2 MeV (nominal energy 6.0 MeV) and 59 shocks at the energy range 15.1–21.9 MeV (nominal energy 18.2 MeV). At these two energies 71 % and 68 % of the ESP events were associated with solar energetic particle (SEP) events, 85 % and 84 % were associated with decametric–hectometric (DH) type II radio bursts while 67 % and 66 % were associated with both. For each CME - shock pair we calculated the predicted shock transit speed (VTR) by using the method of [Belov et al. \(2022\)](#) and used this as the primary parameter in the investigation. We performed correlation analyses between the logarithm of the peak intensities of the ESP events (\log_{10} [IESP_{peak}]) and the solar parameters related to the CMEs, solar flares, IP shocks, SEP events, and type II radio bursts. When using a single explanatory variable, we found best correlation coefficients for VTR (0.68 ± 0.05 and 0.71 ± 0.06), the CME space speed (VCME_{space}) (0.59 ± 0.05 and 0.68 ± 0.07), and the logarithm of SEP peak intensity (\log_{10} [ISEP_{peak}]) (0.55 ± 0.08 and 0.70 ± 0.08) at 6.0 and 18.2 MeV, respectively. Weak to moderate correlations were found for the logarithm of the soft X-ray flux (\log_{10} [SXRF]) and the logarithm of the duration of DH type II radio burst (\log_{10} [DTII]).

Using linear combinations of two or more variables improved the correlations. The best two-variable combination explaining \log_{10} [IESP_{peak}] was VTR combined with \log_{10} [ISEP_{peak}] and the best three- and four-variable combinations also included these two parameters. We found two methods for forecasting ESP peak intensities, one of which can be used for long lead time and the other for medium lead time forecasting. For long lead time forecasting VTR, VCME_{space} and \log_{10} [SXRF] are used. The correlation coefficients between the calculated and observed \log_{10} [IESP_{peak}] were 0.71 ± 0.05 at 6.0 MeV and 0.74 ± 0.06 at 18.2 MeV. This method only depends on the coronagraph and X-ray observations at the Sun. For medium lead time forecasting the four parameters used are VTR, \log_{10} [ISEP_{peak}], VCME_{space} (or \log_{10} [SXRF]), and \log_{10} [DTII]. The correlation coefficients were 0.80 ± 0.04 at 6.0 MeV and 0.84 ± 0.05 at 18.2 MeV. Coronagraph observations at the Sun and solar energetic particle and DH type II burst measurements in IP space are required for this method. The medium lead time forecasting provides an average warning time of 30 ± 16 h.

Relationships between energetic storm particle events and interplanetary shocks driven by full and partial halo coronal mass ejections

D. Ameri, E. Valtonen, A. Al-Sawad, R. Vainio

Adv. Space Res., **Volume 71, Issue 5**, (2023), pp. 2521-2533,

<https://doi.org/10.1016/j.asr.2022.12.014>

<https://www.sciencedirect.com/science/article/pii/S0273117722011061>

We have analysed energetic storm particle (ESP) events in 116 interplanetary (IP) shocks driven by front-side full and partial halo coronal mass ejections (CMEs) with speeds $>400 \text{ km s}^{-1}$ during the years 1996–2015. We investigated the occurrence and relationships of ESP events with several parameters describing the IP shocks, and the associated CMEs, type II radio bursts, and solar energetic particle (SEP) events. Most of the shocks (57 %) were associated with an ESP event at proton energies $>1 \text{ MeV}$.

The shock transit speeds from the Sun to 1 AU of the shocks associated with an ESP event were significantly greater than those of the shocks without an ESP event, and best distinguished these two groups of shocks from each other. The occurrence and maximum intensity of the ESP events also had the strongest dependence on the shock transit speed compared to the other parameters investigated. The correlation coefficient between ESP peak intensities and shock transit speeds was highest (0.73 ± 0.04) at 6.2 MeV. Weaker dependences were found on the shock speed at 1 AU, Alfvénic and magnetosonic Mach numbers, shock compression ratio, and CME speed. On average all these parameters were significantly different for shocks capable to accelerate ESPs compared to shocks not associated with ESPs, while the differences in the shock normal angle and in the width and longitude of the CMEs were insignificant.

The CME-driven shocks producing energetic decametric–hectometric (DH) type II radio bursts and high-intensity SEP events proved to produce also more frequently ESP events with larger particle flux enhancements than other shocks.

Together with the shock transit speed, the characteristics of solar DH type II radio bursts and SEP events play an important role in the occurrence and maximum intensity of ESP events at 1 AU.

Potential role of energetic particle observations in geomagnetic storm forecasting

Dheyaa Ameri, Eino Valtonen

Advances in Space Research **Volume 64, Issue 3**, 1 August 2019, Pages 801-813

<https://sci-hub.se/10.1016/j.asr.2019.05.012>

We have searched for solar proton events consisting of both solar energetic particles (SEPs) accelerated near the Sun and energetic storm particles (ESPs) accelerated by interplanetary shocks driven by coronal mass ejections (CMEs) and observed near the time when the shock passes the observer. The purpose of this study is to investigate the possibilities and advantages of using energetic particle observations for mid-term (warning time several hours) forecasting of geomagnetic storms or as a support for longer-term forecasting methods based on solar observations. The study period extends from May 1996 to December 2017 covering the entire solar cycle 23 and the major part of solar cycle 24. Using two particle energies, 2 and 20 MeV, we found 95 SEP–ESP events of which 65 were associated with geomagnetic storms with $Dst \leq -50 \text{ nT}$ caused by CMEs. We performed correlation analysis between $\log_{10}|Dst \text{ (nT)}|$ and various parameters characterising the particle events or the associated CMEs. We found the best correlations for the single independent variables $\Delta t_{ESP-SEP}$ ($r = -0.47 \pm 0.08$), which is the difference between the ESP peak time and SEP onset time, the CME direction parameter DP ($r = 0.47 \pm 0.10$), and the logarithm of the maximum ESP energy $\log_{10}[E_{ESPmax} \text{ (MeV)}]$ ($r = 0.44 \pm 0.11$). Using a linear combination of these three variables improves the correlation ($r = 0.68 \pm 0.07$). We suggest that an empirical equation based on these three parameters and requiring only coronagraph observations of CMEs and energetic particle measurements in interplanetary space can be used for mid-term forecasting of geomagnetic storm strengths. We found that 74% of the strongest storms ($Dst \leq -200 \text{ nT}$) during the study period were associated with energetic particle events. The average warning time and its standard deviation for all geomagnetic storms associated with SEP–ESP events was (15 ± 10) hours. **5-6 Aug 2011**

Table A.3 SEP–ESP events and associated CME direction parameters and values of the minimum Dst in 1996–2017.

Investigation of the Geoeffectiveness of Disk-Centre Full-Halo Coronal Mass Ejections

Dheyaa Ameri, Eino Valtonen

Solar Physics June 2017, 292:79 **File**

<https://link.springer.com/content/pdf/10.1007%2Fs11207-017-1102-7.pdf>

We studied the occurrence and characteristics of geomagnetic storms associated with disk-centre full-halo coronal mass ejections (DC-FH-CMEs). Such coronal mass ejections (CMEs) can be considered as the most plausible cause of geomagnetic storms. We selected front-side full-halo coronal mass ejections detected by the Large Angle and

Spectrometric Coronagraph onboard the Solar and Heliospheric Observatory (SOHO/LASCO) from the beginning of 1996 till the end of 2015 with source locations between solar longitudes E10 and W10 and latitudes N20 and S20. The number of selected CMEs was 66 of which 33 (50%) were deduced to be the cause of 30 geomagnetic storms with $Dst \leq -50$ nT. Of the 30 geomagnetic storms, 26 were associated with single disk-centre full-halo CMEs, while four storms were associated, in addition to at least one disk-centre full-halo CME, also with other halo or wide CMEs from the same active region. Thirteen of the 66 CMEs (20%) were associated with 13 storms with $-100 \text{ nT} < Dst \leq -50$ nT, and 20 (30%) were associated with 17 storms with $Dst \leq -100$ nT. We investigated the distributions and average values of parameters describing the DC-FH-CMEs and their interplanetary counterparts encountering Earth. These parameters included the CME sky-plane speed and direction parameter, associated solar soft X-ray flux, interplanetary magnetic field strength, B_t , southward component of the interplanetary magnetic field, B_s , solar wind speed, V_{sw} , and the y -component of the solar wind electric field, E_y . We found only a weak correlation between the Dst of the geomagnetic storms associated with DC-FH-CMEs and the CME sky-plane speed and the CME direction parameter, while the correlation was strong between the Dst and all the solar wind parameters (B_t , B_s , V_{sw} , E_y) measured at 1 AU. We investigated the dependences of the properties of DC-FH-CMEs and the associated geomagnetic storms on different phases of solar cycles and the differences between Solar Cycles 23 and 24. In the rise phase of Solar Cycle 23 (SC23), five out of eight DC-FH-CMEs were geoeffective ($Dst \leq -50$ nT). In the corresponding phase of SC24, only four DC-FH-CMEs were observed, three of which were non-geoeffective ($Dst > -50$ nT). The largest number of DC-FH-CMEs occurred at the maximum phases of the cycles (21 and 17, respectively). Most of the storms with $Dst \leq -100$ nT occurred at or close to the maximum phases of the cycles. When comparing the storms during epochs of corresponding lengths in Solar Cycles 23 and 24, we found that during the first 85 months of Cycle 23 the geoeffectiveness rate of the disk-centre full-halo CMEs was 58% with an average minimum value of the Dst index of -146 nT. During the corresponding epoch of Cycle 24, only 35% of the disk-centre full-halo CMEs were geoeffective with an average value of Dst of -97 nT. **Table 2** Storms and ICMEs associated with single DC-FH-CMEs.

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2020SW002553>

In this study, we evaluate a coronal mass ejection (CME) arrival prediction tool that utilizes the wide-angle observations made by STEREO's heliospheric imagers (HI). The unsurpassable advantage of these imagers is the possibility to observe the evolution and propagation of a CME from close to the Sun out to 1 AU and beyond. We believe that by exploiting this capability, instead of relying on coronagraph observations only, it is possible to improve today's CME arrival time predictions. The ELLipse Evolution model based on HI observations (ELEvoHI) assumes that the CME frontal shape within the ecliptic plane is an ellipse, and allows the CME to adjust to the ambient solar wind speed, i.e. it is drag-based. ELEvoHI is used to perform ensemble simulations by varying the CME frontal shape within given boundary conditions that are consistent with the observations made by HI. In this work, we evaluate different set-ups of the model by performing hindcasts for 15 well-defined isolated CMEs that occurred when STEREO was near L4/5, between the end of 2008 and the beginning of 2011. In this way, we find a mean absolute error of between 6.2 ± 7.9 h and 9.9 ± 13 h depending on the model set-up used. ELEvoHI is specified for using data from future space weather missions carrying HIs located at L5 or L1. It can also be used with near real-time STEREO-A HI beacon data to provide CME arrival predictions during the next ~ 7 years when STEREO-A is observing the Sun-Earth space. **12 Dec 2008, 26 Oct 2010**

The Solar TERrestrial RELations Observatory (STEREO) and its heliospheric imagers (HI) have provided us the possibility to enhance our understanding of the interplanetary propagation of coronal mass ejections (CMEs). HI-based methods are able to forecast arrival times and speeds at any target and use the advantage of tracing a CME's path of propagation up to 1 AU. In our study we use the ELEvoHI model for CME arrival prediction together with an ensemble approach to derive uncertainties in the modeled arrival time and impact speed. The CME from **3 November 2010** is analyzed by performing 339 model runs that are compared to in situ measurements from lined-up spacecraft MESSENGER and STEREO-B. Remote data from STEREO-B showed the CME as halo event, which is comparable to an HI observer situated at L1 and observing an Earth-directed CME. A promising and easy approach is found by using the frequency distributions of four ELEvoHI output parameters, drag parameter, background solar wind speed, initial distance and speed. In this case study, the most frequent values of these outputs lead to the predictions with the smallest errors. Restricting the ensemble to those runs, we are able to reduce the mean absolute arrival time error from 3.5 ± 2.6 h to 1.6 ± 1.1 h at 1 AU. Our study suggests that L1 may provide a sufficient vantage point for an Earth-directed CME, when observed by HI, and that ensemble modeling could be a feasible approach to use ELEvoHI operationally.

Parametric Study of ICME Properties Related to Space Weather Disturbances via a Series of Three-Dimensional MHD Simulations

Junmo An, Tetsuya Magara, Keiji Hayashi, Yong-Jae Moon

Solar Physics October 2019, 294:143

<https://link.springer.com/content/pdf/10.1007%2Fs11207-019-1531-6.pdf>

Interplanetary coronal mass ejections (ICMEs) are important drivers of space-weather disturbances observed at the Earth. We use a parameterized ICME model to investigate the relation between the physical properties of an ICME and these disturbances. Compared to those studies focused on deriving a best set of ICME parameter values matched with observed disturbances, this study is aimed at investigating the role of each parameter in producing space-weather disturbances. Toward this end, we performed a series of three-dimensional magnetohydrodynamic (MHD) simulations with different sets of ICME parameter values. These parameters are the location, speed, mass, magnetic field strength, and magnetic field orientation of a spheromak-shaped ICME, which is injected into the solar wind reconstructed from near-Sun data and interplanetary scintillation (IPS) data via an MHD-IPS tomography method. By comparing simulation results to in situ observations near the Earth we discuss how the physical properties of an ICME affect space-weather disturbances at the Earth.

Internal structure of a coronal mass ejection revealed by Akatsuki radio occultation observations†

H. Ando, D. Shiota, T. Imamura, M. Tokumaru, A. Asai, H. Isobe, M. Pätzold, B. Häusler, M. Nakamura
JGR 2015

A coronal mass ejection (CME) was observed at the heliocentric distance of 12.7 Rs by radio occultation measurements using the Akatsuki spacecraft. The temporal developments of the bulk velocity and the electron column density along the ray path traversing the CME were obtained, and under the assumption that the irregularities are transported across the ray path, the internal structure of the CME covering the region from the core to the tail was retrieved. The suggested internal structure was compared with LASCO coronagraph images, a numerical study and previous radio occultation observations of CMEs to propose a CME model: the bulk velocity and the electron density have relatively large values in the core, decrease behind the core, and increase again in the tail region where the fast plasma flow associated with the magnetic reconnection converges. This implies that the magnetic reconnection behind the CMEs might continue up to at least the heliocentric distance of ~ 13 Rs.

Analysis of the substructure within a complex magnetic cloud on 3–4 September 2008

K.A. Andréová, E.K. Kilpua, H.H. Hietala, H.E.K. Koskinen, A.I. Isavnin, and R.V. Vainio
Ann. Geophys., 31, 555-562, 2013

<http://www.ann-geophys.net/31/555/2013/>

In this paper we have analyzed a substructure found within a leading part of a north–south-oriented magnetic cloud (MC) observed on **3–4 September 2008** in the near-Earth solar wind by multiple spacecraft (ACE, Wind, THEMIS B and C). The MC was preceded by a stream interface (SI) and followed by a high-speed stream (HSS). The identified substructure featured a strong depletion of suprathermal halo electrons and showed distinct magnetic field and plasma signatures. It occurred where suprathermal electron flow within a cloud changed from bidirectional to unidirectional, indicating change in the field line connectivity to the Sun. We found that the substructure maintained roughly its

integrity from the first Lagrangian point to the vicinity of the Earth's bow shock in the front edge of the MC, but revealed small changes in the structure which could be explained either by temporal evolution or spatial configuration of the spacecraft.

Relevance vector machines as a tool for forecasting geomagnetic storms during years 1996–2007

T. **Andriyas**, S. Andriyas

JASTP, Volumes 125–126, April 2015, Pages 10–20

In this paper, we investigate the use of relevance vector machine (RVM) as a learning tool in order to generate 1-h (one hour) ahead forecasts for geomagnetic storms driven by the interaction of the solar wind with the Earth's magnetosphere during the years 1996–2007. This epoch included solar cycle 23 with storms that were both ICME (interplanetary coronal mass ejection) and CIR (corotating interaction region) driven. Merged plasma and magnetic field measurements of the solar wind from the Advanced Composition Explorer (ACE) and WIND satellites located upstream of the Earth's magnetosphere at 1-h cadence were used as inputs to the model. The magnetospheric response to the solar wind driving measured by the disturbance storm time or the Dst index (measured in nT) was used as the output to be forecasted. The model was first tested on previously reported storms in [Wu and Lundstedt \(1997\)](#) and it gave a linear correlation coefficient, ρ , of above 90% and prediction efficiency (PE) above 80%. During 1996–2007, several storms (within each year) were chosen as test cases to analyze the forecasting robustness of the model. The top three forecasts per year were analyzed to assess the generalization ability of the model. These included storms with varying intensities ranging from weak (–53.01 nT) to strong (–422.02 nT) and durations (119–445 h). The top RVM forecast in a given year had ρ above 85% (87.00–96.85%), PE >73% (73.59–93.59%), and a root mean square error (RMSE) ranging from 9.31 to 33.45 nT. A qualitative comparison is made with model forecasts previously reported by [Ji et al. \(2012\)](#). We found that the robustness of the model with regards to fast learning and generating forecasts within acceptable error bounds makes it a very good proposition as a prediction tool (given the solar wind parameters) for space weather monitoring.

Forecasting the Dst index during corotating interaction region events using synthesized solar wind parameters

Andriyas, T.; Spencer, E.; Raj, A.; Sojka, J.; Mays, M. L.

J. Geophys. Res., Vol. 117, No. A3, A03204, 2012; **File**

sci-hub.se/10.1029/2011JA017018

Observations from SOHO, STEREO, and ACE during the declining phase of the solar cycle towards the deep minimum in 2008 are analyzed to establish the timing of CIR activity. This analysis is then employed to synthesize signals of the z component of the interplanetary magnetic field (IMF B_z), solar wind radial velocity v_x , and solar wind proton density N_p at 1 AU. The synthesized signals are used as a substitute for ACE measurements to represent solar wind forcing due to coronal hole driven CIR events occurring during multiple Bartel rotations (BR 2381 - BR 2393). The signals drive a low order physics based model of the magnetosphere called WINDMI, one of whose outputs is the ground based measurement of the Dst index. Estimating the arrival of CIR events for future rotations using ACE and SOHO data during BR 2381 produced what we refer to as an uncalibrated yearly forecast. We next generated a video calibrated estimate of the arrival times of CIR events in addition to information from BR 2381 using SOHO and STEREO images of the Sun in order to produce a simulated 3.5 day ahead forecast of possible geomagnetic activity. The time of arrival of CIR events is taken to be the travel time of density compressions as seen in a non-inertial frame according to a radial solar wind speed of 500 km/s and a distance of 1 AU. We were able to forecast the timing of CIR induced geomagnetic activity to within 12 hours for 17 out of 28 events by using the expected recurrence of the events through multiple Bartel rotations together with SOHO and STEREO coronal hole sightings made 3.5 days before every event. The uncertainty in the IMF B_z led to a forecast of levels of geomagnetic activity on an ensemble basis, yielding a distribution of different possible Dst signatures. We used a 10 sample ensemble and a 50 sample ensemble to obtain typical representations of geomagnetic activity. Depending on the periodicity and intensity of fluctuations in B_z , we obtained higher or lower levels of activity, and shorter or longer times for the recovery of the Dst to quiet levels.

Periodicities in solar wind-magnetosphere coupling functions and geomagnetic activity during the past solar cycles

T. **Andriyas**, S. Andriyas

[Astrophysics and Space Science](#) September 2017, 362:160

In this paper, we study the solar-terrestrial relation through the wavelet analysis. We report periodicities common between multiple solar wind coupling functions and geomagnetic indices during five solar cycles and also the strength of this correspondence. The DstDst (found to be most predictable in Newell et al., *J. Geophys. Res. Space Phys.* 112(A1):A01206, 2007) and ALAL (least predictable in Newell et al., *J. Geophys. Res. Space Phys.* 112(A1):A01206, 2007) indices are used for this purpose. During the years 1966–2016 (which includes five solar cycles 20, 21, 22, 23, and 24), prominent periodicities $\leq 720 \leq 720$ days with power above 95% confidence level were found to occur around 27, 182, 385, and 648 days in the DstDst index while those in the ALAL index were found in bands around 27, 187, and 472 days. Ten solar wind coupling functions were then used to find periodicities common with the indices. All the coupling functions had significant power in bands centered around 27, 280, and 648 days while powers in fluctuations around 182, 385, and 472 days were only found in some coupling functions. All the drivers and their variants had power above the significant level in the 280–288 days band, which was absent in the DstDst and ALAL indices. The normalized scale averaged spectral power around the common periods in the coupling functions and the indices indicated that the coupling functions most correlated with the DstDst index were the Newell (27 and 385 days), Wygant (182 days), and Scurry-Russell and Boynton (648 days) functions. An absence of common power between the coupling functions and the DstDst index around the annual periodicity was noted during the even solar cycles. A similar analysis for the ALAL index indicated that Newell (27 days), Rectified (187 days), and Boynton (472 days) were the most correlated functions. It was also found that the correlation numbers were relatively weaker for the ALAL index, specially for the 187 day periodicity. It is concluded that as the two indices respond to solar wind forcing with varying levels of strength at various prominent scales and the coupling function used, the response might be dependent on the scale (days or months or years) of interest at which the solar wind driving is to be predicted.

Solar Filaments and Interplanetary Magnetic Field Bz

V. **Aparna** and Petrus C. Martens

2020 ApJ 897 68

<https://doi.org/10.3847/1538-4357/ab908b>

<https://sci-hub.tw/10.3847/1538-4357/ab908b> File

The direction of the axis of an interplanetary coronal mass ejection (ICME) plays an important role in determining if it will cause a geomagnetic disturbance in the Earth's magnetosphere upon impact. Long period southward-pointing ICME fields are known to cause significant space weather impacts and thus geomagnetic storms. We present an extensive analysis of CME–ICME directionality using 86 halo-CMEs observed between 2007 and 2017 to compare the direction of the source filament axial magnetic field on the Sun and the direction of the interplanetary magnetic field near the Earth at the L1 Lagrangian point. Excluding 12 cases that were too ambiguous to determine, for the remaining 74 ICMEs, we find an agreement in terms of the northward/southward orientation of Bz between ICMEs and their CME source regions in 85% of cases. Some of the previous studies discussed here have obtained an agreement of 77% and 55%. We therefore suggest that our method can be meaningful as a first step in efficiently predicting geoeffective ICMEs by observing and analyzing the source regions of CMEs on the Sun. **2012-03-26, 2013.04.11-16, 2013.12.07-13, 2014-12-21, 2016-01-01,**

Search for Large-scale Anisotropy in the Arrival Direction of Cosmic Rays with KASCADE-Grande

W. D. **Apel**, J. C. Arteaga-Velázquez, K. Bekk, M. Bertaina, J. Blümer, R. Bonino, H. Bozdog, I. M. Brancus, E. Cantoni, A. Chiavassa, F. Cossavella, K. Daumiller,...

2019 ApJ 870 91

<http://iopscience.iop.org/article/10.3847/1538-4357/aaf1ca/pdf>

We present the results of the search for large-scale anisotropies in the arrival directions of cosmic rays performed with the KASCADE-Grande experiment at energies higher than 10^{15} eV. To eliminate spurious anisotropies due to atmospheric or instrumental effects we apply the east–west method. We show, using the solar time distribution of the number of counts, that this technique allow us to remove correctly the count variations not associated to real anisotropies. By applying the east–west method we obtain the distribution of number of counts in intervals of 20 minutes of sidereal time. This distribution is then analyzed by searching for a dipole component; the significance of the amplitude of the first harmonic is 3.5σ , therefore, we derive its upper limit. The phase of the first harmonic is determined with an error of a few hours and is in agreement with the measurements obtained in the $10^{14} < E < 2 \times 10^{15}$ eV energy range by the EAS-TOP, IceCube, and IceTop experiments. This supports the hypothesis of a change of the phase of the first harmonic at energies greater than $\sim 2 \times 10^{14}$ eV.

Comparing the Performance of a Solar Wind model from the Sun to 1 AU using Real and Synthetic Magnetograms

Kalpa Henadhira [Arachhige](#), 1, 2 Ofer Cohen, 1, 2 Andres Muñoz Jaramillo[~], 3 and Anthony R. Yeates⁴
ApJ **938** 39 **2022**

<https://arxiv.org/pdf/2208.13668.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac8d59/pdf>

The input of the Solar wind models plays a significant role in accurate solar wind predictions at 1 AU. This work introduces a synthetic magnetogram produced from a dynamo model as an input for Magnetohydrodynamics (MHD) simulations. We perform a quantitative study that compares the Space Weather Modeling Framework (SWMF) results for the observed and the synthetic solar magnetogram input. For each case, we compare the results for Extreme Ultra-Violet (EUV) images and extract the simulation data along the earth trajectory to compare with in-situ observations. We initialize SWMF using the real and synthetic magnetogram for a set of Carrington Rotations (CR)s within the solar cycle 23 and 24. Our results help quantify the ability of dynamo models to be used as input to solar wind models and thus, provide predictions for the solar wind at 1 AU.

Proposed Resolution to the Solar Open Magnetic Flux Problem

C.Nick Arge (1), [Andrew Leisner](#) (2), [Samantha Wallace](#) (1), [Carl J. Henney](#) (3)

2024 ApJ **964** 115

<https://arxiv.org/pdf/2304.07649.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ad20e2/pdf>

The solar magnetic fields emerging from the photosphere into the chromosphere and corona are comprised of a combination of "closed" and "open" fields. The closed magnetic field lines are defined as those having both ends rooted in the solar surface, while the open field lines are those having one end extending out into interplanetary space and the other rooted at the Sun's surface. Since the early 2000's, the amount of total unsigned open magnetic flux estimated by coronal models have been in significant disagreement with in situ spacecraft observations, especially during solar maximum. Estimates of total open unsigned magnetic flux using coronal hole observations (e.g., using extreme ultraviolet (EUV) or Helium (He) I) are in general agreement with the coronal model results and thus show similar disagreements with in situ observations. While several possible sources producing these discrepancies have been postulated over the years, there is still no clear resolution to the problem. This paper provides a brief overview of the problem and summarizes some proposed explanations for the discrepancies. In addition, two different ways of estimating the total unsigned open magnetic flux are presented, utilizing the Wang-Sheeley-Arge (WSA) model, and one of the methods produce surprisingly good agreement with in situ observations. The findings presented here suggest that active regions residing near the boundaries of mid-latitude coronal holes are the probable source of the missing open flux. This explanation also brings in line many of the seemingly contradictory facts that have made resolving this problem so difficult.

How are Forbush decreases related to interplanetary magnetic field enhancements?

Aims: A Forbush decrease (FD) is a transient decrease followed by a gradual recovery in the observed galactic cosmic ray intensity. We seek to understand the relationship between the FDs and near-Earth interplanetary magnetic field (IMF) enhancements associated with solar coronal mass ejections (CMEs).

Methods: We used muon data at cutoff rigidities ranging from 14 to 24 GV from the GRAPES-3 tracking muon telescope to identify FD events. We selected those FD events that have a reasonably clean profile, and magnitude >0.25%. We used IMF data from ACE/WIND spacecrafts. We looked for correlations between the FD profile and that of the one-hour averaged IMF. We wanted to find out whether if the diffusion of high-energy protons into the large scale magnetic field is the cause of the lag observed between the FD and the IMF.

Results: The enhancement of the IMF associated with FDs occurs mainly in the shock-sheath region, and the turbulence level in the magnetic field is also enhanced in this region. The observed FD profiles look remarkably similar to the IMF enhancement profiles. The FDs typically lag behind the IMF enhancement by a few hours. The lag corresponds to the time taken by high-energy protons to diffuse into the magnetic field enhancement via cross-field diffusion.

Conclusions: Our findings show that high-rigidity FDs associated with CMEs are caused primarily by the cumulative diffusion of protons across the magnetic field enhancement in the turbulent sheath region between the shock and the CME.

Earth-directed Coronal mass ejections (CMEs) emanating from the Sun and the shock associated with it are the primary drivers of space weather disturbances. Forbush decrease precursors are advance warning of these upcoming magnetic field disturbances. GRAPES-3 tracking muon telescope which is a part of GRAPES-3 experiment located in Ooty, India, provides high statistics measurement of the muon flux with good temporal resolution. In this study we are using data from GRAPES-3 muon telescope and making use of its multidirectional observations to study the Forbush decrease precursors in greater detail. We have identified few Forbush decrease precursor signatures in muon flux well before the arrival of the actual shock. We can use these Forbush decrease precursors to study the characteristics of magnetic field compression associated with the upcoming CME shock-sheath system. **29 October 2003, 14 December 2006**

Relation of Forbush decrease with interplanetary magnetic fields.

Arunbabu, K. P. ; [Antia, H. M. ;](#) [Dugad, S.](#) Proceedings of the 34th International Cosmic Ray Conference (ICRC2015). 30 July - 6 August, 2015. The Hague, The Netherlands. Online at <http://pos.sissa.it/cgi-bin/reader/conf.cgi?confid=236>, id.43 **2015**
<https://pos.sissa.it/236/043/pdf>

The relation between the Forbush decreases (FDs) and near-Earth interplanetary magnetic field (IMF) enhancements associated with the solar coronal mass ejections (CMEs) is studied. We have used data from GRAPES-3 tracking muon telescope to identify the Forbush decrease events. We have chosen events that are having a reasonably clean profile, and magnitude >0.25%. We have used IMF data from ACE/WIND spacecrafts to investigate how closely the FD profile follow the IMF enhancements. We found that the enhancement of magnetic field responsible for the FD takes place mainly in the sheath region and also the MHD turbulence level get enhanced in this region. We found that the FD profile looks remarkably similar to that of IMF enhancement, yielding good correlation with a time lag. The FD profile lags behind the IMF by few hours. This observed lag corresponds to the time taken by high energy protons to diffuse into the magnetic field enhancement through cross-field diffusion. **24 November 2001**

Cosmic ray Forbush decreases (FDs) are usually thought to be due to Earth-directed coronal mass ejections (CMEs) from the Sun and their associated shocks. When CMEs and their shocks reach the Earth, they cause magnetic field compressions. We investigate the relation between these magnetic field compressions and FDs at rigidities between 12 and 42 GV using data from the GRAPES-3 instrument at Ooty. We find that the shapes of the Forbush decrease profiles show a startling similarity to that of the magnetic field compression in the near-Earth IP medium. We seek to understand the implications of this interesting result. **24 November 2001**

Forbush Decreases and <2 Day GCR Flux Non-recurrent Variations Studied with LISA Pathfinder

Non-recurrent short-term variations of the galactic cosmic-ray (GCR) flux above 70 MeV n^{-1} were observed between **2016 February 18 and 2017 July 3** on board the European Space Agency LISA Pathfinder (LPF) mission orbiting around the Lagrange point L1 at 1.5×10^6 km from Earth. The energy dependence of three Forbush decreases is studied and reported here. A comparison of these observations with others carried out in space down to the energy of a few tens of MeV n^{-1} shows that the same GCR flux parameterization applies to events of different intensity during the main phase. FD observations in L1 with LPF and geomagnetic storm occurrence are also presented. Finally, the characteristics of GCR flux non-recurrent variations (peaks and depressions) of duration < 2 days and their association with interplanetary structures are investigated. It is found that, most likely, plasma compression regions between subsequent corotating high-speed streams cause peaks, while heliospheric current sheet crossing causes the majority of the depressions.

Characteristics and Energy Dependence of Recurrent Galactic Cosmic-Ray Flux Depressions and of a Forbush Decrease with LISA Pathfinder

Galactic cosmic-ray (GCR) energy spectra observed in the inner heliosphere are modulated by the solar activity, the solar polarity and structures of solar and interplanetary origin. A high counting rate particle detector (PD) aboard LISA Pathfinder, meant for subsystems diagnostics, was devoted to the measurement of GCR and solar energetic particle integral fluxes above 70 MeV n^{-1} up to 6500 counts s^{-1} . PD data were gathered with a sampling time of 15 s. Characteristics and energy dependence of GCR flux recurrent depressions and of a Forbush decrease dated **2016 August 2** are reported here. The capability of interplanetary missions, carrying PDs for instrument performance purposes, in monitoring the passage of interplanetary coronal mass ejections is also discussed.

Correlations between Sunspot numbers, Interplanetary Parameters and geomagnetic trends over solar cycles 21, 22 and 23

Kusumita **Arora**, N. Phani Chandrasekhar, Nandini Nagarajan, Ankit Singh

JASTP, Volume 114, Pages 19–29, **2014**

We have analyzed correlations between sunspot numbers, solar wind, ion density, interplanetary magnetic field vis-à-vis magnetic activity. Planetary geomagnetic index (A_p) and local residual measure of magnetic activity ($I\Delta H$) from low-latitude Magnetic Observatory, CSIR-NGRI, Hyderabad (IMO-HYB) spanning solar cycles 21 – 23 are used for this study.

Using correlation coefficients between and wavelet decomposition of sunspot numbers, interplanetary parameters and measures of magnetic activity, the complex and time varying nature of these inter-relationships are brought out. The overall influence of sunspot number could be separated and combined episodic effects of other solar parameters could be distinguished. The demonstrated correlation or lack of it, between measures of magnetic activity (A_p and $I\Delta H$), and all the parameters of solar activity, presented here corroborate established mechanisms as well as delineated clearly the relative impact of different solar mechanisms over phases of three solar cycles. The possible role of non-sunspot related activity from high latitude regions of the sun is indicated.

Comparative study of electric currents and energetic particle fluxes in a solar flare and Earth magnetospheric substorm

Magnetic field-line reconnection is a universal plasma process responsible for the conversion of magnetic field energy to the plasma heating and charged particle acceleration. Solar flares and Earth's magnetospheric substorms are two most investigated dynamical systems where magnetic reconnection is believed to be responsible for global magnetic field reconfiguration and energization of plasma populations. Such a reconfiguration includes formation of a long-living current systems connecting the primary energy release region and cold dense conductive plasma of photosphere/ionosphere. In both flares and substorms the evolution of this current system correlates with formation and dynamics of energetic particle fluxes. Our study is focused on this similarity between flares and substorms. Using a wide range of datasets available for flare and substorm investigations, we compare qualitatively dynamics of currents and energetic particle fluxes for one flare and one substorm. We showed that there is a clear correlation between energetic particle bursts (associated with energy release due to magnetic reconnection) and magnetic field reconfiguration/formation of current system. We then discuss how datasets of in-situ measurements in the magnetospheric substorm can help in interpretation of datasets gathered for the solar flare. **2015 June 22**

How are Forbush decreases related with interplanetary magnetic field enhancements ?

Aims. Forbush decrease (FD) is a transient decrease followed by a gradual recovery in the observed galactic cosmic ray intensity. We seek to understand the relationship between the FDs and near-Earth interplanetary magnetic field (IMF) enhancements associated with solar coronal mass ejections (CMEs).

Methods. We use muon data at cutoff rigidities ranging from 14 to 24 GV from the GRAPES-3 tracking muon telescope to identify FD events. We select those FD events that have a reasonably clean profile, and magnitude $> 0.25\%$. We use IMF data from ACE/WIND spacecrafts. We look for correlations between the FD profile and that of the one hour averaged IMF. We ask if the diffusion of high energy protons into the large scale magnetic field is the cause of the lag observed between the FD and the IMF.

Results. The enhancement of the IMF associated with FDs occurs mainly in the shock-sheath region, and the turbulence level in the magnetic field is also enhanced in this region. The observed FD profiles look remarkably similar to the IMF enhancement profiles. The FDs typically lag the IMF enhancement by a few hours. The lag corresponds to the time taken by high energy protons to diffuse into the magnetic field enhancement via cross-field diffusion. **Conclusions.** Our findings show that high rigidity FDs associated with CMEs are caused primarily by the cumulative diffusion of protons across the magnetic field enhancement in the turbulent sheath region between the shock and the CME.

Table 2. Shock arrival time, time of maximum magnetic field enhancement, magnetic cloud start and end timings and FD onset timings for different directions for FD events which have a well defined shock and magnetic clouds associated with them.

Table B.1. List of FD events for which the correlation coefficient between the profiles of the FD and the IMF enhancement $\geq 70\%$.

How are Forbush decreases related with IP magnetic field enhancements ?

Cosmic ray Forbush decreases (FDs) are usually thought to be due to Earth-directed coronal mass ejections (CMEs) from the Sun and their associated shocks. When CMEs and their shocks reach the Earth, they cause magnetic field compressions. We seek to understand the relation between these magnetic field compressions and FDs at rigidities between 12 and 42 GV using data from the GRAPES-3 instrument at Ooty. We find that the shapes of the Forbush decrease profiles show a startling similarity to that of the magnetic field compression in the near-Earth IP medium. We seek to understand the implications of this interesting result. **24 November 2001**

High-rigidity Forbush decreases: due to CMEs or shocks?*

K. P. [Arunbabu](#)¹, H. M. Antia^{2,3}, S. R. Dugad^{2,3}, S. K. Gupta^{2,3}, Y. Hayashi⁴, S. Kawakami⁴, P. K. Mohanty^{2,3}, T. Nonaka⁴, A. Oshima⁵ and P. Subramanian
A&A 555, A139 (2013)

Aims. We seek to identify the primary agents causing Forbush decreases (FDs) in high-rigidity cosmic rays observed from the Earth. In particular, we ask if these FDs are caused mainly by coronal mass ejections (CMEs) from the Sun that are directed towards the Earth, or by their associated shocks.

Methods. We used the muon data at cutoff rigidities ranging from 14 to 24 GV from the GRAPES-3 tracking muon telescope to identify FD events. We selected those FD events that have a reasonably clean profile, and can be reasonably well associated with an Earth-directed CME and its associated shock. We employed two models: one that considers the CME as the sole cause of the FD (the CME-only model) and one that considers the shock as the only agent causing the FD (the shock-only model). We used an extensive set of observationally determined parameters for both models. The only free parameter in these models is the level of MHD turbulence in the sheath region, which mediates cosmic ray diffusion (into the CME for the CME-only model, and across the shock sheath for the shock-only model).

Results. We find that good fits to the GRAPES-3 multi-rigidity data using the CME-only model require turbulence levels in the CME sheath region that are only slightly higher than those estimated for the quiescent solar wind. On the other hand, reasonable model fits with the shock-only model require turbulence levels in the sheath region that are an order of magnitude higher than those in the quiet solar wind.

Conclusions. This observation naturally leads to the conclusion that the Earth-directed CMEs are the primary contributors to FDs observed in high-rigidity cosmic rays.

Evolution of the anemone AR NOAA 10798 and the related geo-effective flares and CMEs

Ayumi [Asai](#), Kazunari Shibata,⁴ Takako T. Ishii,⁴ Mitsuo Oka,^{4,5} Ryuho Kataoka,⁶
Ken'ichi Fujiki,⁷ and Nat Gopalswamy

JOURNAL OF GEOPHYSICAL RESEARCH, VOL. 114, A00A21, doi:10.1029/2008JA013291, 2009

We present a detailed examination of the features of the active region (AR) NOAA 10798. This AR generated coronal mass ejections (CMEs) that caused a large geomagnetic storm on 24 August 2005 with the minimum **Dst index of -216 nT**. We examined the evolution of the AR and the features on/near the solar surface and in the interplanetary space. The AR emerged in the middle of a small coronal hole, and formed a sea anemone like configuration. Ha filaments were formed in the AR, which have southward axial field. Three M class flares were generated, and the first two that occurred on 22 August 2005 were followed by Halo-type CMEs. The speeds of the CMEs were fast, and recorded about 1200 and 2400 km s⁻¹, respectively. The second CME was especially fast, and caught up and interacted with the first (slower) CME during their travelings toward Earth. These acted synergically to generate an interplanetary disturbance with strong southward magnetic field of about -50 nT, which was followed by the large geomagnetic storm.

PASJ 2021

<https://arxiv.org/pdf/2102.11298.pdf>

X-ray emission generated through solar-wind charge exchange (SWCX) is known to contaminate X-ray observation data, the amount of which is often significant or even dominant, particularly in the soft X-ray band, when the main target is comparatively weak diffuse sources, depending on the space weather during the observation. In particular, SWCX events caused by interplanetary coronal mass ejections (ICMEs) tend to be spectrally rich and to provide critical information about the metal abundance in the ICME plasma. We analyzed the SN1006 background data observed with Suzaku on **2005 September 11** shortly after an X6-class solar flare, signatures of which were separately detected together with an associated ICME. We found that the data include emission lines from a variety of highly ionized ions

generated through SWCX. The relative abundances of the detected ions were found to be consistent with those in past ICME-driven SWCX events. Thus, we conclude that this event was ICME-driven. In addition, we detected a sulfur XVI line for the first time as one from the SWCX emission, the fact of which suggests that it is the most spectrally-rich SWCX event ever observed. We suggest that observations of ICME-driven SWCX events can provide a unique probe to study the population of highly-ionized ions in the plasma, which is difficult to measure in currently-available in-situ observations.

Correlation of the sunspot number and the waiting time distribution of solar flares, coronal mass ejections, and solar wind switchback events observed with the Parker Solar Probe

[Markus J. Aschwanden](#), [Thierry Dudok de Wit](#)

ApJ 912 94 2021

<https://arxiv.org/pdf/2102.02305.pdf>

<https://doi.org/10.3847/1538-4357/abef69>

Waiting time distributions of solar flares and coronal mass ejections (CMEs) exhibit power law-like distribution functions with slopes in the range of $\alpha\tau\approx 1.4-3.2$, as observed in annual data sets during 4 solar cycles (1974-2012). We find a close correlation between the waiting time power law slope $\alpha\tau$ and the sunspot number (SN), i.e., $\alpha\tau = 1.38 + 0.01 \times \text{SN}$. The waiting time distribution can be fitted with a Pareto-type function of the form $N(\tau)=N_0(\tau_0+\tau)^{-\alpha\tau}$, where the offset τ_0 depends on the instrumental sensitivity, the detection threshold of events, and pulse pile-up effects. The time-dependent power law slope $\alpha\tau(t)$ of waiting time distributions depends only on the global solar magnetic flux (quantified by the sunspot number) or flaring rate, independent of other physical parameters of self-organized criticality (SOC) or magneto-hydrodynamic (MHD) turbulence models. Power law slopes of $\alpha\tau\approx 1.2-1.6$ were also found in solar wind switchback events, as observed with the Parker Solar Probe (PSP). We conclude that the annual variability of switchback events in the heliospheric solar wind is modulated by flare and CME rates originating in the photosphere and lower corona.

Solar wind drivers of energetic electron precipitation†

T. [Asikainen](#), M. Ruopsa

JGR 2016

Disturbances of near-Earth space are predominantly driven by coronal mass ejections (CME) mostly originating from sunspots and high-speed solar wind streams (HSS) emanating from coronal holes. Here we study the relative importance of CMEs and HSSs as well as slow solar wind in producing energetic electron precipitation. We use the recently corrected energetic electron measurements from the MEPED instrument onboard low altitude NOAA/POES satellites from 1979 to 2013. Using solar wind observations categorized into three different flow types we study the contributions of these flows to annual electron precipitation and their efficiencies in producing precipitation. We find that HSS contribution nearly always dominates over the other flows and peaks strongly in the declining solar cycle phase. CME contribution mostly follows the sunspot cycle but is enhanced also in the declining phase. The efficiency of both HSSs and CMEs peaks in the declining phase. We also study the dependence of electron precipitation on solar wind southward magnetic field component, speed and density and find that the solar wind speed is the dominant factor affecting the precipitation. Since HSSs enhance the average solar wind speed in the declining phase they also enhance the efficiency of CMEs during these times and thus have a double effect in enhancing energetic electron precipitation.

Long-term evolution of corrected NOAA/MEPED energetic proton fluxes and their relation to geomagnetic indices

Timo [Asikainen](#), Kalevi Mursula

JASTP, 2014

We study the relationship between energetic 120–250 keV proton fluxes and geomagnetic Ap, AE, Dxt indices using the recently corrected measurements of the MEPED instrument onboard the low-altitude NOAA/POES satellites. Corrected database spans from 1979 to present, and allows us to reliably study the long-term variation of energetic proton fluxes over several solar cycles. Contrary to uncorrected fluxes, which can be more than an order of magnitude too low, the corrected fluxes display a systematic solar cycle variation closely resembling the variation of Ap and AE indices with a maximum in the declining solar cycle phase and a minimum in solar minimum. We also find that trapped fluxes are enhanced relative to precipitating fluxes in the declining phases and solar minima. This supports the fact that high-speed solar wind streams are the most significant driver of energetic proton fluxes. We compute the correlations between fluxes and indices in a range of time scales, and show that they are significantly improved by the flux correction. We find that precipitating fluxes correlate better than trapped fluxes with Ap/AE indices at all time scales, and the highest correlation is found with Ap. For precipitating fluxes these correlations depend weakly on time scale, but for trapped

fluxes the correlation significantly increases from daily scale to solar rotation and longer time scales. Comparing the fluxes to Dxt index shows a complex relationship, where the fluxes depend not only on Dxt value but also on its time derivative.

The source of the 2017 cosmic ray half-year modulation event

O.P.M. [Aslam](#), D. MacTaggart, R. Battiston, M.S. Potgieter, M.D. Ngobeni

ApJ **2024**

<https://arxiv.org/pdf/2412.14907>

In 2017, as the solar cycle approached solar minimum, an unusually long and large depression was observed in galactic cosmic ray (GCR) protons, detected with the Alpha Magnetic Spectrometer (AMS-02), lasting for the second half of that year. The depression, as seen in the Bartel rotation-averaged proton flux, has the form of a Forbush decrease (FD). Despite this resemblance, however, the cause of the observed depression does not have such a simple explanation as FDs, due to coronal mass ejections (CMEs), typically last for a few days at 1 AU rather than half a year. In this work, we seek the cause of the observed depression and investigate two main possibilities. First, we consider a mini-cycle - a temporary change in the solar dynamo that changes the behavior of the global solar magnetic field and, by this, the modulation of GCRs. Secondly, we investigate the behavior of solar activity, both CMEs and co-rotating/stream interactions regions (C/SIRs), during this period. Our findings show that, although there is some evidence for mini-cycle behavior prior to the depression, the depression is ultimately due to a combination of recurrent CMEs, SIRs and CIRs. A particular characteristic of the depression is that the largest impacts that help to create and maintain it are due to four CMEs from the same, highly active, magnetic source that persists for several solar rotations. This active magnetic source is unusual given the closeness of the solar cycle to solar minimum, which also helps to make the depression more evident.

Modulation of Cosmic-Ray Antiprotons in the Heliosphere: Simulations for a Solar Cycle

O. P. M. [Aslam](#)¹, M. S. Potgieter^{1,2}, Xi Luo (罗熙)¹, and M. D. Ngobeni³

2023 ApJ 953 101

<https://iopscience.iop.org/article/10.3847/1538-4357/ace31e/pdf>

The precision measurements of galactic cosmic-ray protons from the Payload for Antimatter Matter Exploration and Light-nuclei Astrophysics and the Alpha Magnetic Spectrometer are reproduced using a well-established three-dimensional numerical model for the period 2006 July–2019 November. The resulting modulation parameters are applied to simulate the modulation for cosmic antiprotons over the same period, which includes the times of minimum modulation before and after 2009, the maximum modulation from 2012 to 2015, including the reversal of the Sun's magnetic field polarity, and the approach to new minimum modulation in 2020. Apart from their local interstellar spectra, the modulation of protons and antiprotons differ in their charge sign and consequent drift pattern. The lowest proton flux was in 2014 February–March, but the lowest simulated antiproton flux is found to have been in 2015 March–April. These simulated fluxes are used to predict the proton-to-antiproton ratios as a function of rigidity. The trends in these ratios contribute to clarifying, to a large extent, the phenomenon of charge-sign dependence of heliospheric modulation during vastly different phases of the solar activity cycle. This is reiterated and emphasized by displaying so-called hysteresis loops. It is also illustrated how the values of the parallel and perpendicular mean free paths, as well as the drift scale, vary with rigidity over this extensive period. The drift scale is found to be at its lowest level during the polarity reversal period, while the lowest level of the mean free paths is found to be in 2015 March–April.

Unfolding Drift Effects for Cosmic Rays over the Period of the Sun's Magnetic Field Reversal

O.P.M. [Aslam](#), [Xi Luo](#), [M.S. Potgieter](#), [M.D. Ngobeni](#), [Xiaojian Song](#)

ApJ **947** 72 **2023**

<https://arxiv.org/pdf/2212.13397.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/acc24a/pdf>

A well-established, comprehensive 3-D numerical modulation model is applied to simulate galactic protons, electrons and positrons from May 2011 to May 2015, including the solar magnetic polarity reversal of Solar Cycle 24. The objective is to evaluate how these simulations compare with corresponding AMS observations for 1.0-3.0 GV, and what underlying physics follows from this comparison in order to improve our understanding on how the major physical modulation processes change, especially particle drift, from a negative to a positive magnetic polarity cycle. Apart from their local interstellar spectra, electrons and positrons differ only in their drift patterns, but they differ with protons in other ways such as their adiabatic energy changes at lower rigidity. In order to complete the simulations for oppositely charged particles, antiproton modeling results are obtained as well. Together, the observations and the corresponding modeling indicate the difference in the drift pattern before and after the recent polarity reversal and clarify to a large

extent the phenomenon of charge-sign dependence during this period. The effect of global particle drift became negligible during this period of no well-defined magnetic polarity. The resulting low values of all particles' MFPs during the polarity reversal contrast their large values during solar minimum activity, and as such expose the relative contributions and effects of the different modulation processes from solar minimum to maximum activity. We find that the drift scale starts recovering just after the polarity reversal, but the MFPs keep decreasing or remain unchanged for some period after the polarity reversal.

Study of the Geoeffectiveness and Galactic Cosmic-Ray Response of VarSITI-ISEST Campaign Events in Solar Cycle 24

O. P. M. [Aslam](#), Badruddin

[Solar Physics](#) September 2017, 292:135

We analyze and compare the geomagnetic and galactic cosmic-ray (GCR) response of selected solar events, particularly the campaign events of the group International Study of Earth-affecting Solar Transients (ISEST) of the program Variability of the Sun and Its Terrestrial Impact (VarSITI). These selected events correspond to Solar Cycle 24, and we identified various of their features during their near-Earth passage. We evaluated the hourly data of geomagnetic indices and ground-based neutron monitors and the concurrent data of interplanetary plasma and field parameters. We recognized distinct features of these events and solar wind parameters when the geomagnetic disturbance was at its peak and when the cosmic-ray intensity was most affected. We also discuss the similarities and differences in the geoeffectiveness and GCR response of the solar and interplanetary structures in the light of plasma and field variations and physical mechanism(s), which play a crucial role in influencing the geomagnetic activity and GCR intensity. **14 July 2012, 8 Oct 2012, 17 March 2013, 31 May 2013, 17 March 2015, 21 June 2015,**

Study of Cosmic-Ray Modulation during the Recent Unusual Minimum and Mini Maximum of Solar Cycle 24

O.P.M. [Aslam](#), Badruddin

Solar Phys. Volume 290, Issue 8, pp 2333-2353 **2015**

<http://arxiv.org/ftp/arxiv/papers/1507/1507.07917.pdf>

After a prolonged and deep solar minimum at the end of Cycle 23, the current Solar Cycle 24 is one of the lowest cycles. These two periods of deep minimum and mini maximum are separated by a period of increasing solar activity. We study the cosmic-ray intensity variation in relation with the solar activity, heliospheric plasma and field parameters, including the heliospheric current sheet, during these three periods (phases) of different activity level and nature: (a) a deep minimum, (b) an increasing activity period and (c) a mini maximum. We use neutron monitor data from stations located around the globe to study the rigidity dependence on modulation during the two extremes, i.e., minimum and maximum. We also study the time lag between the cosmic-ray intensity and various solar and interplanetary parameters separately during the three activity phases. We also analyze the role of various parameters, including the current sheet tilt, in modulating the cosmic-ray intensity during the three different phases. Their relative importance and the implications of our results are also discussed.

The Dynamic Coupling of Streamers and Pseudostreamers to the Heliosphere

ApJ **929** 185 **2022**

<https://arxiv.org/pdf/2201.02388.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac5d5b/pdf>

The slow solar wind is generally believed to result from the interaction of open and closed coronal magnetic flux at streamers and pseudostreamers. We use 3-dimensional magnetohydrodynamic simulations to determine the detailed structure and dynamics of open-closed interactions that are driven by photospheric convective flows. The photospheric magnetic field model includes a global dipole giving rise to a streamer together with a large parasitic polarity region giving rise to a pseudostreamer that separates a satellite coronal hole from the main polar hole. Our numerical domain extends out to 30 solar radii and includes an isothermal solar wind, so that the coupling between the corona and heliosphere can be calculated rigorously. This system is driven by imposing a large set of quasi-random surface flows that capture the driving of coronal flux in the vicinity of streamer and pseudostreamer boundaries by the supergranular motions. We describe the resulting structures and dynamics. Interchange reconnection dominates the evolution at both streamer and pseudostreamer boundaries, but the details of the resulting structures are clearly different from one another. Additionally, we calculate in situ signatures of the reconnection and determine the dynamic mapping from the inner heliosphere back to the Sun for a test spacecraft orbit. We discuss the implications of our results for interpreting

observations from inner heliospheric missions, such as Parker Solar Probe and Solar Orbiter, and for space weather modeling of the slow solar wind.

Effects of Pseudostreamer Boundary Dynamics on Heliospheric Field and Wind

<https://iopscience.iop.org/article/10.3847/1538-4357/abd6e6/pdf>

Interchange reconnection has been proposed as a mechanism for the generation of the slow solar wind, and a key contributor to determining its characteristic qualities. In this paper we study the implications of interchange reconnection for the structure of the plasma and field in the heliosphere. We use the Adaptively Refined Magnetohydrodynamic Solver to simulate the coronal magnetic evolution in a coronal topology containing both a pseudostreamer and helmet streamer. We begin with a geometry containing a low-latitude coronal hole that is separated from the main polar coronal hole by a pseudostreamer. We drive the system by imposing rotating flows at the solar surface within and around the low-latitude coronal hole, which leads to a corrugation (at low altitudes) of the separatrix surfaces that separate open from closed magnetic flux. Interchange reconnection is induced both at the null points and separators of the pseudostreamer, and at the global helmet streamer. We demonstrate that a preferential occurrence of interchange reconnection in the "lanes" between our driving cells leads to a filamentary pattern of newly opened flux in the heliosphere. These flux bundles connect to but extend far from the separatrix-web (S-Web) arcs at the source surface. We propose that the pattern of granular and supergranular flows on the photosphere should leave an observable imprint in the heliosphere.

Powerful non-geoeffective interplanetary disturbance of July 2012 observed by muon hodoscope URAGAN

I.I. **Astapova**, , N.S. Barbashina^a, A.A. Petrukchina, V.V. Shutenkoa, I.S. Veselovsky

Advances in Space Research Volume 56, Issue 12, 15 December 2015, Pages 2833–2838

<http://www.sciencedirect.com/science/article/pii/S0273117715001854>

The most powerful coronal mass ejection of the 24th solar cycle took place on the opposite side of the Sun on **July 23, 2012** and had no geomagnetic consequences. Nevertheless, as a result of passing of the ejection through the heliosphere, variations of galactic cosmic rays flux were observed on the Earth. These variations were registered by the muon hodoscope URAGAN (MEPhI, Moscow). Muon flux angular distributions on the Earth's surface are reported and analyzed.

Modelling a multi-spacecraft coronal mass ejection encounter with EUHFORIA

A&A 2021

<https://arxiv.org/pdf/2105.11831.pdf>

Coronal mass ejections (CMEs) are a manifestation of the Sun's eruptive nature. They can have a great impact on Earth, but also on human activity in space and on the ground. Therefore, modelling their evolution as they propagate through interplanetary space is essential. EUropean Heliospheric FOrecasting Information Asset (EUHFORIA) is a data-driven, physics-based model, tracing the evolution of CMEs through background solar wind conditions. It employs a spheromak flux rope, which provides it with the advantage of reconstructing the internal magnetic field configuration of CMEs. This is something that is not included in the simpler cone CME model used so far for space weather forecasting. This work aims at assessing the spheromak CME model included in EUHFORIA. We employed the spheromak CME model to reconstruct a well observed CME and compare model output to in situ observations. We focus on an eruption from **6 January 2013** encountered by two radially aligned spacecraft, Venus Express and STEREO-A. We first analysed the observed properties of the source of this CME eruption and we extracted the CME properties as it lifted off from the Sun. Using this information, we set up EUHFORIA runs to model the event. The model predicts arrival times from half to a full day ahead of the in situ observed ones, but within errors established from similar studies. In the modelling domain, the CME appears to be propagating primarily southward, which is in accordance with white-light images of the CME eruption close to the Sun. In order to get the observed magnetic field topology, we aimed at selecting a spheromak rotation angle for which the axis of symmetry of the spheromak is perpendicular to the direction of the polarity inversion line (PIL). The modelled magnetic field profiles, their amplitude, arrival times, and sheath region length are all affected by the choice of radius of the modelled spheromak.

Using the Evolution of Coronal Dimming Regions to Probe the Global Magnetic Field Topology

[Attrill, G.](#); [Nakwacki, M. S.](#); [Harra, L. K.](#); [van Driel-Gesztelyi, L.](#); [Mandrini, C. H.](#); [Dasso, S.](#); [Wang, J.](#)
Solar Physics, Volume 238, Issue 1, pp.117-139, **2006**; **File**

We demonstrate that study of the evolving magnetic nature of coronal dimming regions can be used to probe the large-scale magnetic structure involved in the eruption of a coronal mass ejection (CME). We analyse the intensity evolution of coronal dimming regions using 195 Å data from the Extreme ultraviolet Imaging Telescope (EIT) on board the Solar and Heliospheric Observatory (SOHO). We measure the magnetic flux, using data from the SOHO/Michelson Doppler Imager (MDI), in the regions that seem most likely to be related to plasma removal. Then, we compare these magnetic flux measurements to the flux in the associated magnetic cloud (MC). Here, we present our analysis of the well-studied event on 12 May 1997 that took place just after solar minimum in a simple magnetic configuration. We present a synthesis of results already published and propose that driven “interchange reconnection” between the expanding CME structure with “open” field lines of the northern coronal hole region led to the asymmetric temporal and spatial evolution of the two main dimming regions, associated with this event. As a result of this reconnection process, we find the southern-most dimming region to be the principal foot-point of the MC. The magnetic flux from this dimming region and that of the MC are found to be in close agreement within the same order of magnitude, 10^{21} Mx.

The 2015 Summer Solstice Storm: one of the major geomagnetic storms of solar cycle 24 observed at ground level

C. R. A. [Augusto](#), [C. E. Navia](#), [M. N. de Oliveira](#), [A. A. Nepomuceno](#), [J. P. Raulin](#), [E. Tueros](#), [R. R. de Mendonça](#), [A. C. Fauth](#), [H. Vieira de Souza](#), [V. Kopenkin](#), [T. Sinzi](#)

Solar Phys. May 2018, 293:84

<https://arxiv.org/pdf/1805.05277.pdf>

<https://link.springer.com/content/pdf/10.1007%2Fs11207-018-1303-8.pdf>

We report on the **22-23 June 2015** geomagnetic storm. There has been a shortage of intense geomagnetic storms during the current solar cycle 24 in relation to the previous cycle. This situation changed after mid-June 2015 when one of the biggest solar active regions (AR 2371) of current solar cycle 24, close to the central meridian produced several coronal mass ejections (CMEs) associated with M-class flares. The CMEs impact on the Earth's magnetosphere resulted in a moderately-severe G4-class geomagnetic storm on 22-23 June 2015 and a G2 (moderate) geomagnetic storms on **24 June**. The G4 solstice storm was the second biggest (so far) geomagnetic storms of cycle 24. We highlight the ground level observations made by New-Tupi, Muonca and the CARPET El Leoncito cosmic ray detectors that are located within the South Atlantic Anomaly (SAA) region. These observations are studied in correlation with data obtained by space-borne detectors and other ground-based experiments. The CME designations are from the Computer Aided CME Tracking (CACTus) automated catalog. As expected, Forbush Decreases (FD) associated with the passing CMEs were recorded by these detectors. We noticed a peculiar feature linked to a severe geomagnetic storm event. The 21 June 2015 CME 0091 was likely associated with the 22 June summer solstice FD event. The angular width of CME 0091 was very narrow and measured 56 degrees seen from Earth. In most cases, only CME halos and partial halos, lead to severe geomagnetic storms. We performed a cross-check analysis of the FD events detected during the rise phase of the current solar cycle 24, the geomagnetic parameters, and the CACTus CME catalog. Our study suggests that narrow angular-width CMEs that erupt in the western region of the ecliptic plane can lead to moderate and severe geomagnetic storms.

Muon Excess at Sea Level during the Progress of a Geomagnetic Storm and High Speed Stream Impact Near the Time of Earth's Heliospheric Sheet Crossing

C. R. A. [Augusto](#), [C. E. Navia](#), [M. N. de Oliveira](#), [A. A. Nepomuceno](#), [V. Kopenkin](#), [T. Sinzi](#)

Solar Phys. 292:107 **2017**

<https://arxiv.org/pdf/1706.00775.pdf>

In this article we present results of the study on the association between the muon flux variation at ground level, registered by the `\textit{New-Tupi}` muon telescopes (22053'00"S, 43006'13"W; 3 m above sea level) and a geomagnetic storm of **25--29 August 2015** that has raged for several days as a result of a coronal mass ejection (CME) impact on Earth's magnetosphere. A sequence of events started with an M3.5 X-ray class flare on **22 August 2015** at 21:19 UTC. The `\textit{New-Tupi}` muon telescopes observed a Forbush decrease (FD) triggered by this geomagnetic storm, with onset on 26 August 2015. After the Earth crossed a heliospheric current sheet (HCS), an increase in the particle flux was observed on 28 August 2015 by spacecrafts and ground level detectors. The observed peak was in temporal coincidence with the impact of a high speed stream (HSS). We study this increase, that has been

observed with a significance above 1.5% by ground level detectors in different rigidity regimes. We also estimate the lower limit of the energy fluence injected on Earth. In addition, we consider the origin of this increase, such as acceleration of particles by shock waves on the front of the HSS and the focusing effect of the HCS crossing. Our results show possible evidence of a prolonged energetic (up to GeV energies) particle injection within the Earth atmosphere system, driven by the HSS. In most cases these injected particles are directed to polar regions. However, the particles from the high energy tail of the spectrum can reach middle latitudes, and that could have consequences for the atmospheric chemistry, for instance, the creation of NO_x species may be enhanced and can lead to increased ozone depletion. This topic requires further study.

VARIATIONS OF THE MUON FLUX AT SEA LEVEL ASSOCIATED WITH INTERPLANETARY ICMEs AND COROTATING INTERACTION REGIONS

C. R. A. [Augusto](#)¹, V. Kopenkin¹, C. E. Navia¹, K. H. Tsui¹, H. Shigueoka¹, A. C. Fauth², E. Kemp², E. J. T. Manganote², M. A. Leigui de Oliveira³, P. Miranda⁴, R. Ticona⁴, and A. Velarde

2012 ApJ 759 143

We present the results of an ongoing survey on the association between the muon flux variation at ground level (3 m above sea level) registered by the Tupi telescopes (Niteri-Brazil, 229S, 432W, 3 m) and the Earth-directed transient disturbances in the interplanetary medium propagating from the Sun (such as coronal mass ejections (CME), and corotating interaction regions (CIRs)). Their location inside the South Atlantic Anomaly region enables the muon telescopes to achieve a low rigidity of response to primary and secondary charged particles. The present study is primarily based on experimental events obtained by the Tupi telescopes in the period from 2010 August to 2011 December. This time period corresponds to the rising phase of solar cycle 24. The Tupi events are studied in correlation with data obtained by space-borne detectors (SOHO, ACE, GOES). Identification of interplanetary structures and associated solar activity was based on the nomenclature and definitions given by the satellite observations, including an incomplete list of possible interplanetary shocks observed by the CELIAS/MTOF Proton Monitor on the Solar and Heliospheric Observatory (SOHO) spacecraft. Among 29 experimental events reported in the present analysis, there are 15 possibly associated with the CMEs and sheaths, and 3 events with the CIRs (forward or reverse shocks); the origin of the remaining 11 events has not been determined by the satellite detectors. We compare the observed time (delayed or anticipated) of the muon excess (positive or negative) signal on Earth (the Tupi telescopes) with the trigger time of the interplanetary disturbances registered by the satellites located at Lagrange point L1 (SOHO and ACE). The temporal correlation of the observed ground-based events with solar transient events detected by spacecraft suggests a real physical connection between them. We found that the majority of observed events detected by the Tupi experiment were delayed in relation to the satellite triggers. This result agrees with theoretical expectations. Our experimental data indicate that the Tupi experiment is able to add new information and can be complementary to other techniques designed to interpret the origin of some interplanetary disturbances observed by satellites.

Confined plasma transition from the solar atmosphere to the interplanetary medium

[Nicolas, Aurélien, Corentin Poirier](#)

2022

<https://arxiv.org/abs/2208.11637>

The last 60 years of space exploration have shown that the interplanetary medium is continually perturbed by a myriad of different solar winds and storms that transport solar material across the whole heliosphere. If there is a consensus on the source of the fast solar wind that is known to originate in coronal holes, the question is still largely debated on the origin of the slow solar wind (SSW). The abundance of heavy ions measured in situ provides a precious diagnostic of potential source regions, because the composition is established very low in the solar atmosphere at the interface between the dense chromosphere and the tenuous corona, and remains invariant during transport in the collisionless solar wind. The similar composition measured in situ in the SSW and spectroscopically in coronal loops suggests that a significant fraction of the SSW originates as plasma material that was initially trapped along corona loops and subsequently released in the solar wind. The recent observations from the Parker Solar Probe (PSP) mission also provide new insights on the nascent solar wind. A great challenge remains to explain both the composition and bulk properties of the SSW in a self-consistent manner. For this purpose we exploit and develop models with various degrees of complexity. This context constitutes the backbone of this thesis which is structured in four major steps: we begin by presenting a new technique that exploits white-light (WL) observations of the SSW taken from multiple vantage points to constrain global models of the solar atmosphere. We then exploit the first images taken by the Wide-Field Imager for Solar PRobe (WISPR) from inside the solar corona to test our global models at smaller scales because WISPR offers an

unprecedented close-up view of the fine structure of streamers and of the nascent SSW. This work provides further evidence for the transient release of plasma trapped in coronal loops into the solar wind, that we interpret by exploiting high-resolution magneto-hydro-dynamics (MHD) simulations. Finally we develop and exploit a new multi-specie model of coronal loops called the Irap Solar Atmosphere Model (ISAM) to provide an in-depth analysis of the plasma transport mechanisms at play between the chromosphere and the corona. ISAM solves for the coupled transport of the main constituents of the solar wind with minor ions through a comprehensive treatment of collisions as well as partial ionization and radiative cooling/heating mechanisms near the top of the chromosphere. We use this model to study the different mechanisms that can preferentially extract ions according to their first-ionization-potential (FIP), from the chromosphere to the corona. In this process we compare the relative roles of frictional and thermal diffusive effects in enriching coronal loops with low-FIP elements that could be subsequently expelled in the SSW through the mechanisms discussed in the first part of this thesis.

A different interpretation of the annual and semiannual anomalies on the magnetic activity over the Earth

[Azpilicueta](#), F., and C. Brunini

J. Geophys. Res., 117, A08202, 2012

The H component of the magnetic field measured at the terrestrial surface presents several periodic signals caused by changes in the ring current that flows within the terrestrial magnetosphere. One of the most important of them is associated to the phenomenon known as the Semiannual Anomaly which produces two significant minima during the equinoxes. This phenomenon is global, i.e., every observatory registers a similar effect independently of the hemisphere where it is located. A second important signal is due to the phenomenon known as the Annual Anomaly that produces significant different values for solstices, with a particular feature: the effect depends on the hemisphere where the observatory is located, with maximum during local summer. In spite of the time since their discoveries (more than a hundred years ago) the physical processes behind them are still open to discussion. In this work we present a new physical interpretation for the combined effects of both anomalies. The main concept developed is that along the year the shape of the magnetospheric cavities within which the ring current flows is deformed according to the geometric configuration between the solar wind and the magnetosphere.

The geomagnetic semiannual anomaly on the four Dst-fundamental observatories: Dependences with Sun-Earth physical parameters

[Azpilicueta](#), Francisco; Brunini, Claudio; CamiliCn, Emilio

J. Geophys. Res., Vol. 117, No. A7, A07204, 2012

<http://dx.doi.org/10.1029/2012JA017730>

The semiannual anomaly (also known as semiannual variation) on the magnetic activity is a phenomenon that produces clear minima during March and September and maxima in June and December on the horizontal components of the geomagnetic field. This phenomenon has been known since the middle of the nineteenth century, but in spite of the accumulation of measurements and the development of three theoretical models, a conclusive physical explanation for it has not been developed. The usual approach to study the semiannual anomaly is by means of geomagnetic indices like the disturbance storm time, Dst, which is based on combining measurements registered on four magnetic observatories. This work follows a different approach based on the raw horizontal components registered at the four observatories. The analyses performed aimed to study and assess the impact of several external parameters, characteristics of the Sun-Earth environment, on the semiannual anomaly. The influence of the global geomagnetic activity level, the solar activity level, the solar magnetic polarity, and the rising/declining phase of the solar radiation cycle is analyzed in detail. The most important finding is that the semiannual anomaly is always present and that none of the previously mentioned parameters significantly favor the development of it. A second result is the presence of a 27 day signal superposed to the semiannual anomaly which is significantly affected by the solar activity level.

Coronal Mass Ejections from the Sun - Propagation and Near Earth Effects

Arun [Babu](#)

THESIS, 2014

<http://arxiv.org/pdf/1407.4258v1.pdf>

Owing to our dependance on spaceborne technology, an awareness of disturbances in the near-Earth space environment is proving to be increasingly crucial. Earth-directed Coronal mass ejections (CMEs) emanating from the Sun are the primary drivers of space weather disturbances. Studies of CMEs, their kinematics, and their near-Earth effects are therefore gaining in importance.

The effect of CMEs near the Earth is often manifested as transient decreases in galactic cosmic ray intensity, which are called **Forbush decreases (FDs)**. In this thesis we probe the structure of CMEs and their associated shocks using FD observations by the GRAPES-3 muon telescope at Ooty. We have established that the cumulative diffusion of galactic cosmic rays into the CME is the dominant mechanism for causing FDs (Chapter 3).

This diffusion takes place through a turbulent sheath region between the CME and the shock. One of our main results concerns the turbulence level in this region. We have quantitatively established that cross-field diffusion aided by magnetic field turbulence accounts for the observed lag between the FD and the magnetic field enhancement of the sheath region (Chapter 4).

We have also investigated the nature of the driving forces acting on CMEs in this thesis. Using CME data from the SECCHI coronagraphs aboard STEREO spacecraft, we have found evidence for the non-force-free nature of the magnetic field configuration inside these CMEs, which is the basis for the (often-invoked) Lorentz self-force driving (Chapter 5).

Taken together the work presented in this thesis is a comprehensive attempt to characterise CME propagation from typical coronagraph fields of view to the Earth.

2000-02-27, 2001-11-24, 10-12 Apr 2001, 17 August 2001, 7 September 2002, 20 November 2003, 26 July 2004, 21 June 2010,

E-print, April 2013; A&A

<http://arxiv.org/abs/1304.5343>

Aims. We seek to identify the primary agents causing Forbush decreases (FDs) observed at the Earth in high rigidity cosmic rays. In particular, we ask if such FDs are caused mainly by coronal mass ejections (CMEs) from the Sun that are directed towards the Earth, or by their associated shocks.

Methods. We use the muon data at cutoff rigidities ranging from 14 to 24 GV from the GRAPES-3 tracking muon telescope to identify FD events. We select those FD events that have a reasonably clean profile, and can be reasonably well associated with an Earth-directed CME and its associated shock. We employ two models: one that considers the CME as the sole cause of the FD (the CME-only model) and one that considers the shock as the only agent causing the FD (the shock-only model). We use an extensive set of observationally determined parameters for both these models.

The only free parameter in these models is the level of MHD turbulence in the sheath region, which mediates cosmic ray diffusion (into the CME, for the CME-only model and across the shock sheath, for the shock-only model).

Results. We find that good fits to the GRAPES-3 multi-rigidity data using the CME-only model require turbulence levels in the CME sheath region that are only slightly higher than those estimated for the quiet solar wind. On the other hand, reasonable model fits with the shock-only model require turbulence levels in the sheath region that are an order of magnitude higher than those in the quiet solar wind.

Conclusions. This observation naturally leads to the conclusion that the Earth-directed CMEs are the primary contributors to FDs observed in high rigidity cosmic rays.

<https://doi.org/10.1029/2023JA031359>

Drawing connections between heliospheric spacecraft and solar wind sources is a vital step in understanding the evolution of the solar corona into the solar wind and contextualizing *in situ* timeseries. Furthermore, making advanced predictions of this linkage for ongoing heliospheric missions, such as Parker Solar Probe (PSP), is necessary for achieving useful coordinated remote observations and maximizing scientific return. The general procedure for estimating such connectivity is straightforward (i.e. magnetic field line tracing in a coronal model) but validating the resulting estimates difficult due to the lack of an independent ground truth and limited model constraints. In its most recent orbits, PSP has reached perihelia of 13.3R_☉ and moreover travels extremely fast prograde relative to the solar

surface, covering over 120 degrees longitude in three days. Here we present footpoint predictions and subsequent validation efforts for PSP Encounter 10, the first of the 13.3R \odot orbits, which occurred in November 2021. We show that the longitudinal dependence of $\textit{in situ}$ plasma data from these novel orbits provides a powerful method of footpoint validation. With reference to other encounters, we also illustrate that the conditions under which source mapping is most accurate for near-ecliptic spacecraft (such as PSP) occur when solar activity is low, but also requires that the heliospheric current sheet is strongly warped by mid-latitude or equatorial coronal holes. Lastly, we comment on the large-scale coronal structure implied by the Encounter 10 mapping, highlighting an empirical equatorial cut of the Alfvén surface consisting of localized protrusions above unipolar magnetic separatrices. **15-26 Nov 2021**

ApJ **2019**

<https://arxiv.org/pdf/1912.02244.pdf>

We compare magnetic field measurements taken by the FIELDS instrument on Parker Solar Probe (PSP) during its first solar encounter to predictions obtained by Potential Field Source Surface (PFSS) modeling. Ballistic propagation is used to connect the spacecraft to the source surface. Despite the simplicity of the model, our results show striking agreement with PSPs first observations of the heliospheric magnetic field from 0.5 AU (107.5 Rs) down to 0.16 AU (35.7 Rs). Further, we show the robustness of the agreement is improved both by allowing the photospheric input to the model to vary in time, and by advecting the field from PSP down to the PFSS model domain using *in situ* PSP/SWEAP measurements of the solar wind speed instead of assuming it to be constant with longitude and latitude. We also explore the source surface height parameter (RSS) to the PFSS model finding that an extraordinarily low source surface height (1.3-1.5Rs) predicts observed small scale polarity inversions which are otherwise washed out with regular modeling parameters. Finally, we extract field line traces from these models. By overlaying these on EUV images we observe magnetic connectivity to various equatorial and mid-latitude coronal holes indicating plausible magnetic footpoints and offering context for future discussions of sources of the solar wind measured by PSP. **2018-10-15 to 2018-11-30**

Forbush decreases and Geomagnetic Storms during a Highly Disturbed Solar and Interplanetary Period, 4-10 September 2017

B. [Badruddin](#), [O. P. M. Aslam](#), [M. Derouich](#), [H. Asiri](#), [K. Kudela](#)
Space Weather [Volume17, Issue3](#) Pages 487-496 **2019**

sci-hub.se/10.1029/2018SW001941

Features and peculiarities of the cosmic ray intensity (CRI) and the geomagnetic activity, along with several solar plasma and interplanetary magnetic field during the period 4-10 September 2017 are studied. The period was characterized by strong solar activity: several solar flares occurred, several halo Coronal Mass Ejections (CMEs) were ejected in space. In the near-Earth interplanetary space, the CMEs driving shock(s) and sheath(s) were identified. At the Earth, strong Forbush decreases (FD) in CRI and geomagnetic storms (GS) were observed. Several large solar flares, one of them of very high X-ray importance (X 9.3) and three halo CMEs were detected in the solar atmosphere. Two shock-associated Interplanetary Coronal Mass Ejections were observed during that interval in near-Earth space; the latter and faster one arrived even as the ejecta of earlier one was still crossing. Variations in interplanetary plasma and field parameters during, before and after the FD and GS that occurred during the considered period were examined. A detailed time-lagged correlation analysis using data at three different temporal resolutions (hourly, 5-min and 1-min) was also performed. Cross-correlations of time series of CRI with geomagnetic activity during the period 4 – 10 September 2017 are computed. This cross-correlation analysis between CRI variability (defined as the difference of the CRI count rate between the current and the previous time step) and the Dst indicates a delay of Dst by 3-4 hours.

Geomagnetic response of interplanetary coronal mass ejections in the Earth's magnetosphere

[Badruddin](#), [F.Mustajab](#) [M.Derouich](#)

[Planetary and Space Science](#) [Volume 154](#), May **2018**, Pages 1-4

<https://www.sciencedirect.com/science/article/pii/S0032063317304695>

A [coronal mass ejections](#) (CME) is the huge mass of plasma with embedded [magnetic field](#) ejected abruptly from the Sun. These CMEs propagate into [interplanetary space](#) with different speed. Some of them hit the [Earth's magnetosphere](#) and create many types of disturbances; one of them is the disturbance in the [geomagnetic field](#). Individual geomagnetic disturbances differ not only in their magnitudes, but the nature of disturbance is also different. It is, therefore, desirable to understand these differences not only to understand the physics of geomagnetic disturbances but also to understand the properties of solar/interplanetary structures producing these disturbances of different magnitude and nature. In this work, we use the spacecraft measurements of CMEs with distinct [magnetic properties](#) propagating in the interplanetary space and generating disturbances of different levels and nature. We utilize their distinct plasma and field properties to search for the interplanetary parameter(s) playing important role in influencing the geomagnetic response of different coronal mass ejections.

Study of the geoeffectiveness of coronal mass ejections, corotating interaction regions and their associated structures observed during Solar Cycle 23

A. [Badruddin](#), Z. Falak

Astrophysics and Space Science August 2016, 361:253

<https://link.springer.com/content/pdf/10.1007%2Fs10509-016-2839-4.pdf>

The interplanetary coronal mass ejections (ICMEs) and the corotating interaction regions (CIRs) are the two most important structures of the interplanetary medium affecting the Earth and the near-Earth space environment. We study the solar wind-magnetosphere coupling during the passage of ICMEs and CIRs, in the Solar Cycle 23 (Jan. 1995–Dec. 2009), and their relative geoeffectiveness. We utilize the timings of different features of these structures, their arrival and duration. As geomagnetic parameter, we utilize high time resolution data of Dst and AEAE indices. In addition to these geomagnetic indices, we utilize the simultaneous and similar time resolution data of interplanetary plasma and field, namely, solar wind velocity, interplanetary magnetic field, its north-south component and dawn-dusk electric field. We apply the method of superposed epoch analysis. Utilizing the properties of various structures during the passage of ICMEs and CIRs, and variations observed in plasma and field parameters during their passage along with the simultaneous changes observed in geomagnetic parameters, we identify the interplanetary conditions, plasma/field parameters and their relative importance in solar wind-magnetosphere coupling. Geospace consequences of ICMEs and CIRs, and the implications of these results for solar wind-magnetosphere coupling are discussed.

Study of the Cosmic-Ray Modulation During the Passage of ICMEs and CIRs

[Badruddin](#) , Anand Kumar

Solar Phys Vol. 291, Issue 2, pp.559-580 2016

<https://link.springer.com/content/pdf/10.1007%2Fs11207-015-0843-4.pdf>

We compare the cosmic-ray response to interplanetary coronal mass ejections (ICMEs) and corotating interaction regions (CIRs) during their passage in near-Earth space. We study the relative importance of various structures/features identified during the passage of the ICMEs and CIRs observed during Cycle 23 (1995–2009). The identified ICME structures are the shock front, the sheath, and the CME ejecta. We isolate the shock arrival time, the passage of the sheath region, the arrival of ejecta, and the end time of their passage. Similarly, we isolate the CIR arrival, the associated forward shock, the stream interface, and the reverse shock during the passage of a CIR. For the cosmic-ray intensity, we utilize the data from high counting rate neutron monitors. In addition to neutron monitor data, we utilize near-simultaneous and same time-resolution data of interplanetary plasma and field, namely the solar-wind velocity, the interplanetary magnetic field (IMF) vector, and its variance. Further, we also utilize some derived interplanetary parameters. We apply the method of the superposed-epoch analysis. As the plasma and field properties are different during the passage of different structures, both in ICMEs and CIRs, we systematically vary the epoch time in our superposed-epoch analysis one by one. In this way, we study the role and effects of each of the identified individual structures/features during the passage of the ICMEs and CIRs. Relating the properties of various structures and the corresponding variations in plasma and field parameters with changes of the cosmic-ray intensity, we identify the relative importance of the plasma/field parameters in influencing the amplitude and time profiles of the cosmic-ray intensity variations during the passage of the ICMEs and CIRs.

Study of the Forbush Decreases, Geomagnetic Storms, and Ground-Level Enhancements in Selected Intervals and Their Space Weather Implications

Badruddin & Anand Kumar

Solar Phys. Volume 290, [Issue 4](#), pp 1271-1283 **2015, File**

We analysed geomagnetic storms, ground-level enhancements (GLEs), and Forbush decreases in cosmic-ray intensity that occurred in selected intervals. We used data of ground-based neutron monitors for the cosmic-ray intensity. We used the geomagnetic index Dst as a measure of the geomagnetic storm intensity. Solar observations and interplanetary plasma/field parameters were used to identify the solar cause(s), interplanetary structure(s), and physical mechanism(s) responsible for the geomagnetic storms, the Forbush decreases, and the GLEs of different amplitudes and time profiles; all of them occurring within four selected periods of one month each. The observed differences in cosmic-ray and geomagnetic-activity responses to the same solar sources were used to distinguish the structures and mechanisms responsible for transient cosmic-ray modulation and geomagnetic storms. **July 2000 , April 2001, Jan 2005, 5-18 Dec 2006**

Fluctuations in the interplanetary electric potential and energy coupling between the solar-wind and the magnetosphere

Badruddin and Aslam, O.P.M.

E-print, Dec **2013**; Proc. International Symposium on Solar-Terrestrial Physics 2012 (ISSTP 2012)

We utilize solar rotation average geomagnetic index ap and various solar wind plasma and field parameters for four solar cycles 20-23. We perform analysis to search for a best possible coupling function at 27-day time resolution. Regression analysis using these data at different phases of solar activity (increasing including maximum/decreasing including minimum) led us to suggest that the time variation of interplanetary electric potential is a better coupling function for solar wind-magnetosphere coupling. We suspect that a faster rate of change in interplanetary electric potential at the magnetopause might enhance the reconnection rate and energy transfer from the solar wind into the magnetosphere. The possible mechanism that involves the interplanetary potential fluctuations in influencing the solar wind-magnetosphere coupling is being investigated.

Study of the solar wind-magnetosphere coupling on different time scales

Badruddin and Aslam, O.P.M.

E-print, Nov **2013**; Planetary and Space Science

Solar wind-magnetosphere coupling, its causes and consequences have been studied for the last several decades. However, the assessment of continuously changing behaviour of the sun, plasma and field flows in the interplanetary space and their influence on geomagnetic activity is still a subject of intense research. Search for the best possible coupling function is also important for space weather prediction. We utilise four geomagnetic indices (ap, aa, AE and Dst) as parameters of geomagnetic activity level in the earth's magnetosphere. In addition to these indices, we utilise various solar wind plasma and field parameters for the corresponding periods. We analyse the geomagnetic activity and plasma/field parameters at yearly, half-yearly, 27-day, daily, 3-hourly, and hourly time resolutions. Regression analysis using geomagnetic and solar wind data of different time resolutions, over a continuous long period, and at different phases of solar activity (increasing including maximum/decreasing including minimum) led us to suggest that two parameters BV/1000(mV/m) and BV2(mV/s) are highly correlated with the all four geomagnetic activity indices not only at any particular time scale but at different time scales. It probably suggests for some role of the fluctuations/variations in interplanetary electric potential, its spacial variation [i.e., interplanetary electric field BV (mV/m)] and/or time variation [BV2 (mV/s)], in influencing the reconnection rate.

Using Gradient Boosting Regression to Improve Ambient Solar Wind Model Predictions

R. L. **Bailey**, [M. A. Reiss](#), [C. N. Arge](#), [C. Möstl](#), [C. J. Henney](#), [M. J. Owens](#), [U. V. Amerstorfer](#), [T. Amerstorfer](#), [A. J. Weiss](#), [J. Hinterreiter](#)

Studying the ambient solar wind, a continuous pressure-driven plasma flow emanating from our Sun, is an important component of space weather research. The ambient solar wind flows in interplanetary space determine how solar storms evolve through the heliosphere before reaching Earth, and especially during solar minimum are themselves a driver of activity in the Earth's magnetic field. Accurately forecasting the ambient solar wind flow is therefore imperative to space weather awareness. Here, we present a machine learning approach in which solutions from magnetic models of the solar corona are used to output the solar wind conditions near the Earth. The results are compared to observations and existing models in a comprehensive validation analysis, and the new model outperforms existing models in almost all measures.

In addition, this approach offers a new perspective to discuss the role of different input data to ambient solar wind modeling, and what this tells us about the underlying physical processes. The final model discussed here represents an extremely fast, well-validated and open-source approach to the forecasting of ambient solar wind at Earth.

<https://agupubs.onlinelibrary.wiley.com/doi/pdf/10.1029/2019SW002424>

<https://arxiv.org/pdf/2005.00249.pdf>

Geomagnetic storms resulting from high-speed streams can have significant negative impacts on modern infrastructure due to complex interactions between the solar wind and geomagnetic field. One measure of the extent of this effect is the Kyoto Dst index. We present a method to predict Dst from data measured at the Lagrange 5 (L5) point, which allows for forecasts of solar wind development 4.5 days in advance of the stream reaching the Earth. Using the STEREO-B satellite as a proxy, we map data measured near L5 to the near-Earth environment and make a prediction of the Dst from this point using the Temerin-Li Dst model enhanced from the original using a machine learning approach. We evaluate the method accuracy with both traditional point-to-point error measures and an event-based validation approach. The results show that predictions using L5 data outperform a 27-day solar wind persistence model in all validation measures but do not achieve a level similar to an L1 monitor. Offsets in timing and the rapidly-changing development of Bz in comparison to Bx and By reduce the accuracy. Predictions of Dst from L5 have an RMSE of 9 nT, which is double the error of 4 nT using measurements conducted near the Earth. The most useful application of L5 measurements is shown to be in predicting the minimum Dst for the next four days. This method is being implemented in a real-time forecast setting using STEREO-A as an L5 proxy, and has implications for the usefulness of future L5 missions.

Shock Connectivity in the August 2010 and July 2012 Solar Energetic Particle Events Inferred from Observations and ENLIL Modeling

H. M. [Bain](#), M. L. Mays, J. G. Luhmann, Y. Li, L. K. Jian, and D. Odstrcil

2016 ApJ 825 1 **File**

During periods of increased solar activity, coronal mass ejections (CMEs) can occur in close succession and proximity to one another. This can lead to the interaction and merger of CME ejecta as they propagate in the heliosphere. The particles accelerated in these shocks can result in complex solar energetic particle (SEP) events, as observing spacecraft form both remote and local shock connections. It can be challenging to understand these complex SEP events from in situ profiles alone. Multipoint observations of CMEs in the near-Sun environment, from the Solar Terrestrial Relations Observatory "Sun Earth Connection Coronal and Heliospheric Investigation and the Solar and Heliospheric Observatory Large Angle and Spectrometric Coronagraph, greatly improve our chances of identifying the origin of these accelerated particles. However, contextual information on conditions in the heliosphere, including the background solar wind conditions and shock structures, is essential for understanding SEP properties well enough to forecast their characteristics. Wang "Sheeley? Arge WSA-ENLIL + Cone modeling provides a tool to interpret major SEP event periods in the context of a realistic heliospheric model and to determine how much of what is observed in large SEP events depends on nonlocal magnetic connections to shock sources. We discuss observations of the SEP-rich periods of **2010 August and 2012 July** in conjunction with ENLIL modeling. We find that much SEP activity can only be

understood in the light of such models, and in particular from knowing about both remote and local shock source connections. These results must be folded into the investigations of the physics underlying the longitudinal extent of SEP events, and the source connection versus diffusion pictures of interpretations of SEP events.

Observational Evidence of S-Web Source of the Slow Solar Wind

D. Baker, P. Demoulin, S.L. Yardley, T. Mihalescu, L. van Driel-Gesztelyi, et al.

ApJ 950:65 2023

<https://arxiv.org/pdf/2303.12192.pdf>

From 2022 March 18-21, active region (AR) 12967 was tracked simultaneously by Solar Orbiter (SO) at 0.35 au and Hinode/EIS at Earth. During this period, strong blue-shifted plasma upflows were observed along a thin, dark corridor of open field originating at the AR's leading polarity and continuing towards the southern extension of the northern polar coronal hole. A potential field source surface (PFSS) model shows large lateral expansion of the open magnetic field along the corridor. Squashing factor Q-maps of the large scale topology further confirm super-radial expansion in support of the S-Web theory for the slow wind. The thin corridor of upflows is identified as the source region of a slow solar wind stream characterised by approx. 300 km s⁻¹ velocities, low proton temperatures of approx. 5 eV, extremely high density over 100 cm⁻³, and a short interval of moderate Alfvénicity accompanied by switchback events. When connectivity changes from the corridor to the eastern side of the AR, the in situ plasma parameters of the slow wind indicate a distinctly different source region. These observations provide strong evidence that the narrow open field corridors, forming part of the S-Web, produce extreme properties in their associated solar wind streams.

A major solar eruptive event in July 2012: Defining extreme space weather scenarios

D. N. Baker, X. Li, A. Pulkkinen, C. M. Ngwira, M. L. Mays, A. B. Galvin and K. D. C. Simunac
Space Weather, Volume 11, Issue 10, pages 585–591, October 2013

<http://onlinelibrary.wiley.com/doi/10.1002/swe.20097/pdf>

A key goal for space weather studies is to define severe and extreme conditions that might plausibly afflict human technology. On 23 July 2012, solar active region 1520 (~141°W heliographic longitude) gave rise to a powerful coronal mass ejection (CME) with an initial speed that was determined to be 2500 ± 500 km/s. The eruption was directed away from Earth toward 125°W longitude. STEREO-A sensors detected the CME arrival only about 19 h later and made in situ measurements of the solar wind and interplanetary magnetic field. In this paper, we address the question of what would have happened if this powerful interplanetary event had been Earthward directed. Using a well-proven geomagnetic storm forecast model, we find that the 23–24 July event would certainly have produced a geomagnetic storm that was comparable to the largest events of the twentieth century (Dst ~ -500 nT). Using plausible assumptions about seasonal and time-of-day orientation of the Earth's magnetic dipole, the most extreme modeled value of storm-time disturbance would have been Dst = -1182 nT. This is considerably larger than estimates for the famous Carrington storm of 1859. This finding has far reaching implications because it demonstrates that extreme space weather conditions such as those during March of 1989 or September of 1859 can happen even during a modest solar activity cycle such as the one presently underway. We argue that this extreme event should immediately be employed by the space weather community to model severe space weather effects on technological systems such as the electric power grid.

Signatures of Interchange Reconnection: STEREO, ACE and Hinode Observations Combined

D. Baker¹, A. P. Rouillard^{2,3}, L. van Driel-Gesztelyi^{1,4,5}, P. D'émoulin⁴, L. K. Harra¹, B. Lavraud^{6,7}, J.A. Davies³, A. Opitz^{6,7}, J. G. Luhmann⁸, J.-A. Sauvaud^{6,7}, and A. B. Galvin⁹

E-print, Sept 2009; Ann. Geophys., 27, 3883–3897, 2009, File

Combining STEREO, ACE and Hinode observations has presented an opportunity to follow a filament eruption and coronal mass ejection (CME) on the 17th of October 2007 from an active region (AR) inside a coronal hole (CH) into the heliosphere. This particular combination of 'open' and closed magnetic topologies provides an ideal scenario for interchange reconnection to take place. With Hinode and STEREO data we were able to identify the emergence time and type of structure seen in the in-situ data four days later. On the 21st, ACE observed in-situ the passage of an ICME with 'open' magnetic topology. The magnetic field configuration of the source, a mature AR located inside an equatorial CH,

has important implications for the solar and interplanetary signatures of the eruption. We interpret the formation of an 'anemone' structure of the erupting AR and the passage in-situ of the ICME being disconnected at one leg, as manifested by uni-directional suprathermal electron flux in the ICME, to be a direct result of interchange reconnection between closed loops of the CME originating from the AR and 'open' field lines of the surrounding CH.

<https://www.aanda.org/articles/aa/pdf/2020/07/aa37840-20.pdf>

Solar wind electron velocity distributions at 1 au consist of a thermal "core" population and two suprathermal populations: "halo" and "strahl". The core and halo are quasi-isotropic, whereas the strahl typically travels radially outwards along the parallel or anti-parallel direction with respect to the interplanetary magnetic field. Using Cluster-PEACE data, we analyse energy and pitch angle distributions and use machine learning techniques to provide robust classifications of these solar wind populations. Initially, we used unsupervised algorithms to classify halo and strahl differential energy flux distributions to allow us to calculate relative number densities, which are of the same order as previous results. Subsequently, we applied unsupervised algorithms to phase space density distributions over ten years to study the variation of halo and strahl breakpoint energies with solar wind parameters. In our statistical study, we find both halo and strahl suprathermal breakpoint energies display a significant increase with core temperature, with the halo exhibiting a more positive correlation than the strahl. We conclude low energy strahl electrons are scattering into the core at perpendicular pitch angles. This increases the number of Coulomb collisions and extends the perpendicular core population to higher energies, resulting in a larger difference between halo and strahl breakpoint energies at higher core temperatures. Statistically, the locations of both suprathermal breakpoint energies decrease with increasing solar wind speed. In the case of halo breakpoint energy, we observe two distinct profiles above and below 500 km s⁻¹. We relate this to the difference in origin of fast and slow solar wind.

Testing the estimated hypothetical response of a major CME impact on Earth and its implications to space weather

Ramkumar **Bala**, Patricia Reiff, C. T. Russell

JGR Volume 120, Issue 5 May 2015 Pages 3432–3443

The high-speed coronal mass ejection (CME), ejected on **23 July 2012**, observed by STEREO-A on the same day as the leading edge of the CME arrived at 1AU was unique both in respect to the observed plasma and magnetic structure and the large solar energetic particle flux that dynamically regulated the shock front. Because of its great intensity, it has been hailed as "Carrington 2" by some, warning that, had that CME been heading toward the Earth, it might have caused a major space weather event. We used the Rice Artificial Neural Network algorithms with the solar wind and interplanetary magnetic field parameters measured in situ by STEREO-A as inputs to infer what the "geoeffectiveness" of that storm might have been. We have also used an MHD model in Open Geospace General Circulation Model to understand the global magnetospheric process in time sequence. We presently show our neural network models of Kp and Dst on our real-time prediction site: <http://mms.rice.edu/realtime/forecast.html>. Running this event through our models showed that, in fact, this would have been an exceptional event. Our results show a prediction resulting in a Kp value of 8+, a Dst of nearly -250 nT, but when assumptions about maximum dipole angle tilt and density are made, predictions resulting in Kp of 11- and Dst dipping close to -700 nT are found. Finally, when solar energetic proton flux is included, the Kp and Dst predictions drop to 8- and ≈-625 nT, respectively.

Improvements in short-term forecasting of geomagnetic activity

Bala, Ramkumar; Reiff, Patricia

Space Weather, Vol. 10, No. 0, S06001, 2012

<http://dx.doi.org/10.1029/2012SW000779>

We have improved our space weather forecasting algorithms to now predict Dst and AE in addition to Kp for up to 6 h of forecast times. These predictions can be accessed in real time at <http://mms.rice.edu/realtime/forecast.html>. In

addition, in the event of an ongoing or imminent activity, e-mail “alerts” based on key discriminator levels have been going out to our subscribers since October 2003. The neural network–based algorithms utilize ACE data to generate full 1, 3, and 6 h ahead predictions of these indices from the Boyle index, an empirical approximation that estimates the Earth's polar cap potential using solar wind parameters. Our models yield correlation coefficients of over 0.88, 0.86, and 0.83 for 1 h predictions of Kp, Dst, and AE, respectively, and 0.86, 0.84, and 0.80 when predicting the same but 3 h ahead. Our 6 h ahead predictions, however, have slightly higher uncertainties. Furthermore, the paper also tests other solar wind functions—the Newell driver, the Borovsky control function, and adding solar wind pressure term to the Boyle index—for their ability to predict geomagnetic activity.

A scheme for forecasting severe space weather

N. **Balan**, Y. Ebihara, R. Skoug, K. Shiokawa, I. S. Batista, S. Tulasi Ram, Y. Omura, T. Nakamura, M.-C. Fok

JGR **2017** DOI: 10.1002/2016JA023853

<http://sci-hub.cc/doi/10.1002/2016JA023853>

A scheme is suggested and tested for forecasting severe space weather (SvSW) using solar wind velocity (V) and the north-south component (Bz) of the interplanetary magnetic field (IMF) measured using the ACE (Advanced Composition Explorer) satellite from 1998 to 2016. SvSW has caused all known electric power outages and telegraph system failures. Earlier SvSW events such as the Carrington event of 1859, Quebec event of 1989 and an event in 1958 are included with information from the literature. Dst storms are used as references to identify 89 major space weather events ($Dst_{Min} \leq -100$ nT) in 1998–2016. The coincidence of high CME front (or CME shock) velocity ΔV (sudden increase in V over the background by over 275 km/s) and sufficiently large Bz southward at the time of the ΔV increase is associated with SvSW; and their product ($\Delta V \times Bz$) is found to exhibit a large negative spike at the speed increase. Such a product ($\Delta V \times Bz$) exceeding a threshold seems suitable for forecasting SvSW. However, the coincidence of high V (not containing ΔV) and large Bz southward does not correspond to SvSW, indicating the importance of the impulsive action of large Bz southward and high ΔV coming through when they coincide. The need for the coincidence is verified using the CRCM (Comprehensive Ring Current Model) model, that produces extreme Dst storms ($\langle Dst_{MP} \rangle < -250$ nT) characterizing SvSW when there is coincidence. **15–16 July 2000, 30–31 March 2001, 03–26 November 2001, 26 Oct–25 Nov 2003, 30–31 October 2003,**

CME front and severe space weather

JGR, Volume 119, Issue 12, pages 10041–10058, December **2014**

<http://onlinelibrary.wiley.com/doi/10.1002/2014JA020151/pdf>

Thanks to the work of a number of scientists it is known that severe space weather can cause extensive social and economic disruptions in the modern high-tech society. It is therefore important to understand what determines the severity of space weather, and whether it can be predicted. We present results obtained from the analysis of coronal mass ejections (CME), solar energetic particle (SEP) events, interplanetary magnetic field (IMF), CME-magnetosphere coupling and geomagnetic storms associated with the major space weather events since 1998 by combining data from the ACE and GOES satellites with geomagnetic parameters, and the Carrington event of 1859, the Quebec event of 1989, and an event in 1958. The results seem to indicate that (1) it is the impulsive energy mainly due to the impulsive velocity and orientation of IMF Bz at the leading edge of the CMEs (or CME front) that determine the severity of space weather. (2) CMEs having high impulsive velocity (sudden non-fluctuating increase by over 275 km s⁻¹ over the background) caused severe space weather (SvSW) in the heliosphere (failure of the SWI mode of SWEPAM in ACE) probably by suddenly accelerating the high energy particles in the SEPs ahead directly or through the shocks. (3) The impact of such CMEs which also show the IMF Bz southward from the leading edge caused SvSW at the Earth including extreme geomagnetic storms of mean $Dst_{MP} < -250$ nT during main phases; and the known electric power outages happened during some of these SvSW events. (4) The higher the impulsive velocity, the more severe the space weather, like faster weather fronts and tsunami fronts causing more severe damage through impulsive action. (5) The CMEs having IMF Bz northward at the leading edge do not seem to cause SvSW on Earth though, later when the IMF Bz turns southward, they can lead to super geomagnetic storms of intensity (Dst_{Min}) less than even -400 nT.

Table 1. Characteristics of the Geomagnetic Storms Associated With 13 Major Space Weather Events Since 1998 and the Carrington Event of September 1959, the Quebec Event of March 1989, and an Event in February

Complex Systems Methods Characterizing Nonlinear Processes in the Near-Earth Electromagnetic Environment: Recent Advances and Open Challenges

Review

Georgios **Balasis**, [Michael A. Balikhin](#), [Sandra C. Chapman](#), [Giuseppe Consolini](#), +++
[Space Science Reviews](#) volume 219, Article number: 38 (2023)
<https://link.springer.com/content/pdf/10.1007/s11214-023-00979-7.pdf>

Learning from successful applications of methods originating in statistical mechanics, complex systems science, or information theory in one scientific field (e.g., atmospheric physics or climatology) can provide important insights or conceptual ideas for other areas (e.g., space sciences) or even stimulate new research questions and approaches. For instance, quantification and attribution of dynamical complexity in output time series of nonlinear dynamical systems is a key challenge across scientific disciplines. Especially in the field of space physics, an early and accurate detection of characteristic dissimilarity between normal and abnormal states (e.g., pre-storm activity vs. magnetic storms) has the potential to vastly improve space weather diagnosis and, consequently, the mitigation of space weather hazards. This review provides a systematic overview on existing nonlinear dynamical systems-based methodologies along with key results of their previous applications in a space physics context, which particularly illustrates how complementary modern complex systems approaches have recently shaped our understanding of nonlinear magnetospheric variability. The rising number of corresponding studies demonstrates that the multiplicity of nonlinear time series analysis methods developed during the last decades offers great potentials for uncovering relevant yet complex processes interlinking different geospace subsystems, variables and spatiotemporal scales. **16 March 1997**

Universality in solar flare, magnetic storm and earthquake dynamics using Tsallis statistical mechanics

G. **Balasis**, I. A. Daglis, A. Anastasiadis, C. Papadimitriou, M. Mandea, K. Eftaxias
E-print, Sept 2010; Accepted for publication in : *Physica A* (2010)

The universal character of the dynamics of various extreme phenomena is an outstanding scientific challenge. We show that X-ray flux and Dst time series during powerful solar flares and intense magnetic storms, respectively, obey a nonextensive energy distribution function for earthquake dynamics with similar values for the Tsallis entropic index q . Thus, evidence for universality in solar flares, magnetic storms and earthquakes arise naturally in the framework of Tsallis statistical mechanics. The observed similarity suggests a common approach to the interpretation of these diverse phenomena in terms of driving physical mechanisms that have the same character.

A solar source of Alfvénic magnetic field switchbacks: *in situ* remnants of magnetic funnels on supergranulation scales

One of the striking observations from the Parker Solar Probe (PSP) spacecraft is the prevalence in the inner heliosphere of large amplitude, Alfvénic magnetic field reversals termed 'switchbacks'. These $\delta B/B \sim O(1)$ fluctuations occur on a range of timescales and in *in situ* patches separated by intervals of quiet, radial magnetic field. We use measurements from PSP to demonstrate that patches of switchbacks are localized within the extensions of plasma structures originating at the base of the corona. These structures are characterized by an increase in alpha particle abundance, Mach number, plasma β and pressure, and by depletions in the magnetic field magnitude and electron temperature. These intervals are in pressure-balance, implying stationary spatial structure, and the field depressions are consistent with overexpanded flux tubes. The structures are asymmetric in Carrington longitude with a steeper leading edge and a small ($\sim 1^\circ$) edge of hotter plasma and enhanced magnetic field fluctuations. Some structures contain suprathermal ions to ~ 85 keV that we argue are the energetic tail of the solar wind alpha population. The structures are separated in longitude by angular scales associated with supergranulation. This suggests that these switchbacks originate near the leading edge of the diverging magnetic field funnels associated with the network magnetic field - the primary wind sources. We propose an origin of the magnetic field switchbacks, hot plasma and suprathermals, alpha particles in interchange reconnection events just above the solar transition region and our measurements represent the extended regions of a turbulent outflow exhaust. **27 Sep 2020**

Highly structured slow solar wind emerging from an equatorial coronal hole

S. D. **Bale**, [S. T. Badman](#), [J. R. Wygant](#)

[Nature](#) volume 576, pages237–242 (2019)

<https://www.nature.com/articles/s41586-019-1818-7.pdf>

During the solar minimum, when the Sun is at its least active, the solar wind^{1,2} is observed at high latitudes as a predominantly fast (more than 500 kilometres per second), highly Alfvénic rarefied stream of plasma originating from deep within coronal holes. Closer to the ecliptic plane, the solar wind is interspersed with a more variable slow wind³ of less than 500 kilometres per second. The precise origins of the slow wind streams are less certain⁴; theories and observations suggest that they may originate at the tips of helmet streamers^{5,6}, from interchange reconnection near coronal hole boundaries^{7,8}, or within coronal holes with highly diverging magnetic fields^{9,10}. The heating mechanism required to drive the solar wind is also unresolved, although candidate mechanisms include Alfvén-wave turbulence^{11,12}, heating by reconnection in nanoflares¹³, ion cyclotron wave heating¹⁴ and acceleration by thermal gradients¹. At a distance of one astronomical unit, the wind is mixed and evolved, and therefore much of the diagnostic structure of these sources and processes has been lost. Here we present observations from the **Parker Solar Probe**¹⁵ at 36 to 54 solar radii that show evidence of slow Alfvénic solar wind emerging from a small equatorial coronal hole. The measured magnetic field exhibits patches of large, intermittent reversals that are associated with jets of plasma and enhanced Poynting flux and that are interspersed in a smoother and less turbulent flow with a near-radial magnetic field. Furthermore, plasma-wave measurements suggest the existence of electron and ion velocity-space micro-instabilities^{10,16} that are associated with plasma heating and thermalization processes. Our measurements suggest that there is an impulsive mechanism associated with solar-wind energization and that micro-instabilities play a part in heating, and we provide evidence that low-latitude coronal holes are a key source of the slow solar wind.

The FIELDS instrument suite for solar Probe plus. Measuring the coronal plasma and magnetic field, plasma waves and turbulence, and Radio signatures of solar transients.

Bale, S. D., Goetz, K., Harvey, P. R., Turin, P., Bonnell, J. W., Dudok de Wit, T., et al.

(2016). *Space Sci. Rev.* 204, 49–82.

doi:10.1007/s11214-016-0244-5

NASA's Solar Probe Plus (SPP) mission will make the first in situ measurements of the solar corona and the birthplace of the solar wind. The FIELDS instrument suite on SPP will make direct measurements of electric and magnetic fields, the properties of in situ plasma waves, electron density and temperature profiles, and interplanetary radio emissions, amongst other things. Here, we describe the scientific objectives targeted by the SPP/FIELDS instrument, the instrument design itself, and the instrument concept of operations and planned data products.

Sub-Alfvénic Solar Wind Observed by the Parker Solar Probe: Characterization of Turbulence, Anisotropy, Intermittency, and Switchback

In the lower solar coronal regions where the magnetic field is dominant, the Alfvén speed is much higher than the wind speed. In contrast, the near-Earth solar wind is strongly super-Alfvénic, i.e., the wind speed greatly exceeds the Alfvén speed. The transition between these regimes is classically described as the "Alfvén point" but may in fact occur in a distributed Alfvén critical region. NASA's Parker Solar Probe (PSP) mission has entered this region, as it follows a series of orbits that gradually approach more closely to the Sun. During its 8th and 9th solar encounters, at a distance of $\approx 16 R_{\odot}$ from the Sun, PSP sampled four extended periods in which the solar wind speed was measured to be smaller than the local Alfvén speed. These are the first in situ detections of sub-Alfvénic solar wind in the inner heliosphere by PSP. Here we explore properties of these samples of sub-Alfvénic solar wind, which may provide important previews of the physical processes operating at lower altitude. Specifically, we characterize the turbulence, anisotropy, intermittency, and directional switchback properties of these sub-Alfvénic winds and contrast these with the neighboring super-Alfvénic periods.

Geometry of Magnetic Fluctuations near the Sun from PSP

Riddhi **Bandyopadhyay**, [David J. McComas](#)

ApJ 2021

<https://arxiv.org/ftp/arxiv/papers/2110/2110.14756.pdf>

Solar wind magnetic fluctuations exhibit anisotropy due to the presence of a mean magnetic field in the form of the Parker spiral. Close to the Sun, direct measurements were not available until the recently launched Parker Solar Probe (PSP) mission. The nature of anisotropy and geometry of the magnetic fluctuations play a fundamental role in

dissipation processes and in the transport of energetic particles in space. Using PSP data, we present measurements of geometry and anisotropy of the inner heliosphere magnetic fluctuations, from fluid to kinetic scales. The results are surprising and different from 1 au observations. We find that fluctuations evolve characteristically with size scale. However, unlike 1 au solar wind, at the outer scale, the fluctuations are dominated by wavevectors quasi-parallel to the local magnetic field. In the inertial range, average wave vectors become less field-aligned, but still remain more field aligned than near-Earth solar wind. In the dissipation range, the wavevectors become almost perpendicular to the local magnetic field in the dissipation range, to a much higher degree than those indicated by 1 au observations. We propose that this reduced degree of anisotropy in the outer scale and inertial range is due to the nature of large-scale forcing outside the solar corona.

Observations of Energetic-particle Population Enhancements along Intermittent Structures near the Sun from the Parker Solar Probe

Riddhi [Bandyopadhyay](#)¹, W. H. Matthaeus^{1,2}, T. N. Parashar^{1,2}, R. Chhiber^{1,3}, D. Ruffolo⁴, M. L. Goldstein^{3,5}, B. A. Maruca^{1,2}, A. Chasapis⁶, R. Qudsi¹, D. J. McComas⁷Show full author list

<https://doi.org/10.3847/1538-4365/ab6220>

Observations at 1 au have confirmed that enhancements in measured energetic-particle (EP) fluxes are statistically associated with "rough" magnetic fields, i.e., fields with atypically large spatial derivatives or increments, as measured by the Partial Variance of Increments (PVI) method. One way to interpret this observation is as an association of the EPs with trapping or channeling within magnetic flux tubes, possibly near their boundaries. However, it remains unclear whether this association is a transport or local effect; i.e., the particles might have been energized at a distant location, perhaps by shocks or reconnection, or they might experience local energization or re-acceleration. The Parker Solar Probe (PSP), even in its first two orbits, offers a unique opportunity to study this statistical correlation closer to the corona. As a first step, we analyze the separate correlation properties of the EPs measured by the Integrated Science Investigation of the Sun (IS \odot IS) instruments during the first solar encounter. The distribution of time intervals between a specific type of event, i.e., the waiting time, can indicate the nature of the underlying process. We find that the IS \odot IS observations show a power-law distribution of waiting times, indicating a correlated (non-Poisson) distribution. Analysis of low-energy ($\sim 15 - 200$ keV/nuc) IS \odot IS data suggests that the results are consistent with the 1 au studies, although we find hints of some unexpected behavior. A more complete understanding of these statistical distributions will provide valuable insights into the origin and propagation of solar EPs, a picture that should become clear with future PSP orbits.

Enhanced Energy Transfer Rate in Solar Wind Turbulence Observed near the Sun from Parker Solar Probe

<https://arxiv.org/pdf/1912.02959.pdf>

Direct evidence of an inertial-range turbulent energy cascade has been provided by spacecraft observations in heliospheric plasmas. In the solar wind, the average value of the derived heating rate near 1 au is $\sim 103 \text{ J kg}^{-1} \text{ s}^{-1}$, an amount sufficient to account for observed departures from adiabatic expansion. Parker Solar Probe (PSP), even during its first solar encounter, offers the first opportunity to compute, in a similar fashion, a fluid-scale energy decay rate, much closer to the solar corona than any prior in-situ observations. Using the Politano-Pouquet third-order law and the von Kármán decay law, we estimate the fluid-range energy transfer rate in the inner heliosphere, at heliocentric distance R ranging from $54R_{\odot}$ (0.25 au) to $36R_{\odot}$ (0.17 au). The energy transfer rate obtained near the first perihelion is about 100 times higher than the average value at 1 au. This dramatic increase in the heating rate is unprecedented in previous solar wind observations, including those from Helios, and the values are close to those obtained in the shocked plasma inside the terrestrial magnetosheath.

Tracking Cosmic-Ray Spectral Variation during 2007–2018 Using Neutron Monitor Time-delay Measurements

C. [Banglieng](#)^{1,2}, H. Jantaloet¹, D. Ruffolo^{1,2}, A. Sáiz¹, W. Mitthumsiri¹, P. Muangha^{1,2}, P. Evenson³, T. Nataro⁴, R. Pyle⁵, S. Seunarine⁶Show full author list

2020 ApJ 890 21

<https://doi.org/10.3847/1538-4357/ab6661>

The energy spectrum of Galactic cosmic-ray (GCR) ions at Earth varies with solar activity as these ions cross the heliosphere. Thus, this "solar modulation" of GCRs provides remote sensing of heliospheric conditions throughout the ~11 yr sunspot cycle and ~22 yr solar magnetic cycle. A neutron monitor (NM) is a stable ground-based detector that measures cosmic-ray rate variations above a geomagnetic or atmospheric cutoff rigidity with high precision (~0.1%) over such timescales. Furthermore, we developed electronics and analysis techniques to indicate variations in the cosmic-ray spectral index using neutron time-delay data from a single station. Here we study solar modulation using neutron time-delay histograms from two high-altitude NM stations: (1) the Princess Sirindhorn Neutron Monitor at Doi Inthanon, Thailand, with the world's highest vertical geomagnetic cutoff rigidity, 16.7 GV, from 2007 December to 2018 April; and (2) the South Pole NM, with an atmosphere-limited cutoff of ~1 GV, from 2013 December to 2018 April. From these histograms, we extract the leader fraction L , i.e., inverse neutron multiplicity, as a proxy of a GCR spectral index above the cutoff. After correction for pressure and precipitable water vapor variations, we find that L roughly correlates with the count rate but also exhibits hysteresis, implying a change in spectral shape after a solar magnetic polarity reversal. Spectral variations due to Forbush decreases, 27 day variations, and a ground-level enhancement are also indicated. These methods enhance the high-precision GCR spectral information from the worldwide NM network and extend it to higher rigidity.

Multi spacecraft study with the Icarus model: Modelling the propagation of CMEs to Mercury and Earth

Tinatín [Baratashvili](#), [Benjamin Grison](#), [Brigitte Schmieder](#), [Pascal Demoulin](#), [Stefaan Poedts](#)

A&A 689, 98 2024

<https://arxiv.org/pdf/2405.17988>

<https://doi.org/10.1051/0004-6361/202450430>

<https://www.aanda.org/articles/aa/pdf/2024/09/aa50430-24.pdf>

Coronal Mass Ejections (CMEs) are the main drivers of the disturbances in interplanetary space. Understanding the CME interior magnetic structure is crucial for advancing space weather studies. Assessing the capabilities of a numerical heliospheric model is crucial, as understanding the nature and extent of its limitations can be used for improving the model and the space weather predictions based on it. The present paper aims to test the capabilities of the recently developed heliospheric model Icarus and the linear force-free spheromak model that has been implemented in it.

To validate the Icarus space weather modeling tool, two CME events were selected that were observed by two spacecraft located near Mercury and Earth, respectively. This enables testing the heliospheric model computed with Icarus at two distant locations. The source regions for the CMEs were identified, and the CME parameters were determined and later optimized. Different adaptive mesh refinement levels were applied in the simulations to assess its performance by comparing the simulation results to in-situ measurements.

The first CME event erupted on SOL2013-07-09T15:24. The modeled time series were in good agreement with the observations both at MESSENGER and ACE. The second CME event started on SOL2014-02-16T10:24 and was more complicated, as three CME interactions occurred in this event. It was impossible to recover the observed profiles without modeling the other two CMEs that were observed, one before the main CME and one afterward. For both CME studies, AMR level 3 was sufficient to reconstruct small-scale features near Mercury, while at Earth, AMR level 4 was necessary due to the radially stretched grid that was used.

The effect of AMR and grid stretching on the magnetized CME model in Icarus

[Baratashvili](#) Tinatín, [Poedts Stefaan](#)

A&A 2024

<https://arxiv.org/pdf/2401.02504.pdf>

Context. Coronal mass ejections (CMEs) are the main driver of solar wind disturbances near Earth. When directed towards us, the internal magnetic field of the CME can interact with the Earth's magnetic field and cause geomagnetic storms. In order to better predict and avoid damage coming from such events, the optimized heliospheric model Icarus has been implemented. Aims. The impact of a CME at Earth is greatly affected by its internal magnetic field structure. The aim of this work is to enable modelling the evolution of the magnetic field configuration of the CME throughout its

propagation in Icarus. The focus of the study is on the global magnetic structure of the CME and its evolution and interaction with the solar wind. **Methods.** The magnetized CME model that is implemented in Icarus is the Linear Force-Free Spheromak and is imported from EUHFORIA. Advanced techniques, such as grid stretching and AMR are applied. Different AMR levels are applied in order to obtain high resolution locally, where needed. The results of all the simulations are compared in detail and the wall-clock times of the simulations are provided. **Results.** The results from the performed simulations are analyzed. The arrival time is better approximated by the EUHFORIA simulation, with the CME shock arriving 1.6 and 1.09 hours later than in the AMR level 4 and 5 simulations, respectively. The profile features and variable strengths are best modelled by Icarus simulations with AMR level 4 and 5. **Conclusions.** The arrival time is closer to the observed time in the EUHFORIA simulation, but the profiles of the different variables show more features and details in the Icarus simulations. Considering the small difference in the modelled results, and the large difference in computational resources, the AMR level 4 simulation is considered to have performed the best. **July 12, 2012**

Exploring the effects of numerical methods and slope limiters in heliospheric modeling

Tinatini [Baratashvili](#), [Christine Verbeke](#), [Rony Keppens](#), [Stefaan Poedts](#)

Sun and Geosphere **2023**

<https://arxiv.org/ftp/arxiv/papers/2305/2305.14905.pdf>

Coronal mass ejections (CMEs) are large eruptions close to the solar surface, where plasma is ejected outwards into space at large speeds. When directed towards Earth, they interfere with Earth's magnetic fields and cause strong geoeffective storms. In order to mitigate the potential damage, forecasting tools are implemented. Recently, a novel heliospheric modelling tool, Icarus, has been implemented, which exploits the open-source framework MPI-AMRVAC as its core MHD solver. This new model efficiently performs 3D MHD simulations of the solar wind and the evolution of interplanetary CMEs with the help of advanced techniques, such as adaptive mesh refinement and gradual radial grid stretching. The numerical methods applied in the simulations can have significant effects on the simulation results and on the efficiency of the model. In this study, the effect of different combinations of numerical schemes and slope limiters, for reconstructing edge-based variables used in fluxes, is considered. We explore frequently exploited combinations from the available numerical schemes in MPI-AMRVAC: TVDLF, HLL and HLLC along with the slope limiters 'woodward', 'minmod', 'vanleer', and 'koren'. For analysis purposes, we selected one particular solar wind configuration and studied the influence on variables at 1 AU in the equatorial plane. The goal is to find the optimal combination to produce accurate results fast and in a robust way so that the model can be reliable for day-to-day use by space weather scientists. As a conclusion, the best result assessed with these two criteria is the combination of the TVDLF scheme with the 'woodward' limiter.

Improving CME evolution and arrival predictions with AMR and grid stretching in Icarus

T. [Baratashvili](#)1, C. Verbeke1,2, N. Wijzen1 and S. Poedts1,3

A&A 667, A133 (2022)

<https://www.aanda.org/articles/aa/pdf/2022/11/aa44111-22.pdf>

Context. Coronal mass ejections (CMEs) are one of the main drivers of disturbances in interplanetary space. Strong CMEs, when directed towards the Earth, cause geomagnetic storms upon interacting with the Earth's magnetic field, and can cause significant damage to our planet and affect everyday life. As such, efficient space weather prediction tools are necessary to forecast the arrival and impact of CME eruptions. Recently, a new heliospheric model called Icarus was developed based on MPI-AMRVAC, which is a 3D ideal magnetohydrodynamics model for the solar wind and CME propagation, and it introduces advanced numerical techniques to make the simulations more efficient. In this model the reference frame is chosen to be co-rotating with the Sun, and radial grid stretching together with adaptive mesh refinement (AMR) can be applied to the numerical domain.

Aims. Grid stretching and AMR speed up simulation results and performance. Our aim is to combine the advanced techniques available in the Icarus model in order to obtain better results with fewer computational resources than with the equidistant grid. Different AMR strategies are suggested, depending on the purpose of the simulation.

Methods. In this study, we model the CME event that occurred on **July 12, 2012**. A cone model was used to study the CME's evolution through the background solar wind, and its arrival at and impact with the Earth. Grid stretching and AMR were combined in the simulations by using multiple refinement criteria, to assess its influence on the simulations' accuracy and the required computational resources. We compare simulation results to the EUHFORIA model.

Results. We applied different refinement criteria to investigate the potential of solution AMR for different applications. As a result, the simulations were sped up by a factor of ~ 17 for the most optimal configuration in Icarus. For the cone CME model, we found that limiting the AMR to the region around the CME-driven shock yields the best results. The results modelled by the simulations with radial grid stretching and AMR level 4 are similar to the results provided by the

original EUHFORIA and Icarus simulations with the ‘standard’ resolution and equidistant grids. The simulations with 5 AMR levels yielded better results than the simulations with an equidistant grid and standard resolution. Conclusions. Solution AMR is flexible and provides the user the freedom to modify and locally increase the grid resolution according to the purpose of the simulation. We find that simulations with a combination of grid stretching and AMR can reproduce the simulations performed on equidistant grids significantly faster. The advanced techniques implemented in Icarus can be further used to improve the forecasting procedures, since the reduced simulation time is essential to make physics-based forecasts less computationally expensive. **July 12-15, 2012**

Slow solar wind sources

High-resolution observations with a quadrature view★

Krzysztof [Barczynski](#)^{1,2}, Louise Harra^{2,1}, Conrad Schwanitz^{1,2}, Nils Janitzek^{1,2}, David Berghmans³, Frédéric Auchère⁴, +++
A&A 673, A74 (2023)

Context. The origin of the slow solar wind is still an open issue. One possibility that has been suggested is that upflows at the edge of an active region can contribute to the slow solar wind.

Aims. We aim to explain how the plasma upflows are generated, which mechanisms are responsible for them, and what the upflow region topology looks like.

Methods. We investigated an upflow region using imaging data with the unprecedented temporal (3 s) and spatial (2 pixels = 236 km) resolution that were obtained on 30 March 2022 with the 174 Å channel of the Extreme-Ultraviolet Imager (EUI)/High Resolution Imager (HRI) on board Solar Orbiter. During this time, the EUI and Earth-orbiting satellites (Solar Dynamics Observatory, Hinode, and the Interface Region Imaging Spectrograph, IRIS) were located in quadrature (~92°), which provides a stereoscopic view with high resolution. We used the Hinode/EIS (Fe XII) spectroscopic data to find coronal upflow regions in the active region. The IRIS slit-jaw imager provides a high-resolution view of the transition region and chromosphere.

Results. For the first time, we have data that provide a quadrature view of a coronal upflow region with high spatial resolution. We found extended loops rooted in a coronal upflow region. Plasma upflows at the footpoints of extended loops determined spectroscopically through the Doppler shift are similar to the apparent upward motions seen through imaging in quadrature. The dynamics of small-scale structures in the upflow region can be used to identify two mechanisms of the plasma upflow: Mechanism I is reconnection of the hot coronal loops with open magnetic field lines in the solar corona, and mechanism II is reconnection of the small chromospheric loops with open magnetic field lines in the chromosphere or transition region. We identified the locations in which mechanisms I and II work.

A comparison of the active region upflow and core properties using simultaneous spectroscopic observations from IRIS and Hinode

[Krzysztof Barczynski](#), [Louise Harra](#), [Lucia Kleint](#), [Brandon Panos](#), [David H. Brooks](#)

A&A 2021

<https://arxiv.org/pdf/2104.10234.pdf>

The origin of the slow solar wind is still an open issue. It has been suggested that upflows at the edge of active regions (AR) can contribute to the slow solar wind. Here, we compared the upflow region and the AR core and studied how the plasma properties change from the chromosphere via the transition region to the corona. We studied limb-to-limb observations NOAA 12687 (14th - 25th Nov 2017). We analysed spectroscopic data simultaneously obtained from IRIS and Hinode/EIS in six spectral lines. We studied the mutual relationships between the plasma properties for each emission line, as well as comparing the plasma properties between the neighbouring formation temperature lines. To find the most characteristic spectra, we classified the spectra in each wavelength using the machine learning technique k-means. We found that in the upflow region the Doppler velocities of the coronal lines are strongly correlated, but the transition region and coronal lines show no correlation. However, their fluxes are strongly correlated. The upflow region has lower density and lower temperature than the AR core. In the upflow region, the Doppler and non-thermal velocity show a strong correlation in the coronal lines, but the correlation is not seen in the AR core. At the boundary between the upflow region and the AR core, the upflow region shows an increase in the coronal non-thermal velocity, the emission obtained from the DEM, and the domination of the redshifted regions in the chromosphere. The obtained results suggest that at least three parallel mechanisms generate the plasma upflow: (1) the reconnection between closed loops and open magnetic field lines in the lower corona or upper chromosphere; (2) the reconnection between the chromospheric small-scale loops and open magnetic field; (3) the expansion of the magnetic field lines that allows the chromospheric plasma to escape to the solar corona.

Periodic behaviour of coronal mass ejections, eruptive events, and solar activity proxies during solar cycles 23 and 24

We report on the parallel analysis of the periodic behaviour of [coronal mass ejections](#) (CMEs) based on 21 years [1996–2016] of observations with the SOHO/LASCO–C2 coronagraph, [solar flares](#), prominences, and several proxies of [solar activity](#). We consider values of the rates globally and whenever possible, distinguish solar hemispheres and [solar cycles](#) 23 and 24. Periodicities are investigated using both frequency (periodogram) and time-frequency (wavelet) analysis. We find that these different processes, in addition to following the ≈ 11 -year Solar Cycle, exhibit diverse statistically significant oscillations with [properties common](#) to all solar, coronal, and heliospheric processes: variable periodicity, intermittence, asymmetric development in the northern and southern solar hemispheres, and largest amplitudes during the maximum phase of solar cycles, being more pronounced during solar cycle 23 than the weaker cycle 24. However, our analysis reveals an extremely complex and diverse situation. For instance, there exists very limited commonality for periods of less than one year. The few exceptions are the periods of 3.1–3.2 months found in the global occurrence rates of CMEs and in the [sunspot](#) area (SSA) and those of 5.9–6.1 months found in the northern hemisphere. Mid-range periods of ≈ 1 and ≈ 2 years are more wide spread among the studied processes, but exhibit a very distinct behaviour with the first one being present only in the northern hemisphere and the second one only in the [southern hemisphere](#). These periodic behaviours likely results from the complexity of the underlying physical processes, prominently the emergence of [magnetic flux](#).

SIR-HUXt -- a particle filter data assimilation scheme for assimilating CME time-elongation profiles

Space Weather Volume 21, Issue 6, June 2023 e2023SW003487

<https://arxiv.org/pdf/2210.02122.pdf>

<https://doi.org/10.1029/2023SW003487>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2023SW003487>

We present the development of SIR-HUXt, the integration of a sequential importance resampling (SIR) data assimilation scheme with the HUXt solar wind model. SIR-HUXt is designed to assimilate the time-elongation profiles of CME fronts in the low heliosphere, such as those typically extracted from heliospheric imager data returned by the STEREO, Parker Solar Probe, and Solar Orbiter missions. We use Observing System Simulation Experiments to explore the performance of SIR-HUXt for a simple synthetic CME scenario of a fully Earth directed CME flowing through a uniform ambient solar wind, where the CME is initialised with the average observed CME speed and width. These experiments are performed for a range of observer locations, from 20 deg to 90 deg behind Earth, spanning the L5 point where ESA's future Vigil space weather monitor will return heliospheric imager data for operational space weather forecasting.

We show that SIR-HUXt performs well at constraining the CME speed, and has some success at constraining the CME longitude. The CME width is largely unconstrained by the SIR-HUXt assimilations, and more experiments are required to determine if this is due to this specific CME scenario, or is a general feature of assimilating time-elongation profiles. Rank-histograms suggest that the SIR-HUXt ensembles are well calibrated, with no clear indications of bias or under/over dispersion. Improved constraints on the initial CME speed lead directly to improvements in the CME transit time to Earth and arrival speed. For an observer in the L5 region, SIR-HUXt returned a 69% reduction in the CME transit time uncertainty, and a 63% reduction in the arrival speed uncertainty. This suggests SIR-HUXt has potential to improve the real-world representivity of HUXt simulations, and therefore has potential to reduce the uncertainty of CME arrival time hindcasts and forecasts.

Quantifying the uncertainty in CME kinematics derived from geometric modelling of Heliospheric Imager data

Space Weather [Volume 20, Issue 1](#) e 2021SW002841 2022

<https://arxiv.org/pdf/2111.13337>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2021SW002841>

<https://doi.org/10.1029/2021SW002841>

Geometric modelling of Coronal Mass Ejections (CMEs) is a widely used tool for assessing their kinematic evolution. Furthermore, techniques based on geometric modelling, such as ELEvoHI, are being developed into forecast tools for space weather prediction. These models assume that solar wind structure does not affect the evolution of the CME, which is an unquantified source of uncertainty. We use a large number of Cone CME simulations with the HUXt solar wind model to quantify the scale of uncertainty introduced into geometric modelling and the ELEvoHI CME arrival times by solar wind structure. We produce a database of simulations, representing an average, a fast, and an extreme CME scenario, each independently propagating through 100 different ambient solar wind environments. Synthetic heliospheric imager observations of these simulations are then used with a range of geometric models to estimate the CME kinematics. The errors of geometric modelling depend on the location of the observer, but do not seem to depend on the CME scenario. In general, geometric models are biased towards predicting CME apex distances that are larger than the true value. For these CME scenarios, geometric modelling errors are minimised for an observer in the L5 region. Furthermore, geometric modelling errors increase with the level of solar wind structure in the path of the CME. The ELEvoHI arrival time errors are minimised for an observer in the L5 region, with mean absolute arrival time errors of 8.2 ± 1.2 h, 8.3 ± 1.0 h, and 5.8 ± 0.9 h for the average, fast, and extreme CME scenarios.

Extracting Inner-Heliosphere Solar Wind Speed Information From Heliospheric Imager Observations

Space Weather 2019

sci-hub.se/10.1029/2019SW002226

We present evidence that variability in the STEREO-A Heliospheric Imager (HI) data is correlated with in situ solar wind speed estimates from WIND, STEREO-A, and STEREO-B. For 2008–2012, we compute the variability in HI differenced images in a plane-of-sky shell between 20 to 22.5 solar radii and, for a range of position angles, compare daily means of HI variability and in situ solar wind speed estimates. We show that the HI variability data and in situ solar wind speeds have similar temporal autocorrelation functions. Carrington rotation periodicities are well documented for in situ solar wind speeds, but, to our knowledge, this is the first time they have been presented in statistics computed from HI images. In situ solar wind speeds from STEREO-A, STEREO-B, and WIND are all correlated with the HI variability, with a lag that varies in a manner consistent with the longitudinal separation of the in situ monitor and the HI instrument. Unlike many approaches to processing HI observations, our method requires no manual feature tracking; it is automated, is quick to compute, and does not suffer the subjective biases associated with manual classifications. These results suggest we could possibly estimate solar wind speeds in the low heliosphere directly from HI observations. This motivates further investigation, as this could be a significant asset to the space weather forecasting community; it might provide an independent observational constraint on heliospheric solar wind forecasts, through, for example, data assimilation. Finally, these results are another argument for the potential utility of including a HI on an operational space weather mission. **2009-05-01**

Testing the current paradigm for space weather prediction with heliospheric imagers

Luke A. [Barnard](#), Curt A. de Koning, Christopher J. Scott, Mathew J. Owens, Julia Wilkinson, Jackie A. Davies

Space Weather Volume 15, Issue 6 June 2017 Pages 782–803

<http://onlinelibrary.wiley.com/doi/10.1002/2017SW001609/full>

<http://sci-hub.cc/10.1002/2017SW001609>

Predictions of the arrival of four coronal mass ejections (CMEs) in geospace are produced through use of three CME geometric models combined with CME drag modeling, constraining these models with the available Coronagraph and Heliospheric Imager data. The efficacy of these predications is assessed by comparison with the Space Weather Prediction Center (SWPC) numerical MHD forecasts of these same events. It is found that such a prediction technique cannot outperform the standard SWPC forecast at a statistically meaningful level. We test the Harmonic Mean, Self-Similar Expansion, and Ellipse Evolution geometric models, and find that, for these events at least, the differences between the models are smaller than the observational errors. We present a new method of characterizing CME fronts in the Heliospheric Imager field of view, utilizing the analysis of citizen scientists working with the Solar Stormwatch project, and we demonstrate that this provides a more accurate representation of the CME front than is obtained by experts analyzing elongation time maps for the studied events. Comparison of the CME kinematics estimated independently from the STEREO-A and STEREO-B Heliospheric Imager data reveals inconsistencies that cannot be explained within the observational errors and model assumptions. We argue that these observations imply that the

assumptions of the CME geometric models are routinely invalidated and question their utility in a space weather forecasting context. These results argue for the continuing development of more advanced techniques to better exploit the Heliospheric Imager observations for space weather forecasting. **2012-08-31, 2012-09-28, 2012-10-05, 2012-11-20**

Differences between the CME fronts tracked by an expert, an automated algorithm, and the Solar Stormwatch project

L. **Barnard**, C. J. Scott, M. Owens, M. Lockwood, S. R. Crothers, J. A. Davies and R. A. Harrison
Space Weather 13(10) (pages 709–725) **2015**

<http://onlinelibrary.wiley.com/doi/10.1002/2015SW001280/epdf>

Observations from the Heliospheric Imager (HI) instruments aboard the twin STEREO spacecraft have enabled the compilation of several catalogues of coronal mass ejections (CMEs), each characterizing the propagation of CMEs through the inner heliosphere. Three such catalogues are the Rutherford Appleton Laboratory (RAL)-HI event list, the Solar Stormwatch CME catalogue, and, presented here, the J-tracker catalogue. Each catalogue uses a different method to characterize the location of CME fronts in the HI images: manual identification by an expert, the statistical reduction of the manual identifications of many citizen scientists, and an automated algorithm. We provide a quantitative comparison of the differences between these catalogues and techniques, using 51 CMEs common to each catalogue. The time-elongation profiles of these CME fronts are compared, as are the estimates of the CME kinematics derived from application of three widely used single-spacecraft-fitting techniques. The J-tracker and RAL-HI profiles are most similar, while the Solar Stormwatch profiles display a small systematic offset. Evidence is presented that these differences arise because the RAL-HI and J-tracker profiles follow the sunward edge of CME density enhancements, while Solar Stormwatch profiles track closer to the antisunward (leading) edge. We demonstrate that the method used to produce the time-elongation profile typically introduces more variability into the kinematic estimates than differences between the various single-spacecraft-fitting techniques. This has implications for the repeatability and robustness of these types of analyses, arguably especially so in the context of space weather forecasting, where it could make the results strongly dependent on the methods used by the forecaster. **14-20/12/2009, 9-17/02/2010**

The Solar Stormwatch CME catalogue: Results from the first space weather citizen science project

Solar Stormwatch was the first space weather citizen science project, the aim of which is to identify and track coronal mass ejections (CMEs) observed by the Heliospheric Imagers aboard the STEREO satellites. The project has now been running for approximately 4 years, with input from >16,000 citizen scientists, resulting in a data set of >38,000 time-elongation profiles of CME trajectories, observed over 18 preselected position angles. We present our method for reducing this data set into a CME catalogue. The resulting catalogue consists of **144 CMEs over the period January 2007 to February 2010, of which 110 were observed by STEREO-A and 77 were observed by STEREO-B**. For each CME, the time-elongation profiles generated by the citizen scientists are averaged into a consensus profile along each position angle that the event was tracked. We consider this catalogue to be unique, being at present the only citizen science-generated CME catalogue, tracking CMEs over an elongation range of 4° out to a maximum of approximately 70°. Using single spacecraft fitting techniques, we estimate the speed, direction, solar source region, and latitudinal width of each CME. This shows that at present, the Solar Stormwatch catalogue (which covers only solar minimum years) contains almost exclusively **slow CMEs, with a mean speed of approximately 350 km s⁻¹**. The full catalogue is available for public access at www.met.reading.ac.uk/~spate/solarstormwatch. This includes, for each event, the unprocessed time-elongation profiles generated by Solar Stormwatch, the consensus time-elongation profiles, and a set of summary plots, as well as the estimated CME properties. **2008-06-02**

We present an analysis of coronal mass ejections (CMEs) observed by the Heliospheric Imagers (HIs) on board NASA's Solar Terrestrial Relations Observatory (STEREO) spacecraft. Between August 2008 and April 2014 we identify 273 CMEs that are observed simultaneously, by the HIs on both spacecraft. For each CME, we track the observed leading edge, as a function of time, from both vantage points, and apply the Stereoscopic Self-Similar Expansion (SSSE) technique to infer their propagation throughout the inner heliosphere. The technique is unable to accurately locate CMEs when their observed leading edge passes between the spacecraft, however, we are able to successfully apply the technique to 151, most of which occur once the spacecraft separation angle exceeds 180 degrees, during solar maximum. We find that using a small half-width to fit the CME can result in observed acceleration to unphysically high velocities and that using a larger half-width can fail to accurately locate the CMEs close to the Sun because the method does not account for CME over-expansion in this region. Observed velocities from SSSE are found to agree well with single-spacecraft (SSEF) analysis techniques applied to the same events. CME propagation directions derived from SSSE and SSEF analysis agree poorly because of known limitations present in the latter. This work was carried out as part of the EU FP7 HELCATS (Heliospheric Cataloguing, Analysis and Techniques Service) project ([this http URL](#)). **20110602, 20131026**

Remote Sensing Estimates of CME Density in the Ecliptic Using the STEREO Heliospheric Imagers

David **Barnes**

JGR [Volume125, Issue2](#) February 2020 e2019JA027175

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2019JA027175>

We present a method to estimate electron densities in the ecliptic plane using the STEREO Heliospheric Imagers (HIs). The nature of Thomson scattering of photospheric light by solar wind electrons is such that visible-light observations by HI provide a means to infer information about plasma density from afar. This is achieved using discrete tomography, whereby line-of-sight integrals from HI are used to estimate electron density in the heliosphere over a predefined grid. The technique is applied to the Earth-impacting coronal mass ejection (CME) launched on 12 **December 2008**. The two vantage points afforded by STEREO are insufficient to reproduce the density structure of the CME in detail; however, the technique is successful in locating the presence of a density enhancement associated with the CME. When applied to consecutive images, we are able to use the technique as a means to track the CME through interplanetary space. From these observations we make estimates of the CME radial velocity and density profiles, the results of which are consistent with measurements made in situ by Wind at L1. This method is presented as a new approach to determine CME propagation from HI observations, one that avoids many of the assumptions of CME morphology and dynamics that are often applied when tracking CMEs in such data. We also expect that this technique will prove useful, and a test of the long-standing heliospheric reconstruction technique employed by using single images over time (Jackson et al., 2006, <https://doi.org/10.1029/2004JA010942>) when views from many wide-angle imagers become available.

CMEs in the Heliosphere: II. A Statistical Analysis of the Kinematic Properties Derived from Single-Spacecraft Geometrical Modelling Techniques Applied to CMEs Detected in the Heliosphere from 2007 to 2017 by STEREO/HI-1

D. **Barnes**, [J. A. Davies](#), [R. A. Harrison](#), [J. P. Byrne](#), [C. H. Perry](#)...

[Solar Physics](#) May 2019, 294:57

<https://link.springer.com/content/pdf/10.1007%2Fs11207-019-1444-4.pdf>

Recent observations with the Heliospheric Imagers (HIs) onboard the twin NASA Solar Terrestrial Relations Observatory (STEREO) spacecraft have provided unprecedented observations of a large number of coronal mass ejections (CMEs) in the inner heliosphere. In this article we discuss the generation of the **HIGeoCAT CME catalogue** and perform a statistical analysis of its events. The catalogue was generated as part of the EU FP7 HELCATS (Heliospheric Cataloguing, Analysis and Techniques Service) project (www.helcats-fp7.eu/). It is created by generating time/elongation maps for CMEs using observations from the inner (HI-1) and outer (HI-2) cameras along a position angle close to the CME apex. Next, we apply single-spacecraft geometric-fitting techniques to determine the kinematic properties of these CMEs, including their speeds, propagation directions, and launch times. The catalogue contains a total of 1455 events (801 from STEREO-A and 654 from STEREO-B) from April 2007 to the end of August 2017. We perform a statistical analysis of the properties of CMEs in HIGeoCAT and compare the results with those from the Large Angle Spectrometric Coronagraph (LASCO) CDAW catalogues (Yashiro et al. *J. Geophys. Res. Space Phys.* 109, A07105, [2004](#)) and the COR-2 catalogue of Vourlidas et al. (*Astrophys. J.* 838, 141, [2004](#)) during the same

period. We find that the distributions of both speeds and latitudes for the HIGeoCAT CMEs correlate with the sunspot number over the solar cycle. We also find that the HI-derived CME speed distributions are generally consistent with coronagraph catalogues over the solar cycle, albeit with greater absolute speeds due to the differing methods with which each is derived. **2011/01/30-31**,

HUXt -- An open source, computationally efficient reduced-physics solar wind model, written in Python

Luke [Barnard](#), [Mathew Owens](#)

Snakes on a Spaceship - An Overview of Python in Space Physics special issue of Frontiers in Astronomy and Space Science - Space Physics **2022**

<https://arxiv.org/pdf/2210.00455>

HUXt is an open source numerical model of the solar wind written in Python. It is based on the solution of the 1D inviscid Burger's equation. This reduced-physics approach produces solar wind flow simulations that closely emulate the flow produced by 3-D magnetohydrodynamic solar wind models at a small fraction of the computational expense. While not intended as a replacement for 3-D MHD, the simplicity and computational efficiency of HUXt offers several key advantages that enable experiments and the use of techniques that would otherwise be cost prohibitive. For example, large ensembles can easily be run with modest computing resources, which are useful for exploring and quantifying the uncertainty in space weather predictions, as well as for the application of some data assimilation methods. We present the developments in the latest version of HUXt, v4.0, and discuss our plans for future developments and applications of the model. The three key developments in v4.0 are: a restructuring of the models solver to enable fully time-dependent boundary conditions, such that HUXt can in principle be initialised with in-situ observations from any of the fleet of heliospheric monitors; new functionality to trace streaklines through the HUXt flow solutions, which can be used to track features such as the Heliospheric Current Sheet; introduction of a small test-suite so that we can better ensure the reliability and reproducibility of HUXt simulations for all users across future versions. Other more minor developments are discussed in the article.

Future applications of HUXt are discussed, including the development data assimilation schemes for assimilation of both remote sensing and in-situ plasma measures. We discuss the progress of transitioning HUXt into an operational model at the UK's Met Office Space Weather Operations Center as part of the UK governments SWIMMR programme.

Ensemble CME Modeling Constrained by Heliospheric Imager Observations

L. [Barnard](#) , [M. J. Owens](#) , [C. J. Scott](#) , [C. A. de Koning](#)

AGU Advances [Volume1, Issue3](#) September **2020** e2020AV000214

<https://doi.org/10.1029/2020AV000214>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2020AV000214>

Predicting the arrival of coronal mass ejections (CMEs) is one key objective of space weather forecasting. In operational space weather forecasting, solar wind numerical models are used for this task and ensemble techniques are being increasingly explored as a means to improve these forecasts. Currently, these forecasts are not constrained by the available in situ and remote sensing observations, such as those from the heliospheric imagers (HIs) on the National Aeronautics and Space Administration's (NASA's) STEREO spacecraft, which record white-light images of solar wind and CMEs. We report case studies of four CMEs and show how HI observations can be used to improve the skill and reduce the uncertainty of ensemble hindcasts of these events. Using a computationally efficient solar wind model, we produce 200-member ensemble hindcasts, perturbing the modeled CME parameters within uniform distributions about the best estimates. By comparing the trajectory of the modeled CME flanks with HI observations, we compute a weight for each ensemble member. Weighting the ensemble distribution of CME arrival times improves the skill and reduces the hindcast uncertainty of each event. For these four events, the weighted ensembles show a mean reduction in arrival time error of $20.1 \pm 4.1\%$, and a mean reduction in arrival time uncertainty of $15.0 \pm 7.2\%$, relative to the unweighted ensembles. This technique could be applied in operational space weather forecasting, if real-time HI observations were available. Therefore, as NASA and the European Space Agency are currently planning the next space weather monitoring missions, our proof-of-concept study provides some evidence of the potential value of including HIs on these missions. **2012-09-01, 2012-09-04, 2012-09-30, 2012-10-08, 2012-11-24**

Extracting inner-heliosphere solar wind speed information from Heliospheric Imager observations

L.A. [Barnard](#), [M.J. Owens](#), [C.J. Scott](#) , [S.R. Jones](#)

Space Weather [Volume17, Issue6](#) Pages 925-938 **2019**

[sci-hub.se/10.1029/2019SW002226](https://doi.org/10.1029/2019SW002226)

We present evidence that variability in the STEREO-A Heliospheric Imager (HI) data is correlated with in-situ solar wind speed estimates from WIND, STEREO-A, and STEREO-B. For 2008-2012, we compute the variability in HI differenced images in a plane-of-sky shell between 20-22.5 solar radii, and, for a range of position angles, compare daily means of HI variability and in-situ solar wind speed estimates.

We show that the HI variability data and in-situ solar wind speeds have similar temporal autocorrelation functions. Carrington rotation periodicities are well documented for in-situ solar wind speeds, but, to our knowledge, this is the first time they have been presented in statistics computed from HI images. In-situ solar wind speeds from STEREO-A, STEREO-B, and WIND are all correlated with the HI variability, with a lag that varies in a manner consistent with the longitudinal separation of the in-situ monitor and the HI instrument.

Unlike many approaches to processing HI observations, our method requires no manual feature tracking; it is automated, quick to compute, and does not suffer the subjective biases associated with manual classifications. These results suggest we could possibly estimate solar wind speeds in the low heliosphere directly from HI observations. This motivates further investigation as this could be a significant asset to the space weather forecasting community; it might provide an independent observational constraint on heliospheric solar wind forecasts, through, for example, data assimilation.

Finally, these results are another argument for the potential utility of including a HI on an operational space weather mission. **2009-05-01**

The Solar Stormwatch CME catalogue: Results from the first space weather citizen science project

Radio Observational Constraints on Turbulent Astrophysical Plasmas **Review**

Tim Bastian, James Cordes, Justin Kasper, Adam Kobelski, Kelly Korreck, Gregory Howe, Steven Spangler, Chadi Salem, Angelos Vourlidas

White paper submitted to the Astronomy and Astrophysics decadal survey **2019**

<https://arxiv.org/pdf/1904.05807.pdf>

Remarkable progress has been made in understanding turbulent astrophysical plasmas in past decades including, notably, the solar wind and the interstellar medium. In the case of the solar wind, much of this progress has relied on in situ measurements from space-borne instruments. However, ground-based radio observations also have played a significant role and have the potential to play an even bigger role. In particular, using distant background sources (quasars, pulsars, satellite beacons) to transilluminate the foreground corona and solar wind, a variety of radio propagation phenomena can be used to map plasma properties of the solar corona and heliosphere, as well as the warm interstellar medium. These include angular broadening, interplanetary and interstellar scintillations, and differential Faraday rotation. These observations are highly complementary to in situ observations of the solar wind, and could be a mainstay of investigations into turbulence of the ISM. We point out that the Next Generation Very Large Array (ngVLA) fulfills all the requirements necessary to exploit radio observations of astrophysical turbulence fully.

Predicting CMEs using ELEvoHI with STEREO-HI beacon data

Space Weather **Volume19**, **Issue12** e2021SW002873 **2021**

<https://arxiv.org/pdf/2108.08072.pdf>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2021SW002873>

<https://doi.org/10.1029/2021SW002873>

Being able to accurately predict the arrival of coronal mass ejections (CMEs) at Earth has been a long-standing problem in space weather research and operations. In this study, we use the ELlipse Evolution model based on Heliospheric Images (ELEvoHI) to predict the arrival time and speed of 10 CME events that were observed by HI on the STEREO-A spacecraft between 2010 and 2020. Additionally, we introduce a Python tool for downloading and preparing STEREO-HI data, as well as tracking CMEs. In contrast to most previous studies, we use not only science data, which has a relatively high spatial and temporal resolution, but also low-quality beacon data, which is - in contrast to science data - provided in real-time by the STEREO-A spacecraft. We do not use data from the STEREO-B spacecraft. We get a mean absolute error of 8.81 ± 3.18 h / 59 ± 31 kms⁻¹ for arrival time/speed predictions using science data and 11.36 ± 8.69 h / 106 ± 61 kms⁻¹ for beacon data. We find that using science data generally leads to more accurate predictions, but using beacon data with the ELEvoHI model is certainly a viable choice in the absence of higher resolution real-time data. We propose that these differences could be minimized if not eliminated altogether if higher quality real-time data was available, either by enhancing the quality of the already available data or coming from a new mission carrying a HI instrument on-board. **8 April 2010, 24 May 2010, 16 June 2010, 1 August 2010, 15 February 2011, 2 August 2011, 7 Sep 2011, 22 October 2011, 12 July 2012, 9 July 2020**

Solar energetic particle events in 2006-2012 in the PAMELA experiment data

G A [Bazilevskaya](#) et al

2013 J. Phys.: Conf. Ser. 409 012188

The PAMELA magnetic spectrometer launched in June 2006 has observed the last strong energetic solar particle event of the 23rd solar cycle in December 2006. Subsequent long minimum of solar activity and weak development of the 24th solar cycle led to a deficit in the solar energetic particle events on the Earth orbit. As a result, only few events with protons accelerated above 100 MeV occurred in 2010-2012. The paper gives the preliminary results on energetic solar particles in the beginning of the 24th solar circle as measured with the PAMELA instrument.

Magnetic axis safety factor of finite beta spheromaks and transition from spheromaks to toroidal magnetic bubbles

Paul M. [Bellan](#) and Roberto Paccagnella

Physics of Plasmas, **2015**

<http://arxiv.org/pdf/1502.01656v1.pdf>

The value of the safety factor on the magnetic axis of a finite-beta spheromak is shown to be a function of beta in contrast to what was used in P. M. Bellan, Phys. Plasmas 9, 3050 (2002); this dependence on beta substantially reduces the gradient of the safety factor compared to the previous calculation. The method for generating finite-beta spheromak equilibria is extended to generate equilibria describing toroidal magnetic ?bubbles? where the hydrodynamic pressure on the magnetic axis is less than on the toroid surface. This ?anti-confinement? configuration can be considered an equilibrium with an inverted beta profile and is relevant to interplanetary magnetic clouds as these clouds have lower hydrodynamic pressure in their interior than on their surface.

On the Most Interesting Solar-Wind and Cosmic-Ray Events in February–April 2023.

Belov, S.M., Shlyk, N.S., Abunina, M.A. et al.

Sol Phys 299, 164 (2024).

<https://doi.org/10.1007/s11207-024-02406-8>

The article focuses on identifying and studying several large-scale solar-wind disturbances and associated Forbush effects in the first months of 2023. Variations of the cosmic-ray flux (with 10 GV rigidity) are obtained using the Global Survey Method with data from the global network of neutron monitors. The beginning of 2023 is characterized by a relatively large number of Forbush effects; the largest ones were recorded on **26 – 28 February, 15 – 16 March, 23 – 25 March, and 23 – 24 April**. These events and their relationship with solar-wind parameters, geomagnetic activity, and associated solar sources are discussed in detail. In terms of the number and magnitude of interplanetary disturbances and corresponding cosmic-ray variations, February–April 2023 proves to be the first active period since the beginning of Solar Cycle 25.

Forbush Effects and Geomagnetic Storms.

Belov, A.V., Belova, E.A., Shlyk, N.S. *et al.*

Geomagn. Aeron. **64**, 289–301 (2024).

<https://doi.org/10.1134/S0016793224600097>

Forbush effects in galactic cosmic rays (according to the neutron monitor network data) and accompanying geomagnetic disturbances over a long period from 1957 to 2022 have been identified and studied. Statistical relationships between various parameters of cosmic ray flux variations and geomagnetic activity indices are analyzed. It has been established that the magnitude of Forbush effects depends nonlinearly on the class of geomagnetic storm. A moderate correlation (up to 0.67) was found between the extreme values of various geomagnetic activity indices (*Ap*, *Kp*, *Dst*) and cosmic ray characteristics. It is shown that the extreme values of cosmic ray and geomagnetic activity parameters are not always detected simultaneously: it depends on the sign of the *Bz*-component of the interplanetary magnetic field in a specific event.

Study of the radial dependence of Forbush decreases at 0.28–1 au using data from the *Helios 1* and *2* spacecraft

Anatoly **Belov**, [Nataly Shlyk](#), [Maria Abunina](#), [Artem Abunin](#), [Athanasios Papaioannou](#), [Ian G Richardson](#), [David Lario](#)

Monthly Notices of the Royal Astronomical Society, Volume 521, Issue 3, May 2023, Pages 4652–4668,

<https://doi.org/10.1093/mnras/stad732>

We identify and investigate cosmic ray Forbush decreases (FDs) observed in the $E > 50$ MeV data from the *Helios 1* and *2* spacecraft, spanning from 1974–1985 and covering heliocentric distances in the range 0.28–1 au. A *Helios* FD catalogue is compiled, including the characteristics of the cosmic ray variations, as well as those of the solar wind (SW) and the interplanetary magnetic field (IMF) of the associated interplanetary disturbances. An extended statistical study considers the radial dependence of the FD magnitude, the SW velocity, and the IMF intensity in these disturbances. It is found that the *Helios* FD sizes at different distances from the Sun are determined by the parameters of the interplanetary disturbances. In particular, the FD magnitudes observed at *Helios*, as well as near Earth, correlate well with VB, which is the product of the maximum SW velocity and the IMF intensity when normalized by the average values of these parameters at the radial distance of the observations. However, we found that, on average, the *Helios* FD sizes are statistically independent of the radial distance in the range of 0.28–1 au.

Estimating the Transit Speed and Time of Arrival of Interplanetary Coronal Mass Ejections Using CME and Solar Flare Data

Belov, Anatoly ; [Shlyk, Nataly](#) ; [Abunina, Maria](#) ; [Abunin, Artem](#) ; [Papaioannou, Athanasios](#)

Universe **2022**, 8(6), 327;

<https://doi.org/10.3390/universe8060327>

The dependence of Interplanetary Coronal Mass Ejections' (ICMEs) transit speed on the corresponding Coronal Mass Ejections' (CMEs) initial speed is investigated. It is shown that the transit speed and transit time depend not only on the CME's initial speed, but also on the longitude of the solar source. The longitudinal dependence of the expected transit speeds and times are obtained from the analysis of 288 CMEs, associated with solar flares, observed from 1995 to 2020. A model, estimating the transit and maximum speeds, as well as the time of arrival of an ICME to Earth, based on the initial CME speed and the longitude of the associated solar flare has been created. It is shown that taking into account the longitude of the solar source in addition to the initial CME speed significantly improves the quality of the model, especially for events in the central part of the solar disk ($E10^{\circ}$ – $W10^{\circ}$). The simplicity of the described model makes it accessible to a wide range of users and provides opportunities for further improvement as the statistics and the number of input parameters increase.

Solar Energetic Particle Events and Forbush Decreases Driven by the Same Solar Sources

Belov, Anatoly ; [Shlyk, Nataly](#) ; [Abunina, Maria](#) ; [Belova, Elena](#) ; [Abunin, Artem](#) ; [Papaioannou, Athanasios](#)

Universe **2022**, 8(8), 403;

<https://doi.org/10.3390/universe8080403>

<https://www.mdpi.com/2218-1997/8/8/403/pdf>

The characteristics of Forbush decreases (FDs) and solar energetic particle (SEP) events driven by the same solar source (i.e., coronal mass ejection and associated solar flare) are investigated. The part of the solar disk (04° E– 35° W) in

which most of the solar events lead both to an FD and SEP event on Earth was chosen. SEPs for different energies ($E > 10$ MeV, $E > 100$ MeV, and Ground Level Enhancements) and with different flux thresholds were considered independently. The obtained results were compared with the control group of FDs that had solar sources within the same longitudinal zone but were not accompanied by any SEPs. It is shown that coronal mass ejections (CMEs) followed by SEPs have a very high probability of creating a large FD in the Earth's orbit and to further cause a geomagnetic storm. It is also found that the accelerative and modulating efficiencies of powerful solar events are well correlated; this can be explained mostly by high speeds of the corresponding CMEs. **15–16 May 1997, 14–15 December 2006., 5–7 October 2011, 14–17 July 2012, 12–14 September 2014**

On the Rigidity Spectrum of Cosmic-Ray Variations within Propagating Interplanetary Disturbances: Neutron Monitor and SOHO/EPHIN Observations at ~1–10 GV

Anatoly **Belov**¹, Athanasios Papaioannou², Maria Abunina¹, Mateja Dumbovic³, Ian G. Richardson^{4,5}, Bernd Heber⁶, Patrick Kuhl⁶, Konstantin Herbst⁶, Anastasios Anastasiadis², Angelos Vourlidas^{2,7}Show full author list

2021 ApJ 908 5

<https://doi.org/10.3847/1538-4357/abd724>

The rigidity dependence of all Forbush decreases (FDs) recorded from 1995 to 2015 has been determined using neutron monitor (NM) and Solar and Heliospheric Observatory (SOHO) (EPHIN) spacecraft data, covering the energy (rigidity) range from ~433 MeV (1 GV) to 9.10 GeV (10 GV). We analyzed a total of 421 events and determined the spectrum in rigidity with an inverse power-law fit. As a result, the mean spectral index was identified to be $\langle \gamma F \rangle = 0.46 \pm 0.02$. The majority (~66%) of the FDs have γF within the range 0.3–0.7. The remaining one-third of the events (~33%) have either (very) soft or hard FD spectra, with the latter being more common than the former. Significant variations of γF occur within almost every FD event. During the initial FD decay phase the spectrum becomes gradually harder, in contrast to the recovery phase, when it becomes softer. Additionally, low energies (rigidities) seem to be better suited for studying the fine structure of interplanetary disturbances (primarily interplanetary coronal mass ejections) that lead to FDs. In particular, FDs recorded by the EPHIN instrument on SOHO better capture a two-step structure than FDs observed by NMs. Finally, the ejecta of an ICME, especially when identified as a magnetic cloud, often leads to abrupt changes in the slope of γF .

Galactic Cosmic Ray Density Variations in Magnetic Clouds

A. **Belov**, A. Abunin, M. Abunina, [E. Eroshenko](#), [V. Oleneva](#), [V. Yanke](#), [A. Papaioannou](#), [H. Mavromichalaki](#)

[Solar Physics](#) May **2015**, Volume 290, [Issue 5](#), pp 1429-1444

We investigate the characteristics of Galactic cosmic rays in events associated with magnetic clouds that reach Earth. A mathematical model, capable of describing the distribution of the cosmic-ray density in a magnetic cloud is considered. We show that in most cases the behavior of the cosmic-ray density within magnetic clouds at 1 AU can be described accurately by a parabolic function of the distance to the center of the magnetic cloud measured in gyroradii. As expected, the majority of magnetic clouds modulate cosmic rays, resulting in a reduction of their density. However, there is a group of events (about one fifth of the total sample) in which the density of cosmic rays in a magnetic cloud increases. Furthermore, the extremum (a minimum or a maximum) of the cosmic-ray density is found closer to the cloud center and not at its edges. We consider a number of the factors contributing to the model and estimate the effect of each factor.

Coronal Mass Ejections and Non-recurrent Forbush Decreases

Belov, A.; Abunin, A.; Abunina, M.; Eroshenko, E.; Oleneva, V.; Yanke, V.; Papaioannou, A.; Mavromichalaki, H.; Gopalswamy, N.; Yashiro, S.

Solar Physics, Volume 289, Issue 10, pp.3949-3960, 2014 **File**

<http://cosray.phys.uoa.gr/publications/D105.pdf>

Coronal mass ejections (CMEs) and their interplanetary counterparts (interplanetary coronal mass ejections, ICMEs) are responsible for large solar energetic particle events and severe geomagnetic storms. They can modulate the intensity of Galactic cosmic rays, resulting in non-recurrent Forbush decreases (FDs). We investigate the connection between CME manifestations and FDs. We used specially processed data from the worldwide neutron monitor network to pinpoint the characteristics of the recorded FDs together with CME-related data from the detailed online catalog based upon the Solar and Heliospheric Observatory (SOHO)/ Large Angle and Spectrometric Coronagraph (LASCO) data. We report on the correlations of the *FD magnitude to the CME initial speed, the ICME transit speed*, and the maximum solar wind speed. Comparisons between the features of CMEs (mass, width, velocity) and the characteristics of FDs are also discussed. FD features for halo, partial halo, and non-halo CMEs are presented and discussed.

Ground level enhancements of the solar cosmic rays and Forbush decreases in 23rd solar cycle

A. V. **Belov**, E. A. Eroshenko, V. A. Oleneva, V. G. Yanke

PROCEEDINGS OF THE 31st ICRC, ŁÓDŹ 2009 **File**

The outstanding effects of solar activity in 23rd solar cycle, such as ground level enhancements of solar cosmic rays and the largest Forbush decreases (FD), are investigated. The analysis shows that both GLEs and great Forbush effects are connected with anomalously fast ejections of solar matter with similar properties. The main difference between those is in the longitude: the sources of the greatest Forbush effects (FE) are usually located in a central part of visible solar disk whereas flares associated with GLEs are mostly in the western part of disk. It is shown that accelerative and modulative efficiencies of the solar events are tightly correlated. Coronal mass ejection followed by GLE creates with a big probability a very large FE in the Earth orbit. **April, 15-22 2001, 28 Oct - 4 Nov 2003**

Forbush effects and their connection with solar, interplanetary and geomagnetic phenomena

A.V. **Belov**

'Universal Heliophysical Processes' Proceedings IAU Symposium No. 257, P. 439-450, 2009. **File**

sci-hub.tw/10.1017/S1743921309029676

Forbush decrease (or, in a broader sense, Forbush effect) - is a storm in cosmic rays, which is a part of heliospheric storm and very often observed simultaneously with a geomagnetic storm. Disturbances in the solar wind, magnetosphere and cosmic rays are closely interrelated and caused by the same active processes on the Sun. Thus, it is natural and useful to investigate them together. Such an investigation in the present work is based on the characteristics of cosmic rays with rigidity of 10 GV. The results are derived using data from the world wide neutron monitor network and are combined with relevant information into a data base on Forbush effects and large interplanetary disturbances.

Effects of strong geomagnetic storms on Northern railways in Russia.

Belov, A.V., Gaidash, S.P., Eroshenko, E.A., Lobkov, S.L., Pirjola, R., Trichtchenko, L., 2007. In: Proceedings of the 7th International Symposium on Electromagnetic Compatibility and Electromagnetic Ecology, Saint-Petersburg, Russia, 26–29 June 2007, pp. 280–282.

Magnetospheric effects in cosmic rays during the unique magnetic storm on November 2003

Belov A., Baisultanova L., Eroshenko E. et al.

J. Geophys. Res. 2005. V. 110, A09S20, doi:10.1029/2005JA011067, **File**.

Cosmic ray variations due to changes in the magnetosphere are evaluated for severe magnetic storm on November 20, 2003 using data from the worldwide neutron monitor network and the global survey method. From these results the changes in the planetary distribution of magnetic cutoff rigidities during this disturbed period are obtained in dependence of latitude. A correlation between Dst index and cutoff rigidity variations was defined for each cosmic ray station. The maximum changes in cutoff rigidities occurred while Dst index was around -472 nT. Geomagnetic effect in cosmic ray intensity reached at some stations 6-8%, and it seems to be the greatest one over the history of neutron monitor observations. The latitudinal distribution shows a maximum changes at geomagnetic cutoff rigidities around 7-8 GV. This corresponds to unusually low latitudes for maximal effect. Cutoff rigidity variations were also calculated utilizing the last model of Tsyganenko for a disturbed magnetosphere (T01S). A comparison between experimental and modeling results revealed a big discrepancy at cutoff rigidities less than 6 GV. The results on the geomagnetic effect in cosmic rays can be used for validating magnetospheric field models during very severe storms.

What determines the magnitude of forrush decreases?

A. V. **Belov**, E. A. Eroshenko, V. A. Oleneva, A. B. Struminsky and V. G. Yanke

[Advances in Space Research](#), **Volume 27, Issue 3**, 2001, Pages 625-630; **File**

Cosmic ray Forbush effects (FEs) have been studied for more than 60 years, but even today this phenomenon has no universally accepted definition, which leads to misunderstanding among researchers. There are no complete and convincing answers to the following questions: What are the distinctive features of FEs? What determines the magnitude of FEs and their variety? How are FEs associated with disturbances of the interplanetary medium, coronal mass ejections and high speed flows of the solar wind? What relation exists between FEs and geomagnetic storms? In order to answer these and other questions a data base of transient effects in cosmic rays and in the interplanetary medium is constructed and is being upgraded continuously. It combines variations in cosmic ray densities and anisotropies obtained from data of the world-wide neutron monitor (NM) network, characteristics of solar wind disturbances, solar and geomagnetic data. This data base presently contains more than 1400 events, observed during 1978–1996. The preliminary analysis allowed us to get the main characteristics of FEs, to determine what distinguishes this phenomenon among other cosmic ray variations, and propose a definition of the Forbush effect. In addition, an interplanetary disturbance parameter was derived, which is most closely associated with the magnitude of a FE. Using this large observational database, a relation between FEs and geomagnetic activity was analyzed statistically as a dependence of the FE magnitude on the maximum Kp-index measured during the associated magnetic storm.

Relation the forbush effects to the interplanetary and geomagnetic activity

Belov, A. V., Eroshenko, E. A., Oleneva, V. A., & Yanke, V. G.

Proceedings of the 27th International Cosmic Ray Conference. 07-15 August, 2001. Hamburg, Germany. Under the auspices of the International Union of Pure and Applied Physics (IUPAP), p.3552, **File**

<http://articles.adsabs.harvard.edu/full/2001ICRC....9.3552B/0003552.000.html?high=4afba3082a18300>

Properties of the Forbush effects (FE) and their relation to the sources and different parameters of the interplanetary medium and geospace, are the complex topic till now due to the great variety of FEs origin and manifestation. More definite relations appear to be derived employing the cosmic ray (CR) observations and different related parameters in the space and Earth's environment. To provide the statistical estimations a special database is created, which includes variations of the cosmic ray density and anisotropy, solar wind characteristics, interplanetary magnetic field, solar and geomagnetic data for about 2000 events observed in 1977-1980 and 1986-1997. The preliminary analysis allowed the main characteristics of the FEs and their relation with the solar wind and geomagnetic parameters to be derived and studied. A parameter of the interplanetary disturbance was found which is most closely correlated with the magnitude of the FE. A relation of the FE magnitude to the geomagnetic activity was derived as a dependence of the FE amplitude on the maximal Ap-index throughout the associated magnetic storm.

Combining White Light and UV Lyman-alpha Coronagraphic Images to determine the Solar Wind Speed: the Quick Inversion Method

Alessandro **Bemporad**, [Silvio Giordano](#), [Luca Zangrilli](#), [Federica Frassati](#)

A&A 654, A58 2021

<https://arxiv.org/pdf/2107.06811.pdf>

<https://doi.org/10.1051/0004-6361/202141276>

<https://www.aanda.org/articles/aa/pdf/2021/10/aa41276-21.pdf>

This work focuses on the combination of White Light (WL) and UV (Ly-alpha) coronagraphic images to demonstrate the capability to measure the solar wind speed in the inner corona directly with the ratio between these two images (a technique called "quick inversion method"), thus avoiding to account for the line-of-sight (LOS) integration effects in the inversion of data. After a derivation of the theoretical basis and illustration of the main hypotheses in the "quick inversion method", the data inversion technique is tested first with 1D radial analytic profiles, and then with 3D numerical MHD simulations, in order to show the effects of variabilities related with different phases of solar activity cycle and complex LOS distribution of plasma parameters. The same technique is also applied to average WL and UV images obtained from real data acquired by SOHO UVCS and LASCO instruments around the minimum and maximum of the solar activity cycle. Comparisons between input and output velocities show overall a good agreement, demonstrating that this method that allows to infer the solar wind speed with WL-UV image ratio can be complementary to more complex techniques requiring the full LOS integration. The analysis described here also allowed us to quantify the possible errors in the outflow speed, and to identify the coronal regions where the "quick inversion method"

performs at the best. The "quick inversion" applied to real UVCS and LASCO data allowed also to reconstruct the typical bimodal distribution of fast and slow wind at solar minimum, and to derive a more complex picture around solar maximum. The application of the technique shown here will be very important for the future analyses of data acquired with multichannel WL and UV (Ly-alpha) coronagraphs, such as Metis on-board Solar Orbiter, LST on-board ASO-S, and any other future WL and UV Ly-alpha multi-channel coronagraph.

Exploring the Inner Acceleration Region of Solar Wind: A Study Based on Coronagraphic UV and Visible Light Data

A. **Bemporad**

2017 ApJ 846 86

<http://iopscience.iop.org/sci-hub.cc/0004-637X/846/1/86/>

This work combined coronagraphic visible light (VL) and UV data to provide with an unprecedented view of the inner corona where the nascent solar wind is accelerated. The UV ($H\ i$ Ly α) and VL (polarized brightness) images (reconstructed with SOHO/UVCS, LASCO, and Mauna Loa data) have been analyzed with the Doppler dimming technique to provide for the first time daily 2D images of the radial wind speed between 1 and 6 R_{\odot} over 1 month of observations. Results show that both polar and equatorial regions are characterized at the base of the corona by plasma outflows at speeds > 100 km s $^{-1}$. The plasma is then decelerated within $\sim 1.5 R_{\odot}$ at the poles and $\sim 2.0 R_{\odot}$ at the equator, where local minima of the expansion speeds are reached, and gently reaccelerated higher up, reaching speeds typical of fast and slow wind components. The mass flux is highly variable with latitude and time at the equator and more uniform and stable over the poles. The polar flow is asymmetric, with speeds above the south pole lower than those above the north pole. A correlation (anticorrelation) between the wind speed and its density is found below (above) $\sim 1.8 R_{\odot}$. The 2D distribution of forces responsible for deceleration and reacceleration of solar wind is provided and interpreted in terms of Alfvén waves. These results provide a possible connection between small-scale outflows reported with other instruments at the base of the corona and bulk wind flows measured higher up.

Variations of the electron fluxes in the terrestrial radiation belts due to the impact of Corotating Interaction Regions and Interplanetary Coronal Mass Ejections

R. **Benacquista**, D. Boscher, S. Rochel and V. Maget

JGR **Volume 123, Issue 2** Pages 1191-1199 2018

<http://onlinelibrary.wiley.com/doi/10.1002/2017JA024796/epdf>

<http://sci-hub.tw/10.1002/2017JA024796>

In this paper, we study the variations of the radiation belts electron fluxes induced by the interaction of two types of solar wind structures with the Earth magnetosphere: the corotating interaction regions and the interplanetary coronal mass ejections. We use a statistical method based on the comparison of the pre- and post-events fluxes. Applied to the NOAA-POES data, this gives us the opportunity to extend previous studies focused on relativistic electrons at geosynchronous orbit. We enlighten how CIRs and ICMEs can impact differently the electron belts depending on the energy and the Lshell. In addition, we provide a new insight concerning these variations by considering their amplitude. Finally, we show strong relations between the intensity of the magnetic storms related to the events and the variation of the flux. These relations concern both the capacity of the events to increase the flux and the deepness of these increases.

A New Method to Model Magnetic Cloud-driven Forbush Decreases: The 2016 August 2 Event

Simone **Benella**^{1,2,6}, Monica Laurenza³, Rami Vainio⁴, Catia Grimani^{1,2}, Giuseppe Consolini³, Qiang Hu⁵, and Alexandr Afanasiev⁴

2020 ApJ 901 21

<https://doi.org/10.3847/1538-4357/abac59>

Interplanetary coronal mass ejections (ICMEs), generally containing magnetic clouds (MCs), are associated with galactic-cosmic ray (GCR) intensity depressions known as Forbush decreases (FDs). An ICME was observed at L1 between **2016 August 2** at 14:00 UT and **August 3** at 03:00 UT. The MC region was identified and its magnetic configuration was retrieved by using the Grad-Shafranov (GS) reconstruction. A weak FD in the GCR count-rate was observed on 2016 August 2 by a particle detector on board the European Space Agency LISA Pathfinder mission. The spacecraft orbited around L1 and the particle detector allowed us to monitor the GCR intensity at energies above 70 MeV n $^{-1}$. A 9% decrease in the cosmic-ray intensity was observed during the ICME passage. The first structure of the

ICME caused a 6.4% sharp decrease, while the MC produced a 2.6% decrease. A suited full-orbit test-particle simulation was performed on the MC configuration obtained through the GS reconstruction. The FD amplitude and time profile obtained through the simulation show an excellent agreement with observations. The test-particle simulation allows us to derive the energy dependence of the MC-driven FD providing an estimate of the amplitude at different rigidities, here compared with several neutron monitor observations. This work points out the importance of the large-scale MC configuration in the interaction between GCRs and ICMEs and suggests that particle drifts have a primary role in modulating the GCR intensity within the MC under study and possibly in at least all slowly expanding ICMEs lacking a shock/sheath region.

Coronal Electron Temperature inferred from the Strahl Electrons in the Inner Heliosphere: Parker Solar Probe and Helios observations

Laura [Bercic](#), [Davin Larson](#), [Phyllis Whittlesey](#), [Milan Maksimovic](#), [Samuel T. Badman](#), [Simone Landi](#), [Lorenzo Matteini](#), [Stuart D. Bale](#), [John W. ApJ **892** 88 2020

<https://arxiv.org/pdf/2003.04016.pdf>

<https://doi.org/10.3847/1538-4357/ab7b7a>

The shape of the electron velocity distribution function plays an important role in the dynamics of the solar wind acceleration. Electrons are normally modelled with three components, the core, the halo, and the strahl. We investigate how well the fast strahl electrons in the inner heliosphere preserve the information about the coronal electron temperature at their origin. We analysed the data obtained by two missions, Helios spanning the distances between 65 and 215 RS, and Parker Solar Probe (PSP) reaching down to 35 RS during its first two orbits around the Sun. The electron strahl was characterised with two parameters, pitch-angle width (PAW), and the strahl parallel temperature ($T_{s\parallel}$). PSP observations confirm the already reported dependence of strahl PAW on core parallel plasma beta ($\beta_{c\parallel}$) (Bercic2019). Most of the strahl measured by PSP appear narrow with PAW reaching down to 30°. The portion of the strahl velocity distribution function aligned with the magnetic field is for the measured energy range well described by a Maxwellian distribution function. $T_{s\parallel}$ was found to be anti-correlated with the solar wind velocity, and independent of radial distance. These observations imply that $T_{s\parallel}$ carries the information about the coronal electron temperature. The obtained values are in agreement with coronal temperatures measured using spectroscopy (David et al. 2998), and the inferred solar wind source regions during the first orbit of PSP agree with the predictions using a PFSS model (Bale et al. 2019, Badman et al. 2019).

On Fields and Mass Constraints for the Uniform Propagation of Magnetic-Flux Ropes Undergoing Isotropic Expansion

Daniel Benjamín [Berdichevsky](#)

[Solar Physics](#) May 2013, Volume 284, [Issue 1](#), pp 245–259

<https://link.springer.com/content/pdf/10.1007%2Fs11207-012-0176-5.pdf>

An analytical 3-D magnetohydrodynamic (MHD) solution of a magnetic-flux rope (FR) is presented. This FR solution may explain the uniform propagation, beyond ~ 0.05 AU, of coronal mass ejections (CMEs) commonly observed by today's missions like The Solar Mass Ejection Imager (SMEI), Solar and Heliospheric Observatory (SOHO) and Solar Terrestrial Relations Observatory (STEREO), tracked to tens of times the radius of the Sun, and in some cases up to 1 AU, and/or beyond. Once a CME occurs, we present arguments regarding its evolution based on its mass and linear momentum conservation. Here, we require that the gravitational and magnetic forces balance each other in the framework of the MHD theory for a simple model of the evolution of a CME, assuming it interacts weakly with the steady solar wind. When satisfying these ansätze we identify a relation between the transported mechanical mass of the interplanetary CME with its geometrical parameters and the intensity of the magnetic field carried by the structure. In this way we are able to estimate the mass of the interplanetary CME (ICME) for a list of cases, from the Wind mission records of ICME encountered near Earth, at 1 AU. We obtain a range for masses of ~ 109 to 1013 kg, or assuming a uniform distribution, of ~ 0.5 to 500 cm^{-3} for the hadron density of these structures, a result that appears to be consistent with observations.

DERIVING THE PHYSICAL PARAMETERS OF A SOLAR EJECTION WITH AN ISOTROPIC MAGNETOHYDRODYNAMIC EVOLUTIONARY MODEL

Daniel B. [Berdichevsky](#)¹, Guillermo Stenborg² and Angelos Vourlidas

2011 ApJ 741 47

The time-space evolution of a $\sim 50^\circ$ wide coronal mass ejection (CME) on 2007 May 21 is followed remotely with the Solar Terrestrial Relations Observatory heliospheric imager HI-1, and measured in situ near Venus by the MESSENGER and Venus-Express spacecraft. The paper compares the observations of the CME structure with a simple, analytical magnetohydrodynamic force-free solution. It corresponds to a self-similar evolution, which gives a consistent picture of the main spatial-temporal features for both remote and in situ observations. Our main findings are (1) the self-similar evolution allows us to map the CME bright front into about 1/3 of the whole interplanetary counterpart of the coronal mass ejection (ICME, i.e., corresponding to the in situ observed passage of the plasma and magnetic field structure), in good quantitative agreement with the imaging measurements, (2) the cavity following the CME front maps into the rest of the ICME structure, 80% or more of which is consistent with a force free, cylindrically shaped flux rope, and (3) time and space conditions constrain the translational speed of the FR center to 301 km s^{-1} , and the expansion speed of the FR core to 26 km s^{-1} . A careful determination of the ICME cross-section and volume allows us to calculate the mass of the CME bright region ($4.3 \pm 1.1 \cdot 10^{14} \text{ g}$) from the in situ measurements of the proton number density, which we assume to be uniform inside the bright region, of excellent agreement with the value estimated from the SECCHI HI-1 observations for the same structure. We provide model estimates for several global parameters including FR helicity ($\sim 2 \times 10^{26}$ Weber²).

Extreme Event Statistics in Dst, SYM-H, and SMR Geomagnetic Indices

A. [Bergin](#), [S. C. Chapman](#), [N. W. Watkins](#), [N. R. Moloney](#), [J. W. Gjerloev](#)

<https://doi.org/10.1029/2022SW003304>

<https://agupubs.onlinelibrary.wiley.com/doi/10.1029/2022SW003304>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2022SW003304>

Extreme space weather events are rare, and quantifying their likelihood is challenging, often relying on geomagnetic indices obtained from ground-based magnetometer observations that span multiple solar cycles. The Dst index ring-current monitor, derived from an hourly average over four low-latitude stations, is a benchmark for extreme space weather events, and has been extensively studied statistically. We apply extreme value theory (EVT) to two geomagnetic ring current indices: SYM-H (derived from 6 stations) and SMR (derived from up to 120 stations). EVT analysis reveals a divergence between the return level found for Dst, and those for SYM-H and SMR, that increases non-linearly with return period. For return periods below 10 years, hourly averaged SYM-H and SMR have return levels similar to Dst, but at return periods of 50 and 100 years, they respectively exceed that of Dst by about 10% and 15% (SYM-H) and about 7% and 12% (SMR). One minute resolution SYM-H and SMR return levels progressively exceed that of Dst; their 5, 10, 50, and 100 year return levels exceed that of Dst by about 10%, 12%, 20% and 25% respectively. Our results indicate that consideration should be given to the differences between the indices if selecting one to use as a benchmark in model validation or resilience planning for the wide range of space weather sensitive systems that underpin our society.

Forecasting the Geomagnetic Activity Several Days in Advance Using Neural Networks Driven by Solar EUV Imaging

Guillaume [Bernoux](#), [Antoine Brunet](#), [Éric Buchlin](#), [Miho Janvier](#), [Angélica Sicard](#)

JGR e2022JA030868 [Volume 127, Issue 10](#) 2022

<https://doi.org/10.1029/2022JA030868>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2022JA030868>

Many models of the near-Earth's space environment (radiation belts, ionosphere, upper atmosphere, etc.) are driven by geomagnetic indices, representing the state of disturbance of the Earth's magnetosphere. Over the past decade, machine learning-based methods for forecasting geomagnetic indices from near-Earth solar wind parameters have become popular in the space weather community. These methods often prove to be very accurate and skilled. However, these approaches have the notable drawback of being effective in an operational context only for limited forecasting horizons (often up to a couple of hours ahead at best). In order to increase this prediction horizon, we introduce SERENADE, a novel deep learning-based proof-of-concept model using images delivered by the Atmospheric Imaging Assembly instrument onboard the Solar Dynamics Observatory spacecraft to directly provide probabilistic forecasts of the daily maximum of the geomagnetic index Kp up to a few days ahead. We show in particular that SERENADE is able to capture information on the geomagnetic dynamics from solar imaging alone. In addition, despite it being a prototypical

model, our model is more accurate in most situations than three empirical baseline models. However, the model still shows some strong limitations inherent to its structure and the used data set, which could be the focus of future works. This opens the way to a better mid-to-long term data-driven magnetospheric modeling within space weather and geophysical pipelines. **8 September 2017**

Characterizing extreme geomagnetic storms using Extreme Value Analysis: a discussion on the representativeness of short datasets

G. [Bernoux](#), [V. Maget](#)

Space Weather **Volume 18, Issue 6** e2020SW002450 **2020**

<https://sci-hub.tw/10.1029/2020SW002450>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2020SW002450>

One of the main goals when studying Space Weather is to characterize extreme events occurrences and related characteristics. To do so, dedicated statistical methods from the so-called Extreme Value Analysis (EVA) field have been developed. In this study we used Ca index, derived from aa, in order to characterize geoeffectiveness from the radiation belts point of view with a 150-year long dataset. The analysis performed in this study thus focuses on this newsworthy index to provide clues on the reliability of EVA methods. The first main result we present here is that the 1-in-10, 1-in-50 and 1-in-100 year events respectively match Ca values of 100.39, 131.39 and 142.84 nT. Consequently the only 1-in-100 event observed during the Space Era would be the “Halloween Storm” in 2003 that reached a Ca value of 147.6 nT. The second main result highlighted in this work is that performing the same analysis with shorter subsets (20-year long) can give significantly different results for two reasons. The first reason is that some short time periods do not display the same distribution of events as the full period. The second reason is that the choice of the correct threshold (when using a Peaks Over Threshold approach) is made difficult with a short dataset and leads to inaccurate results. This is a strong result as for accurate estimation of the induced effects of extreme events in radiation belts, we may only rely on short flux datasets from one or another mission (mostly shorter than 20 years). **28 September and 28 October 2013, 15 April-15 May 2017**

The Great Aurora of 4 February 1872 observed by Angelo Secchi in Rome

Francesco [Berrilli](#), [Luca Giovannelli](#)

Journal of Space Weather and Space Climate **12, 3** **2022**

<https://arxiv.org/pdf/2201.01171.pdf>

<https://www.swsc-journal.org/articles/swsc/pdf/2022/01/swsc210083.pdf>

Observation of auroras at low latitudes is an extremely rare event typically associated with major magnetic storms due to intense Earth-directed Coronal Mass Ejections. Since these energetic events represent one of the most important components of space weather, their study is of paramount importance to understand the Sun-Earth connection. Due to the rarity of these events, being able to access all available information for the few cases studied is equally important. Especially if we refer to historical periods in which current accurate observations from ground-based instruments or space were not available. Certainly, among these events, we must include the great aurora of February 4, 1872. An event whose effects have been observed in different regions of the Earth. What we could consider today a global event, especially for its effects on the communication systems of the time, such as the transatlantic cable that allowed a connection between the United States and Europe since 1866. In this paper, we describe the main results of the observations and studies carried out by Angelo Secchi at the Observatory of the Roman College and described in his Memoria sull’Aurora Elettrica del 4 Febbraio 1872 for the Notes of the Pontifical Academy of new Lincei. This note is extremely modern both in its multi-instrumental approach to the study of these phenomena and in its association between solar-terrestrial connection and technological infrastructures on the Earth. The Secchi’s note definitely represents the first example of analysis and study of an event on a global scale, such as the Atlantic cable, affecting the Earth. What we nowadays call an extreme space weather event.

Complex **Catalogue of High Speed Streams Associated with Geomagnetic Storms During Solar Cycle 24**

[Solar Physics](#) volume 297, Article number: 65 (2022)

<https://doi.org/10.1007/s11207-022-01998-3>

A complex catalogue of high speed streams produced by coronal holes and their effects in the terrestrial magnetosphere – the so-called geomagnetic storms – for Solar Cycle 24 (2009 to 2019) is presented here. This catalogue is structured in

three parts describing the high-speed stream characteristics, the interplanetary magnetic field state, and the properties of the associated geomagnetic storms. The catalogue is available online at <http://www.geodin.ro/varsiti/>.

Geoeffectiveness Prediction of CMEs

[Diana Besliu-Ionescu](#) and [Marilena Mierla](#)

<https://doi.org/10.3389/fspas.2021.672203>

Coronal mass ejections (CMEs), the most important pieces of the puzzle that drive space weather, are continuously studied for their geomagnetic impact. We present here an update of a logistic regression method model, that attempts to forecast if a CME will arrive at the Earth and it will be associated with a geomagnetic storm defined by a minimum Dst value smaller than -30 nT. The model is run for a selection of CMEs listed in the LASCO catalogue during the solar cycle 24. It is trained on three fourths of these events and validated for the remaining one fourth. Based on five CME properties (the speed at 20 solar radii, the angular width, the acceleration, the measured position angle and the source position – binary variable) the model successfully predicted 98% of the events from the training set, and 98% of the events from the validation one.

Solar flare associated coronal mass ejections causing geo-effectiveness and Forbush decreases

[Bhatt, B.](#) & [Chandra, H.](#)

Astrophys Space Sci (2017) 362: 41.

doi:10.1007/s10509-017-3024-0

https://www.researchgate.net/publication/313238149_Solar_flare_associated_coronal_mass_ejections_causing_geo-effectiveness_and_Forbush_decreases

In the present study, we have selected 35 halo Coronal Mass Ejections (CMEs) associated with solar flares, Geomagnetic Storms (GSs) and Forbush decrease (Fd) chosen from 1st January 2000 to 31st December 2007 (i.e., the descending phase of solar cycle 23) observed by the Large Angle Spectrometric Coronagraph (LASCO) on board the SOHO spacecraft. Statistical analyses are performed to look at the distribution of solar flares associated with halo CMEs causing GSs and Fd and investigated the relationship between solar flare and halo CME parameters with GSs and Fd. Forbush decrease is the phenomenon of rapid decrease in cosmic ray intensity following the CME. Our analysis indicates that during 2000 to 2007 the northern region produced 44 % of solar flares associated with halo CMEs, GSs, and Fd, whereas 56 % solar flares associated with halo CMEs, GSs, and Fd were produced in the southern region. The northern and the southern hemispheres between 10° to 20° latitudinal belts are found to be more effective in producing events leading to Fd. From our selected events, we found that about 60 % of super-intense storms ($Dst \leq -200$ nT) caused by halo CMEs are associated with X-class flares. Fast halo CMEs associated with X-class flares originating from 0° to 25° latitudes are better potential candidates in producing super-intense GSs than the slow halo CMEs associated with other classes of flares.

Forecasting of SYMH and ASYH indices for geomagnetic storms of solar cycle 24 including St. Patrick's day, 2015 storm using NARX neural network

Ankush [Bhaskar](#) and Geeta Vichare

J. Space Weather Space Clim. 2019, 9 A12

<https://www.swsc-journal.org/articles/swsc/pdf/2019/01/swsc180011.pdf>

– Artificial Neural Network (ANN) has proven to be very successful in forecasting a variety of irregular magnetospheric/ionospheric processes like geomagnetic storms and substorms. SYMH and ASYH indices represent longitudinal symmetric and the asymmetric component of the ring current. Here, an attempt is made to develop a prediction model for these indices using ANN. The ring current state depends on its past conditions therefore, it is necessary to consider its history for prediction. To account for this effect Nonlinear Autoregressive Network with exogenous inputs (NARX) is implemented. This network considers input history of 30 min and output feedback of 120 min. Solar wind parameters mainly velocity, density, and interplanetary magnetic field are used as inputs. SYMH and ASYH indices during geomagnetic storms of 1998–2013, having minimum SYMH < 85 nT are used as the target for training two independent networks. We present the prediction of SYMH and ASYH indices during nine geomagnetic storms of solar cycle 24 including the recent largest storm occurred on St. Patrick's day, 2015. The present prediction model reproduces the entire time profile of SYMH and ASYH indices along with small variations of ~ 10 – 30 min to the good extent within noise level, indicating a significant contribution of interplanetary sources and past state of the magnetosphere. Therefore, the developed networks can predict SYMH and ASYH indices about an hour before, provided, real-time upstream solar wind data are available. However, during the main phase of major storms, residuals (observed-modeled) are found to be large, suggesting the influence of internal factors such as magnetospheric processes.

RELATIVE CONTRIBUTION OF THE MAGNETIC FIELD BARRIER AND SOLAR WIND SPEED IN ICME-ASSOCIATED FORBUSH DECREASES

Ankush [Bhaskar](#)¹, Prasad Subramanian^{2,3}, and Geeta Vichare

2016 ApJ 828 104

We study 50 cosmic-ray Forbush decreases (FDs) from the Oulu neutron monitor data during 1997–2005 that were associated with Earth-directed interplanetary coronal mass ejections (ICMEs). Such events are generally thought to arise due to the shielding of cosmic rays by a propagating diffusive barrier. The main processes at work are the diffusion of cosmic rays across the large-scale magnetic fields carried by the ICME and their advection by the solar wind. In an attempt to better understand the relative importance of these effects, we analyze the relationship between the FD profiles and those of the interplanetary magnetic field (B) and the solar wind speed (V_{sw}). Over the entire duration of a given FD, we find that the FD profile is generally (anti)correlated with the B and V_{sw} profiles. This trend holds separately for the FD main and recovery phases too. For the recovery phases, however, the FD profile is highly anti-correlated with the V_{sw} profile, but not with the B profile. While the total duration of the FD profile is similar to that of the V_{sw} profile, it is significantly longer than that of the B profile. Using the convection–diffusion model, a significant contribution of advection by solar wind is found during the recovery phases of the FD.

The roles of the magnetic field barrier and solar wind speed in ICME-associated Forbush decreases

Ankush [Bhaskar](#), Prasad Subramanian, Geeta Vichare

2016

<http://arxiv.org/pdf/1605.09537v1.pdf>

We study 50 cosmic ray Forbush decreases (FDs) from the Oulu neutron monitor data during **1997-2005** that were associated with Earth-directed interplanetary coronal mass ejections (ICMEs). Such events are generally thought to arise due to the shielding of cosmic rays by a propagating diffusive barrier. The main processes at work are the diffusion of cosmic rays across the large-scale magnetic fields carried by the ICME and their advection by the solar wind. In an attempt to better understand the relative importance of these effects, we analyse the relationship between the FD profiles and those of the interplanetary magnetic field (B) and the solar wind speed (V_{sw}). Over the entire duration of a given FD, we find that the FD profile is generally well (anti)correlated with the B and V_{sw} profiles. This trend holds separately for the FD main and recovery phases too. For the recovery phases, however, the FD profile is highly anti-correlated with the V_{sw} profile, but not with the B profile. While the total duration of the FD profile is similar to that of the V_{sw} profile, it is significantly longer than that of the B profile.

Role of solar wind speed and interplanetary magnetic field during two-step Forbush decreases caused by Interplanetary Coronal Mass Ejections

Ankush [Bhaskar](#), Geeta Vichare, K. P. Arunbabu, Anil Raghav

Astrophysics and Space Science July **2016**, 361:242

The relationship of Forbush decreases (FDs) observed in Moscow neutron monitor with the interplanetary magnetic field (B) and solar wind speed (V_{sw}) is investigated in detail for the FDs associated with Interplanetary Coronal Mass Ejections (ICMEs) during 2001–2004. The classical two-step FD events are selected, and characteristics of the first step (mainly associated with shock), as well as of complete decrease (main phase) and recovery phase, are studied here. It is observed that the onset of FD occurs generally after zero to a few hours of shock arrival, indicating in the post-shock region that mainly sheath and ICME act as important drivers of FD. A good correlation is observed between the amplitude of B and associated FD magnitude observed in the neutron count rate of the main phase. The duration of the main phase observed in the neutron count rate also shows good correlation with B. This might indicate that stronger interplanetary disturbances have a large dimension of magnetic field structure which causes longer fall time of FD main phase when they transit across the Earth. It is observed that V_{sw} and neutron count rate time profiles show considerable similarity with each other during complete FD, especially during the recovery phase of FD. Linear relationship is observed between time duration/e-folding time of FD recovery phase and V_{sw} . These observations indicate that the FDs are influenced by the inhibited diffusion of cosmic rays due to the enhanced convection associated with the interplanetary disturbances. We infer that the inhibited cross-field diffusion of the cosmic rays due to enhanced B is mainly responsible for the main phase of FD whereas the expansion of ICME contributes in the early recovery phase and

the gradual variation of V_{sw} beyond ICME boundaries contributes to the long duration of FD recovery through reduced convection–diffusion.

Comparison of Solar Activity Parameters and Associated Forbush Decreases in Solar Cycles 23 and 24

Beena **Bhatt** & [Harish Chandra](#)

Solar Phys. 298, Article number: 132 (2023)

<https://doi.org/10.1007/s11207-023-02227-1>

We examine the Forbush decreases (FDs) associated with solar flares and coronal mass ejections (CMEs) from January 2008 to December 2019, covering the whole of Solar Cycle 24, and we compare them to our earlier study of Solar Cycle 23 (Bhatt and Chandra, Adv. Space Res. 71, 1098, 2023). On a sample of 56 events, we conducted a statistical analysis using solar and geomagnetic parameters to examine their effect on interplanetary space and the decrease in the galactic cosmic rays (GCR). Our research concentrated on an in-depth analysis of the two most significant events. The first event with an FD magnitude of 11.2% on **8 March 2012** and the second with an FD magnitude of 7.7% on **7 September 2017**, respectively. We discovered that compared to other latitude bands, the northern 11 – 20° latitude band had the highest number of FD-associated flare events. We conducted a statistical analysis of FD magnitude, geomagnetic Dst-index, solar and interplanetary parameters.

23rd solar cycle: Solar activity parameters and associated Forbush decreases

Bhatt, Beena; Chandra, Harish

Advances in Space Research, Volume 71, Issue 1, p. 1098-1107. 2023

<https://www.sciencedirect.com/science/article/pii/S027311772200984X/pdf>

We report Forbush decreases (FD) in cosmic ray intensity from January 1996 to December 2008, the whole Solar Cycle 23rd. Statistical analysis is done for only 152 events for which associated solar flare position, flare classes, and Coronal Mass Ejections (CME) speed are given. We applied FD parameters taken from the Forbush Effects and Interplanetary Disturbances databases maintained by the Pushkov Institute of Terrestrial Magnetism, Ionosphere, and Radiowave Propagation (IZMIRAN), obtained by processing the data of the worldwide neutron monitor network using the global survey method (GSM) (A. Belov et al., 2018). For the said number of events, we examine their effect on interplanetary space and the decrease of the galactic cosmic rays (GCR) near Earth. We found that the 11-20° latitudinal belt shows more FD- associated flare events than the other latitudinal belts, and on this belt, the Southern hemisphere is more active. The results reveal that FDs and solar flares are well correlated. Statistical analysis is carried out for the magnitude of the CR decrease with solar and geomagnetic parameters. **May 21–27, 1997**

Table 1 The selected FDs of the cosmic ray Intensity with their associated solar parameters during 1996–2008

On the specific energy and pressure in near-Earth magnetic clouds

Debesh **Bhattacharjee**, [Prasad Subramanian](#), [Angelos Vourlidis](#), [Teresa Nieves-Chinchilla](#), [Niranjana Thejaswi](#), [Nishtha Sachdeva](#)

A&A 669, A153 2022

<https://arxiv.org/pdf/2210.16571.pdf>

<https://www.aanda.org/articles/aa/pdf/2023/01/aa43603-22.pdf>

The pressure and energy density of the gas and magnetic field inside solar coronal mass ejections (in relation to that in the ambient solar wind) is thought to play an important role in determining their dynamics as they propagate through the heliosphere. We compare the specific energy (erg g^{-1}) [comprising kinetic (H_k), thermal (H_{th}) and magnetic field (H_{mag}) contributions] inside MCs and the solar wind background. We examine if the excess thermal + magnetic pressure and specific energy inside MCs (relative to the background) is correlated with their propagation and internal expansion speeds. We ask if the excess thermal + magnetic specific energy inside MCs might make them resemble rigid bodies in the context of aerodynamic drag. We use near-Earth in-situ data from the WIND spacecraft to identify a sample of 152 well observed interplanetary coronal mass ejections and their MC counterparts. We compute various metrics using these data to address our questions. We find that the total specific energy (H) inside MCs is approximately equal to that in the background solar wind. We find that the the excess (thermal + magnetic) pressure and specific energy are not well correlated with the near-Earth propagation and expansion speeds. We find that the excess thermal+magnetic specific energy \geq the specific kinetic energy of the solar wind incident on 81--89 % of the MCs we study. This might explain how MCs retain their structural integrity and resist deformation by the solar wind bulk flow.

Turbulence and Anomalous Resistivity inside Near-Earth Magnetic Clouds

Debesh **Bhattacharjee**, [Prasad Subramanian](#), [Teresa Nieves-Chinchilla](#), [Angelos Vourlidis](#)

MNRAS 2022

<https://arxiv.org/pdf/2210.17359.pdf>

We use in-situ data from the Wind spacecraft to survey the amplitude of turbulent fluctuations in the proton density and total magnetic field inside a large sample of near-Earth magnetic clouds (MCs) associated with coronal mass ejections (CMEs) from the Sun. We find that the most probable value of the modulation index for proton density fluctuations ($\delta n_p/n_p$) inside MCs ranges from 0.13 to 0.16, while the most probable values for the modulation index of the total magnetic field fluctuations ($\delta B/B$) range from 0.04 to 0.05. We also find that the most probable value of the Mach number fluctuations (δM) inside MCs is ≈ 0.1 . The anomalous resistivity inside near-Earth MCs arising from electron scattering due to turbulent magnetic field fluctuations exceeds the (commonly used) Spitzer resistivity by a factor of ≈ 500 – 1000 . The enhanced Joule heating arising from this anomalous resistivity could impact our understanding of the energetics of CME propagation.

On modeling ICME cross-sections as static MHD columns

Debesh [Bhattacharjee](#), [Prasad Subramanian](#), [Volker Bothmer](#), [Teresa Nieves-Chinchilla](#), [Angelos Vourlidas](#)

Solar Phys. 297, Article number: 45 2022

<https://arxiv.org/pdf/2203.06996.pdf>

<https://link.springer.com/content/pdf/10.1007/s11207-022-01982-x.pdf>

Solar coronal mass ejections are well known to expand as they propagate through the heliosphere. Despite this, their cross-sections are usually modeled as static plasma columns within the magnetohydrodynamics (MHD) framework. We test the validity of this approach using in-situ plasma data from 151 magnetic clouds (MCs) observed by the WIND spacecraft and 45 observed by the Helios spacecrafts. We find that the most probable cross-section expansion speeds for the WIND events are only ≈ 0.06 times the Alfvén speed inside the MCs while the most probable cross-section expansion speeds for the Helios events is ≈ 0.03 . MC cross-sections can thus be considered to be nearly static over an Alfvén crossing timescale. Using estimates of electrical conductivity arising from Coulomb collisions, we find that the Lundquist number inside MCs is high (≈ 1013), suggesting that the MHD description is well justified. The Joule heating rates using our conductivity estimates are several orders of magnitude lower than the requirement for plasma heating inside MCs near the Earth. While the (low) heating rates we compute are consistent with the MHD description, the discrepancy with the heating requirement points to possible departures from MHD and the need for a better understanding of plasma heating in MCs.

[Two-dimensional MHD modelling of switchbacks from jetlets in the slow solar wind](#) L14

Ruggero Biondo, Alessandro Bemporad, Paolo Pagano and Fabio Reale

Published online: 28 November 2023

A&A Volume 679, L14, November 2023

DOI: <https://doi.org/10.1051/0004-6361/202347696>

<https://www.aanda.org/articles/aa/pdf/2023/11/aa47696-23.pdf>

Solar wind switchbacks are polarity reversals of the magnetic field, recently frequently measured by Parker Solar Probe inside 0.2 AU. In this Letter we show that magnetic switchbacks, similar to those observed by PSP, are reproduced by injecting a time-limited collimated high-speed stream in the Parker spiral. We performed a 2D magnetohydrodynamics simulation with the PLUTO code of a slightly inclined jet at 1000 km s^{-1} between 5 and $60 R_{\odot}$. The jet rapidly develops a field inversion at its wings and, at the same time, it is bent by the Parker spiral. The match with the radial outward wind field creates two asymmetric switchbacks, one that bends to the anti-clockwise and one that bends to the clockwise direction in the ecliptic plane, with the last one being the most extended. The simulation shows that such S-shaped magnetic features travel with the jet and persist for several hours and to large distances from the Sun (beyond $20 R_{\odot}$). We show the evolution of physical quantities as they would be measured by a hypothetical detector at a fixed position when crossed by the switchback, for comparison with in situ measurements.

Tracing the ICME plasma with a MHD simulation★

The determination of the chemical composition of interplanetary coronal mass ejection (ICME) plasma is an open issue. More specifically, it is not yet fully understood how remote sensing observations of the solar corona plasma during solar disturbances evolve into plasma properties measured in situ away from the Sun. The ambient conditions of the background interplanetary plasma are important for space weather because they influence the evolutions, arrival times, and geo-effectiveness of the disturbances. The Reverse In situ and MHD Approach (RIMAP) is a technique to reconstruct the heliosphere on the ecliptic plane (including the magnetic Parker spiral) directly from in situ measurements acquired at 1 AU. It combines analytical and numerical approaches, preserving the small-scale longitudinal variability of the wind flow lines. In this work, we use RIMAP to test the interaction of an ICME with the interplanetary medium. We model the propagation of a homogeneous non-magnetised (i.e. with no internal flux rope) cloud starting at 800 km s⁻¹ at 0.1 AU out to 1.1 AU. Our 3D magnetohydrodynamics (MHD) simulation made with the PLUTO MHD code shows the formation of a compression front ahead of the ICME, continuously driven by the cloud expansion. Using a passive tracer, we find that the initial ICME material does not fragment behind the front during its propagation, and we quantify the mixing of the propagating plasma cloud with the ambient solar wind plasma, which can be detected at 1 AU.

We report the results of a multi-instrument, multi-technique, coordinated study of the solar eruptive event of 13 May 2005. We discuss the resultant Earth-directed (halo) coronal mass ejection (CME), and the effects on the terrestrial space environment and upper Earth atmosphere. The interplanetary CME (ICME) impacted the Earth's magnetosphere and caused the most-intense geomagnetic storm of 2005 with a Disturbed Storm Time (*Dst*) index reaching -263 nT at its peak. The terrestrial environment responded to the storm on a global scale. We have combined observations and measurements from coronal and interplanetary remote-sensing instruments, interplanetary and near-Earth *in-situ* measurements, remote-sensing observations and *in-situ* measurements of the terrestrial magnetosphere and ionosphere, along with coronal and heliospheric modelling. These analyses are used to trace the origin, development, propagation, terrestrial impact, and subsequent consequences of this event to obtain the most comprehensive view of a geo-effective solar eruption to date. This particular event is also part of a NASA-sponsored Living With a Star (LWS) study and an on-going US NSF-sponsored Solar, Heliospheric, and INTERplanetary Environment (SHINE) community investigation.

THREE-DIMENSIONAL RECONSTRUCTIONS AND MASS DETERMINATION OF THE 2008 JUNE 2 LASCO CORONAL MASS EJECTION USING STELab INTERPLANETARY SCINTILLATION OBSERVATIONS

M. M. **Bisi**¹, B. V. Jackson¹, P. P. Hick^{1,3}, A. Buffington¹, J. M. Clover¹, M. Tokumaru², and K. Fujiki²
Astrophysical Journal Letters, 715:L104–L108, 2010 June

We examine and reconstruct the interplanetary coronal mass ejection (ICME) first seen in space-based coronagraph

white-light difference images on 2008 June 1 and 2. We use observations of interplanetary scintillation (IPS) taken with the Solar-Terrestrial Environment Laboratory (STELab), Japan, in our three-dimensional (3D) tomographic reconstruction of density and velocity. The coronal mass ejection (CME) was first observed by the LASCO C3 instrument at around 04:17 UT on 2008 June 2. Its motion subsequently moved across the C3 field of view with a plane-of-the-sky velocity of 192 km s⁻¹. The 3D reconstructed ICME is consistent with the trajectory and extent of the CME measurements taken from the CDAW CME catalog. However, excess mass estimates vary by an order of magnitude from *Solar and Heliospheric Observatory* and *Solar Terrestrial Relations Observatory* coronagraphs to our 3D IPS reconstructions of the inner heliosphere. We discuss the discrepancies and give possible explanations for these differences as well as give an outline for future studies.

Scintillation Observations of Stream Interaction Regions in the Solar Wind

M. M. Bisi, R. A. Fallows, A. R. Breen & I. J. O'Neill

Solar Phys., 261(1), Page: 149 – 172, 2010

We present a summary of results from ten years of interplanetary scintillation (IPS) observations of stream interaction regions (SIRs) in the solar wind. Previous studies had shown that SIRs were characterized by intermediate-velocity solar wind and – in the case of compressive interactions – higher levels of scintillation. In this study we considered all cases of intermediate velocities in IPS observations from the *European Incoherent SCATter* (EISCAT) radar facility made at low- and mid-heliographic latitudes between 1994 and 2003. After dismissing intermediate-velocity observations which were associated with solar-wind transients (such as coronal mass ejections) we found that the remaining cases of intermediate velocities lay above coronal structures where stream interaction would be expected. An improved ballistic mapping method (compared to that used in earlier EISCAT studies of interaction regions) was used to identify the regions of raypath in IPS observations which might be expected to include interaction regions and to project these regions out to the distances of *in-situ* observations. The early stages of developing compression regions, consistent with their development on the leading edges of compressive stream interaction regions, were clearly detected as close to the Sun as 30 R_{\odot} , and further ballistic projection out to the distances of *in-situ* observations clearly associated these developing structures with density and velocity features characteristic of developed interaction regions in *in-situ* data in the cases when such data were available. The same approach was applied to study non-compressive interaction regions (shear layers) between solar-wind streams of different velocities where the stream interface lay at near-constant latitude and the results compared with those from compressive interaction regions. The results confirm that intermediate velocities seen in IPS observations above stream boundaries may arise from either detection of intermediate-velocity flow in compression regions, or from non-compressive shear layers. The variation in velocity about the mean determined from IPS measurements (representing the spread in velocity across that part of the raypath associated with the interaction region in the analysis) was comparable in compressive and non-compressive regions – a potentially interesting result which may contain important information on the geometry of developing SIRs. It is clear from these results that compressive and non-compressive interaction regions belong to the same class of stream – stream interaction, with the dominant mode determined by the latitudinal gradient of the stream interface. Finally, we discuss the results from this survey in the light of new data from the *Heliospheric Imagers* (HI) on the *Solar TERrestrial RELations Observatory* (STEREO) spacecraft and other instruments, and suggest possible directions for further work.

3-D reconstructions of the early-November 2004 CDAW geomagnetic storms: analysis of Ooty IPS speed and density data

M. M. Bisi¹, B. V. Jackson¹, J. M. Clover¹, P. K. Manoharan², M. Tokumaru³, P. P. Hick^{1,4}, and A. Buffington¹

Ann. Geophys., 27, 4479-4489, 2009; **File**

www.ann-geophys.net/27/4479/2009/

Interplanetary scintillation (IPS) remote-sensing observations provide a view of the solar wind covering a wide range of heliographic latitudes and heliocentric distances from the Sun between ~0.1 AU and 3.0 AU. Such observations are used to study the development of solar coronal transients and the solar wind while propagating out through interplanetary space. They can also be used to measure the inner-heliospheric response to the passage of coronal mass ejections (CMEs) and co-rotating heliospheric structures. IPS observations can, in general, provide a speed estimate of the heliospheric material crossing the observing line of site; some radio antennas/arrays can also provide a radio scintillation level. We use a three-dimensional (3-D) reconstruction technique which obtains perspective views from outward-flowing solar wind and co-rotating structure as observed from Earth by iteratively fitting a kinematic solar wind model to these data. Using this 3-D modelling technique, we are able to reconstruct the velocity and density of CMEs as they travel through interplanetary space. For the time-dependent model used here with IPS data taken from the Ootacamund

(Ooty) Radio Telescope (ORT) in India, the digital resolution of the tomography is 10° by 10° in both latitude and longitude with a half-day time cadence. Typically however, the resolutions range from 10° to 20° in latitude and longitude, with a half- to one-day time cadence for IPS data dependant upon how much data are used as input to the tomography. We compare reconstructed structures during early-November 2004 with in-situ measurements from the Wind spacecraft orbiting the Sun-Earth L_1 -Point to validate the 3-D tomographic reconstruction results and comment on how these improve upon prior reconstructions.

Low-Resolution STELab IPS 3D Reconstructions of the Whole Heliosphere Interval and Comparison with in-Ecliptic Solar Wind Measurements from STEREO and *Wind* Instrumentation

M.M. Bisi · B.V. Jackson · A. Buffington · J.M. Clover · P.P. Hick · M. Tokumaru

Solar Phys (2009) 256: 201–217, DOI 10.1007/s11207-009-9350-9, **2009**

STEREO SCIENCE RESULTS AT SOLAR MINIMUM

We present initial 3D tomographic reconstructions of the inner heliosphere during the Whole Heliosphere Interval (WHI) – Carrington Rotation 2068 (CR2068) – using Solar-Terrestrial Environment Laboratory (STELab) Interplanetary Scintillation (IPS) observations. Such observations have been used for over a decade to visualise and investigate the structure of the solar wind and to study in detail its various features. These features include co-rotating structures as well as transient structures moving out from the Sun. We present global reconstructions of the structure of the inner heliosphere during this time, and compare density and radial velocity with multi-point *in situ* spacecraft measurements in the ecliptic; namely STEREO and *Wind* data, as the interplanetary medium passes over the spacecraft locations.

Three-dimensional reconstructions of the early November 2004 Coordinated Data Analysis Workshop geomagnetic storms: Analyses of STELab IPS speed and SMEI density data,

Bisi, M. M., Jackson, B. V., Hick, P. P., Buffington, A., Odstrcil, D., and Clover, J. M.:

J. Geophys. Res., 113, A00A11, doi:10.1029/2008JA013222, **2008a.**

Combined interplanetary scintillation (IPS) and Solar Mass Ejection Imager (SMEI) remote-sensing observations provide a view of the solar wind at almost all heliographic latitudes and covering distances from the Sun between 0.1 AU and 3.0 AU. They are used to study the development of the solar wind and coronal transients as they move out into interplanetary space, and also the inner heliospheric response to the passage of corotating solar structures and coronal mass ejections (CMEs). The observations take place in both radio scintillation level and speed for IPS, and in Thomson-scattered white light brightness for SMEI. With colleagues at the Solar Terrestrial Environment Laboratory (STELab), Nagoya University, Japan, we have developed a data analysis system for the STELab IPS data which can also be applied to SMEI white light data. This employs a three-dimensional (3-D) reconstruction technique that obtains perspective views from solar corotating plasma and outward flowing solar wind as observed from the Earth by iterative fitting of a kinematic solar wind model to the data. This 3-D modeling technique permits reconstructions of the density and speed of CMEs and other interplanetary transients at relatively coarse spatial and temporal resolutions. For the time-dependent model (used here), these typically range from 5° to 20° in latitude and longitude, with a 1/2 to 1 day time cadence. For events during early November 2004 we compare these reconstructed structures with in situ measurements from the ACE and Wind (near-Earth) spacecraft to validate the 3-D tomographic reconstruction results and provide input to the ENLIL 3-D magnetohydrodynamic (MHD) numerical model.

A Prolonged Southward IMF-Bz Event of May 02--04, 1998: Solar, Interplanetary Causes and Geomagnetic Consequences

Susanta Kumar Biso, D. Chakrabarty, P. Janardhan, R.G. Rastogi, A. Yoshikawa, K. Fujiki, M. Tokumaru, Y. Yan

JGR Vol: 121, Pages: 3882–3904 **2016**

<http://arxiv.org/pdf/1604.04959v1.pdf>

A detailed investigation was carried out to understand a prolonged (~44 hours) weakly southward interplanetary magnetic field (IMF-Bz) condition during **May 02--04, 1998**. In-situ observations, during the period, showed the passage of an expanding magnetic cloud embedded in an interplanetary coronal mass ejection (ICME), followed up by a shock and an interplanetary discontinuity driven by another ICME. It is the arrival of the ICMEs and the upfront shocks that cause the prolonged southward IMF-Bz condition. The magnetic configuration of the source regions of the IMF associated with the ICME interval were also examined, which showed open magnetic field structures, emanating from a small active region on the north of the heliospheric current sheet (HCS). The structures remained constantly to the north of the HCS, both on April 29 and May 01, suggesting no change in their polarity. The draping of these outward directed

radial field lines around the propagating CMEs in the shocked plasma explained the observed polarity changes of the IMF-Bz at 1 AU. In addition, multiple enhancements were also detected in the geomagnetic field variations, which showed a distinct one-to-one correspondence with the density pulses observed at 1 AU, during 0700--1700 UT on May 03. The spectral analysis of both the variations showed the same discrete frequencies of 0.48, 0.65 and 0.75 mHz, demonstrating that the solar wind density enhancements can cause detectable global geomagnetic disturbances. The observations, thus, provide a deeper insight into the possible causes and geomagnetic consequences of a prolonged weakly southward IMF-Bz condition.

Are Switchback boundaries observed by Parker Solar Probe closed?

Switchbacks are sudden and large deflections in the magnetic field that Parker Solar Probe frequently observes in the inner heliosphere. Their ubiquitous occurrence has prompted numerous studies to determine their nature and origin. Our goal is to describe the boundary of these switchbacks using a series of events detected during the spacecraft's first encounter with the Sun. Using FIELDS and SWEAP data, we investigate different methods for determining the boundary normal. The observed boundaries are arc-polarized structures with a rotation that is always contained in a plane. Classical minimum variance analysis (MVA) gives misleading results and overestimates the number of rotational discontinuities. We propose a robust geometric method to identify the nature of these discontinuities, which involves determining whether or not the plane that contains them also includes the origin ($B=0$). Most boundaries appear to have the same characteristics as tangential discontinuities in the context of switchbacks, with little evidence for having rotational discontinuities. We find no effect of the size of the Parker spiral deviation. Furthermore, the thickness of the boundary is within MHD scales. We conclude that most of the switchback boundaries observed by Parker Solar Probe are likely to be closed, in contrast to previous studies. Our results suggest that their erosion may be much slower than expected. **2018-11-02, 2018 November 7**

Space weather effects on Earth's environment associated to the 24–25 October 2011 geomagnetic storm

E. [Blanch](#), S. Marsal, A. Segarra, J. M. Torta, D. Altadill and J. J. Curto

Space Weather, Volume 11, Issue 4, pages 153–168, April 2013

<http://onlinelibrary.wiley.com/doi/10.1002/swe.20035/abstract>

Space weather studies have increased due to human society dependence on spaceborne and terrestrial infrastructure vulnerable to its effects. In this paper, we present an interdisciplinary study of the effects of solar activity on the Earth's environment; specifically, we focus on the effects on the ionosphere and the geomagnetic field. A timeline of effects occurring on the Earth produced by one of the first relevant events of the present solar cycle (24–25 October 2011) is given. We have analyzed the solar wind shockwave from satellite data, the storm-time development, the ionospheric effects at global and local scales using the National Center for Atmospheric Research Thermosphere-Ionosphere-Electrodynamics General Circulation Model fed with geomagnetic field-aligned current data from the Active Magnetosphere and Planetary Electrodynamics Response Experiment, and ground ionosonde data from both hemispheres, at Ebre Observatory and Port Stanley locations. We have compared observed geomagnetic variations at high latitudes with those modeled by the National Center for Atmospheric Research Thermosphere-Ionosphere-Electrodynamics General Circulation Model. We have analyzed rapid geomagnetic variations (e.g., solar flare effect, storm commencement, Pi2) also on both hemispheres, at Ebre Observatory and Livingston Island locations. Finally, we have estimated geoelectric field and geomagnetically induced currents in the northeast of Spain (Catalonia) produced by this geomagnetic disturbance.

Energetic-particle-flux decreases related to magnetic cloud passages as observed by the Helios 1 and 2 spacecraft

J. J. [Blanco](#)¹, M. A. [Hidalgo](#)¹, R. [Gómez-Herrero](#)¹, J. [Rodríguez-Pacheco](#)¹, B. [Heber](#)², R. F. [Wimmer-Schweingruber](#)² and C. [Martín](#)

A&A 556, A146 (2013)

It has been observed that a magnetic cloud (MC) can affect the propagation conditions of solar energetic particles and low-energy cosmic rays. This effect is commonly observed as a decrease in the energetic-particle fluxes, which are partially excluded from the interior of the cloud. The twin spacecraft Helios 1 and Helios 2 explored the inner heliosphere between 0.29 AU and 1 AU from the mid 1970s to early 1980s. The E6 Experiment onboard Helios is the energetic-particle detector able to measure electrons, protons and alphas in the range of 300 keV/n to >50 MeV/n. It has been shown previously that, in absence of strong solar-particle events, the single detector rates of the E6 anti-coincidence and sapphire Cherenkov detectors are sensitive to cosmic rays with rigidities above GV. Because their statistical precision is in the order of hundreds of counts per second, both detectors are very well suited for studying the short-term decreases observed in their count rates during magnetic cloud passages. A total of 35 magnetic clouds have been identified at the Helios locations. Nineteen of them were free of solar energetic-particle contamination. This subset led us to investigate the effect of magnetic clouds on the galactic cosmic ray (GCR) flux. The depth of the decreases are studied in terms of the solar wind and magnetic field properties of the magnetic cloud. We found dependences with the MC magnetic field strength, magnetic rigidity and with the MC time of flight, with the latter supporting the idea of magnetically closed MCs, i.e. with the two legs rooted in the Sun. We also studied MC properties and found evidence of MC expansion during its journey through the inner heliosphere. **Table**

Observable Effects of Interplanetary Coronal Mass Ejections on Ground Level Neutron Monitor Count Rates

J. J. **Blanco**, E. Catalán, M. A. Hidalgo, J. Medina, O. García, J. Rodríguez-Pacheco
Solar Phys., Volume 284, Issue 1, pp 167-178, 2013

In this work, **non-recurrent Forbush decreases (FDs)** triggered by the passage of shock-driving interplanetary coronal mass ejections (ICMEs) have been analyzed. Fifty-nine ICMEs have been studied, but only 25 % of them were associated to a FD. We find that shock-driving magnetic clouds (MCs) produce deeper FDs than shock-driving ejecta. This fact can be explained regarding the observed growing trends between decreases in neutron monitor (NM) count rate and MC/ejecta speed and its associated rigidity. MCs are faster and have higher associated rigidities than ejecta. Also the deceleration of ICMEs seems to be a cause for producing FDs, as can be inferred from the decreasing trend between NM count rate and deceleration. This probably implies that the interaction between the ICME traveling from the corona to the Earth and the solar wind can play an important role in producing deeper FDs. Finally, we conclude that ejecta without flux rope topology are the ones less effective in unchaining FDs.

Interaction between magnetic clouds and the heliospheric current sheet at 1 AU as it is observed by one single observation point

J.J. **Blanco**, a, , M.A. Hidalgo, J. Rodríguez-Pacheco and J. Medina

Journal of Atmospheric and Solar-Terrestrial Physics, Volume 73, Issues 11-12, 2011, Pages 1339-1347

The effect of Magnetic Clouds (MCs) on the Heliospheric Current Sheet (HCS) local structure is yet an open question. Although it is widely accepted that a magnetic cloud has an important effect on the HCS shape, their structural relation, either the MC is part of the HCS or not, is not completely solved. Moreover, the problem grows up when trying to investigate three dimensional structures using one single observation point. We propose an approach to the MC-HCS study using magnetic models for the MC and local HCS structures, which are able of determining their relative orientation from one single spacecraft data. Three events have been selected in which an MC passage was observed close to HCS crossings. The results confirm the strong effect of MC passage on the HCS local orientation and they seem to be consistent with MCs propagating out of the HCS at 1 AU.

Interplanetary shocks and foreshocks observed by STEREO during 2007–2010†

X. **Blanco-Cano**, P. Kajdič, E. Aguilar-Rodríguez, C. T. Russell, L. K. Jian, J. G. Luhmann
JGR 2015

Interplanetary shocks in the heliosphere modify the solar wind through which they pass. In particular, shocks play an important role in particle acceleration. During the extended solar minimum (2007–2010) STEREO observed 65 forward shocks driven by stream interactions (SI), with magnetosonic Mach numbers $M_{ms} \approx 1.1-4.0$ and shock normal angles $\theta_{Bn} \sim 20-87^\circ$. We analyze the waves associated with these shocks and find that the region upstream can be permeated by whistler waves ($f \sim 1$ Hz) and/or ultra low frequency (ULF) waves ($f \sim 10^{-2}-10^{-1}$ Hz). While whistlers appear to be

generated at the shock, the origin of ULF waves is most probably associated with local kinetic ion instabilities. We find that when the Mach number (M_{ms}) is low and the shock is quasi-perpendicular ($\theta_{Bn} > 45^\circ$) whistler waves remain close to the shock. As M_{ms} increases, the shock profile changes and can develop a foot and overshoot associated with ion reflection and gyration. Whistler precursors can be superposed on the foot region, so that some quasi-perpendicular shocks have characteristics of both subcritical and supercritical shocks. When the shock is quasi-parallel ($\theta_{Bn} < 45^\circ$) a large foreshock with suprathermal ions and waves can form. Upstream there are whistler trains at higher frequencies whose characteristics can be slightly modified probably by reflected and/or leaked ions, and by almost circularly polarized waves at lower frequencies that may be locally generated by ion instabilities. In contrast with planetary bow shocks, most of the upstream waves studied here are mainly transverse and no steepening occurs. Some quasi-perpendicular shocks ($45^\circ < \theta_{Bn} < 60^\circ$) are preceded by ULF waves and ion foreshocks. Fluctuations downstream of quasi-parallel shocks tend to have larger amplitudes than waves in the sheath of quasi-perpendicular shocks. We compare SI driven shock properties with those of shocks generated by interplanetary coronal mass ejections (ICMEs). During the same years, STEREO observed 20 ICME driven shocks with $M_{ms} \approx 1.2-4.0$ and $\theta_{Bn} \sim 38-85^\circ$. We find that shocks driven by ICMEs tend to have larger proton foreshocks ($dr \sim 0.1$ AU) than shocks driven by stream interactions ($dr \leq 0.05$ AU). This difference of ion foreshock size should be linked to shock age: ICME driven shocks form at shorter distances to the Sun and therefore can energize particles for longer times as they propagate to 1 AU, while stream interaction shocks form closer to Earth's orbit, and have been accelerating ions for a shorter interval of time.

Kuramoto Model of Nonlinear Coupled Oscillators as a Way for Understanding Phase Synchronization: Application to Solar and Geomagnetic Indices

Elena M. [Blanter](#), Jean-Louis Le Mouél, Mikhail G. Shnirman, Vincent Courtillot
Solar Physics, Volume 289, Issue 11, pp 4309-4333 2014

We apply a Kuramoto model of nonlinear coupled oscillators to the simulation of slow variations of the phase difference between sunspot number [R I] and geomagnetic indices [aa and ζ]. The Kuramoto model is described for the particular case of two oscillators connected by symmetric coupling with quasi-stationary behavior, and its properties are investigated. By solving an inverse problem, we reconstruct the evolution of the couplings between pairs of indices [R I and aa , R I and ζ , aa and ζ], and interpret these in terms of the physics of the solar dynamo. The de-correlation between R I and geomagnetic indices found in Solar Cycle 20 by Le Mouél et al. (J. Geophys. Res. 117, A09103, 2012) is successfully reproduced by the Kuramoto model and corresponds to the alternation of the leading oscillator. Application of the Kuramoto model to the cross-correlations [$C(R I, \zeta)$ and $C(aa, \zeta)$] for ζ -indices computed in eight geomagnetic stations shows the latitudinal dependence of the mean phase difference. We discuss these results in terms of the solar-wind contribution to local geomagnetic indices [ζ].

Loss of synchronization in the 27-day spectral component of geomagnetic indices and its relationship with solar activity

Elena [Blanter](#), Jean-Louis Le Mouél, Mikhail Shnirman, Vincent Courtillot,
JASTP, v. 117, pp. 71-80, 2014

<http://www.sciencedirect.com/science/article/pii/S1364682614000868>

We investigate the “27-day” spectral component of different global (aa and Dst) and local (ζ) geomagnetic indices in two period ranges relevant to the Sun's synodic rotation, as manifested by magnetic activity: 24–28 days (short) and 28–32 days (long). Cross-correlation analysis of the respective energies of the short and long periods of the 27-day rotation signal in the same geomagnetic index reveals well-defined de-synchronization events during certain solar cycles. The largest de-synchronization in the past century occurred during Solar Cycle 21. De-synchronization events first occur in indices of the Dst (and ζ) family, and then in indices of the aa family. We found no evidence that the strength of the de-synchronization of the solar rotation signal in the ζ -index would depend on geomagnetic latitude. Applying the same analysis to proper solar indices (sunspot number, $F10.7$ radio flux, interplanetary magnetic field (IMF) series, solar wind speed), we find that only the B_z component of the IMF demonstrates a de-synchronization, during Solar Cycle 21, between the energies of the 27-day solar rotation signal in the short and long period ranges. We discuss possible implications of these results with respect to the evolution of the toroidal and poloidal components of the Sun's magnetic field and to its large-scale structures.

Data-Driven Classification of Coronal Hole and Streamer Belt Solar Wind

Téo [Bloch](#), [Clare Watt](#), [Mathew Owens](#), [Leland McInnes](#) & [Allan R. Macneil](#)

[Solar Physics](#) volume 295, Article number: 41 (2020)

<https://link.springer.com/content/pdf/10.1007/s11207-020-01609-z.pdf>

<https://doi.org/10.1007/s11207-020-01609-z>

We present two new solar wind origin classification schemes developed independently using unsupervised machine learning. The first scheme aims to classify solar wind into three types: coronal-hole wind, streamer-belt wind, and 'unclassified' which does not fit into either of the previous two categories. The second scheme independently derives three clusters from the data; the coronal-hole and streamer-belt winds, and a differing unclassified cluster. The classification schemes are created using non-evolving solar wind parameters, such as ion charge states and composition, measured during the three Ulysses fast latitude scans. The schemes are subsequently applied to the Ulysses and the Advanced Compositional Explorer (ACE) datasets. The first scheme is based on oxygen charge state ratio and proton specific entropy. The second uses these data, as well as the carbon charge state ratio, the alpha-to-proton ratio, the iron-to-oxygen ratio, and the mean iron charge state. Thus, the classification schemes are grounded in the properties of the solar source regions. Furthermore, the techniques used are selected specifically to reduce the introduction of subjective biases into the schemes. We demonstrate significant best case disparities (minimum $\approx 8\%$, maximum $\approx 22\%$) with the traditional fast and slow solar wind determined using speed thresholds. By comparing the results between the in- (ACE) and out-of-ecliptic (Ulysses) data, we find morphological differences in the structure of coronal-hole wind. Our results show how a data-driven approach to the classification of solar wind origins can yield results which differ from those obtained using other methods. As such, the results form an important part of the information required to validate how well current understanding of solar origins and the solar wind match with the data we have.

A Nonlinear System Science Approach to Find the Robust Solar Wind Drivers of the Multivariate Magnetosphere

S. [Blunier](#) , [B. Toledo](#) , [J. Rogan](#) , [J. A. Valdivia](#)

Space Weather e2020SW002634 2021

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2020SW002634>

We propose a method, based on Neural Networks, that detects the non-linear robust interplanetary solar wind variables, with varying delays, driving the coupled behavior of three geomagnetic indices (Dst, AL, and AU). As opposed to minimizing a prediction error, the method is based on degrading the prediction by distorting the inputs of the trained Neural Networks in order to highlight the most sensible drivers. We show that the z component of the magnetic field, the duskward oriented electric field, and the speed of the particles of the interplanetary medium, at particular time delays, seem to be the most efficient drivers of the three coupled geomagnetic indices. Using only the sensible or robust drivers in the model, we demonstrate that iterated predictions during geomagnetic storm are significantly improved from models that only use one of the outstanding drivers with multiple time delays. The derived robust non-linear Neural Network model is also a significant improvement over linear approximations, specially when used as iterated predictors.

HELCASTS Prediction of Planetary CME arrival times

[Boakes](#), Peter; [Moestl](#), Christian; [Davies](#), Jackie; [Harrison](#), Richard; [Byrne](#), Jason; [Barnes](#), David; [Isavnin](#), Al exey; [Kilpua](#), Emilia; [Rollett](#), Tanja

EGU General Assembly 2015, held 12-17 April, 2015 in Vienna, Austria. id.3601, 2015

We present the first results of CME arrival time prediction at different planetary locations and their comparison to the in situ data within the HELCASTS project. The EU FP7 HELCASTS (Heliospheric Cataloguing, Analysis & Techniques Service) is a European effort to consolidate the exploitation of the maturing field of heliospheric imaging. HELCASTS aims to catalogue solar wind transients, observed by the NASA STEREO Heliospheric Imager (HI) instruments, and validate different methods for the determination of their kinematic properties. This validation includes comparison with arrivals at Earth, and elsewhere in the heliosphere, as well as onsets at the Sun (<http://www.helcats-fp7.eu/>). A preliminary catalogue of manually identified CMEs, with over 1000 separate events, has been created from observations made by the STEREO/HI instruments covering the years 2007-2013. Initial speeds and directions of each CME have been derived through fitting the time elongation profile to the state of the art Self-Similar Expansion Fitting (SSEF) geometric technique (Davies et al., 2012). The technique assumes that, in the plane corresponding to the position angle of interest, CMEs can be modelled as circles subtending a fixed angular width to Sun-center and propagating anti-sunward in a fixed direction at a constant speed (we use an angular width of 30 degrees in our initial results). The model has advantages over previous geometric models (e.g. harmonic mean or fixed phi) as it allows one to predict whether a CME will 'hit' a specific heliospheric location, as well as to what degree (e.g. direct assault or glancing blow). We use correction formulae (Möstl and Davies, 2013) to convert CME speeds, direction and launch time to speed and arrival time at any in situ location. From the preliminary CME dataset, we derive arrival times for over 400 Earth-directed CMEs, and for over 100 Mercury-, Venus-, Mars- and Saturn-directed CMEs predicted to impact each planet. We

present statistics of predicted CME arrival properties. In addition, we independently identify CME arrival at in situ locations using magnetic field data from the Venus Express, Messenger, and Ulysses spacecraft and show first comparisons to predicted arrival times. The results hold important implications for space weather prediction at Earth and other locations, allowing model and predicted CME parameters to be compared to their in situ counterparts.

Estimation of the modulation level of cosmic rays at high energies

Pavol [Bobik](#), [M Putis](#), [Y L Kolesnyk](#), [B A Shakhov](#)

Monthly Notices of the Royal Astronomical Society, Volume 503, Issue 3, May 2021, Pages 3386–3393,

<https://doi.org/10.1093/mnras/stab597>

<https://watermark.silverchair.com/stab597.pdf>

In this article, we focus on the modulation of cosmic rays at high energies. The aim is to determine the limits of the ability of the heliosphere to modulate the intensities of cosmic rays in the inner heliosphere. We address the following questions: how large is the variation in cosmic rays intensities at high energies, i.e. close to 50, 100, and 200 GeV and above? What is the maximum energy at which modulation effects can be measured near the Earth? Specifically, we look at the magnitudes of the variation in cosmic rays intensity at 1 au over the period 1990–2012, at high energies. Attention is paid to energies of around 50, 100, and 150 GeV, where we can expect experimental results within the next decade.

Statistical Analysis of Solar Events Associated with Storm Sudden Commencements over One Year of Solar Maximum during Cycle 23: Propagation from the Sun to the Earth and Effects

Solar Phys. 293:75 2018

<https://arxiv.org/pdf/1803.07593.pdf>

<https://link.springer.com/content/pdf/10.1007%2Fs11207-018-1278-5.pdf>

Taking the 32 storm sudden commencements (SSCs) listed by the International Service of Geomagnetic Indices (ISGI) of the Observatory de l'Ebre during 2002 (solar activity maximum in Cycle 23) as a starting point, we performed a multi-criterion analysis based on observations (propagation time, velocity comparisons, sense of the magnetic field rotation, radio waves) to associate them with solar sources, identified their effects in the interplanetary medium, and looked at the response of the terrestrial ionized and neutral environment. We find that 28 SSCs can be related to 44 coronal mass ejections (CMEs), 15 with a unique CME and 13 with a series of multiple CMEs, among which 19 (68%) involved halo CMEs. Twelve of the 19 fastest CMEs with speeds greater than 1000 km s⁻¹ are halo CMEs. For the 44 CMEs, including 21 halo CMEs, the corresponding X-ray flare classes are: 3 X-class, 19 M-class, and 22 C-class flares. The probability for an SSC to occur is 75% if the CME is a halo CME. Among the 500, or even more, front-side, non-halo CMEs recorded in 2002, only 23 could be the source of an SSC, i.e.5%. The complex interactions between two (or more) CMEs and the modification of their trajectories have been examined using joint white-light and multiple-wavelength radio observations. The detection of long-lasting type IV bursts observed at metric–hectometric wavelengths is a very useful criterion for the CME–SSC events association. The events associated with the most depressed Dst values are also associated with type IV radio bursts. The four SSCs associated with a single shock at L1 correspond to four radio events exhibiting characteristics different from type IV radio bursts. The solar-wind structures at L1 after the 32 SSCs are 12 magnetic clouds (MCs), 6 interplanetary coronal mass ejections (ICMEs) without an MC structure, 4 miscellaneous structures, which cannot unambiguously be classified as ICMEs, 5 corotating or stream interaction regions (CIRs/SIRs), one CIR caused two SSCs, and 4 shock events; note that one CIR caused two SSCs. The 11 MCs listed in 3 or more MC catalogs covering the year 2002 are associated with SSCs. For the three most intense geomagnetic storms (based on Dst minima) related to MCs, we note two sudden increases of the Dst, at the arrival of the sheath and the arrival of the MC itself. In terms of geoeffectiveness, the relation between the CME speed and the magnetic-storm intensity, as characterized using the Dst magnetic index, is very complex, but generally CMEs with velocities at the Sun larger than 1000 km s⁻¹ have larger probabilities to trigger moderate or intense storms. The most geoeffective events are MCs, since 92% of them trigger moderate or intense storms, followed by ICMEs (33%). At best, CIRs/SIRs only cause weak storms. We show that these geoeffective events (ICMEs or MCs) trigger an increased and combined auroral kilometric radiation (AKR) and non-thermal continuum (NTC) wave activity in the magnetosphere, an enhanced convection in the ionosphere, and a stronger response in the thermosphere. However, this trend does not appear clearly in the coupling functions, which exhibit relatively weak correlations between the solar-wind energy input and the amplitude of various geomagnetic indices, whereas the role of the southward component of the solar-wind magnetic field is confirmed. Some saturation appears for Dst values <-100<-100 nT on the integrated values of the polar and auroral indices. **15 March 2002 , 22 March 2002, 17 April 2002**

Diagnostics of Corotating Interaction Regions with the kinetic properties of iron ions as determined with STEREO/PLASTIC

P **Bochsler**, M A Lee, R Karrer, L Ellis, C J Farrugia, A B Galvin, L M Kistler, H Kucharek, E Moebius, M A Popecki, K D C Simunac, L M Blush, H Daoudi, P Wurz, B Klecker, R F Wimmer-Schweingruber, B Thompson, J G Luhmann, C T Russell, L Jian, and A Optiz

Ann. Geophys., 28, 491-497, **2010**

STEREO/PLASTIC determines three-dimensional distributions of solar wind iron ions with unprecedented time resolution. Typically 300 to 1000 counts are registered within each 5 min time interval. For the present study we use the information contained in these distributions to characterize CIRs (Corotating Interaction Regions) in two test cases. We perform a consistency test for both the derived physical parameters and for the analytical model of CIRs of Lee (2000). At 1 AU we find that apart from compositional changes the most indicative parameter for marking the time when a CIR passes a spacecraft is the angular deflection of the flow vector of particles. Changes in particle densities and the changes in magnitudes of speeds are apparently less reliable indicators of stream interfaces.

Langmuir waves associated with magnetic holes in the solar wind

J. J. **Boldú**^{1,2}, D. B. Graham¹, M. Morooka¹, M. André¹, Yu. V. Khotyaintsev¹, T. Karlsson³, J.

Souček⁴, D. Piša⁴ and M. Maksimovic⁵

A&A 674, A220 (**2023**)

<https://www.aanda.org/articles/aa/pdf/2023/06/aa46100-23.pdf>

Context. Langmuir waves (electrostatic waves near the electron plasma frequency) are often observed in the solar wind and may play a role in the energy dissipation of electrons. The largest amplitude Langmuir waves are typically associated with type II and III solar radio bursts and planetary foreshocks. In addition, Langmuir waves not related to radio bursts occur in the solar wind, but their source is not well understood. Langmuir waves have been observed inside isolated magnetic holes, suggesting that magnetic holes play an important role in the generation of Langmuir waves. *Aims.* We provide the statistical distribution of Langmuir waves in the solar wind at different heliocentric distances. In particular, we investigate the relationship between magnetic holes and Langmuir waves. We identify possible source regions of Langmuir waves in the solar wind, other than radio bursts, by analyzing the local plasma conditions. *Methods.* We analyzed data from Solar Orbiter's Radio and Plasma Waves (RPW) and Magnetometer (MAG) instruments. We used the triggered electric field snapshots and onboard statistical data (STAT) of the Time Domain Sampler (TDS) of RPW to identify Langmuir waves and investigate their properties. The plasma densities were derived from the spacecraft potential estimated by RPW. The MAG data were used to monitor the background magnetic field and detect magnetic holes, which are defined as regions with an isolated decrease in $|B|$ of 50% or more compared to the background level. The statistical analysis was performed on data from 2020 to 2021, comprising heliocentric distances between 0.5 AU and 1 AU.

Results. We show that 78% of the Langmuir waves in the solar wind not connected to radio bursts occur in regions of local magnetic field depletions, including the regions classified as isolated magnetic holes. We also show that the Langmuir waves occur more frequently inside magnetic holes than in any other region in the solar wind, which indicates that magnetic holes are important source regions of solar wind Langmuir waves. We find that Langmuir waves associated with magnetic holes in the solar wind typically have lower amplitudes than those associated with radio bursts.

Dynamics of coronal mass ejections in the interplanetary medium:

A. **Borgazzi**, A. Lara, E. Echer and M. V. Alves

A&A 498 (**2009**) 885-889; **File**

Context. Coronal mass ejections (CMEs) are large plasma structures expelled from the low corona to the interplanetary space with a wide range of speeds. In the interplanetary medium CMEs suffer changes in their speeds because of interaction with the ambient solar wind.

Aims. To understand the interplanetary CME (ICME) dynamics, we analyze the interaction between these structures and the ambient solar wind (SW), approaching the problem from the hydrodynamic point of view.

Methods. We assume that the dynamics of the system is dominated by two kinds of drag-force dependence on speed (U), as $\sim U$ and $\sim U^2$. Furthermore, we propose a model that takes variations of the ICME radius (R) and SW density (ρ_{sw})

) into account as a function of the distance (x) as $R(x) = x^{0.78}$ and $\rho_{sw}(x) = 1/x^2$, respectively. Then, we solve the equation of motion and present exact solutions

Results. Considering CME speeds measured at a few solar radii and at one AU, we were able to constrain the values of the constants (viscosity and drag coefficient) for the linear (U) and quadratic (U^2) speed dependences, which seems to reproduce the ICME – SW system well. We found different solutions in which the concavity of the curves of the ICME speed profile changes, depending on the dominant factor, either the ICME radius or the SW density.

Conclusions. This work shows that the macroscopic ICME propagation may be described by the hydrodynamic theory and that it is possible to find analytical solutions for the ICME-SW interaction.

A Statistical Analysis of the Fluctuations in the Upstream and Downstream Plasmas of 109 Strong-Compression Interplanetary Shocks at 1 AU

Joseph E. **Borovsky**

JGR [Volume 125, Issue 6](#) June 2020 e2019JA027518

<https://agupubs.onlinelibrary.wiley.com/doi/10.1029/2019JA027518>

https://agupubs.onlinelibrary.wiley.com/doi/pdf/10.1029/2019JA027518?casa_token=fK3j0CL6N9oAAAAA:nVyVvLmO5v_RdDb-K8ywPdrvLiRa92BiFlibPrE3tjveR-AP2SiSPW4s6Jfq_h1rIq5xNSo1IwrZF2B4

The upstream and downstream plasmas of 109 strong-compression forward interplanetary shocks are statistically analyzed using 3-s measurements from the WIND spacecraft. The goal is a comparison of the fluctuation properties of downstream plasmas in comparison with the fluctuation properties of upstream plasmas in the inertial range of frequencies and the magnetic-structure range of spatial scales. The shocks all have density compression ratios of ~ 2 or more. When possible, each shock is categorized according to the type of solar wind plasma it propagates through: 15 shocks are in coronal-hole-origin plasma, 42 shocks are in streamer-belt-origin plasma, 36 shocks are in sector-reversal-region plasmas, and 11 shocks are in ejecta plasma. The statistical study examines magnetic field and velocity spectral indices, the Alfvénicity, the fluctuation amplitudes, Alfvén ratios, the degree of plasma inhomogeneity, and Taylor microscales, looking in particular at (1) fluctuation values downstream that are related to fluctuation values upstream and (2) systematic differences in fluctuation values associated with the type of plasma. It is argued that inhomogeneity of the downstream plasma can be caused by spatial variations in the shock normal angle θ_{Bn} caused by field direction variations in the upstream magnetic structure. The importance of determining the type of plasma that the shock propagates through is established. **23 January 2001**

Table 1 The Collection of 109 Strong-Compression Forward Interplanetary Shocks as Seen by the WIND Spacecraft and the Type of Solar Wind Plasma They Are Propagating Through (1995-1999)

Plasma and Magnetic-Field Structure of the Solar Wind at Inertial-Range Scale Sizes Discerned From Statistical Examinations of the Time-Series Measurements **Review**

Joseph E. **Borovsky**

Front. Astron. Space Sci., **2020** |

<https://doi.org/10.3389/fspas.2020.00020>

This paper reviews the properties of the magnetic and plasma structure of the solar wind in the inertial range of spatial scales ($500\text{--}5 \times 10^6$ km), corresponding to spacecraft timescales from 1 s to a few hr. Spacecraft data sets at 1 AU have been statistically analyzed to determine the structure properties. The magnetic structure of the solar wind often has a flux-tube texture, with the magnetic flux tube walls being strong current sheets and the field orientation varying strongly from tube to tube. The magnetic tubes also exhibit distinct plasma properties (e.g., number density, specific entropy), with variations in those properties from tube to tube. The ion composition also varies from tube to tube, as does the value of the electron heat flux. When the solar wind is Alfvénic, the magnetic structure of the solar wind moves outward from the Sun faster than the proton plasma does. In the reference frame moving outward with the structure, there are distinct field-aligned plasma flows within each flux tube. In the frame moving with the magnetic structure the velocity component perpendicular to the field is approximately zero; this indicates that there is little or no evolution of the magnetic structure as it moves outward from the Sun. Large sudden velocity shears are seen across the boundaries between the magnetic flux tubes as the magnetic field rotates and the field-aligned flow rotates. The effect of the solar-wind current sheets on the magnetic power spectral density of the solar wind is examined: the current sheets are found to dominate the spectral properties of the solar wind.

On the Motion of the Heliospheric Magnetic Structure Through the Solar Wind Plasma

Joseph E. **Borovsky**

JGR [Volume125, Issue2](#) February 2020 e2019JA027377

<https://agupubs.onlinelibrary.wiley.com/doi/pdf/10.1029/2019JA027377>

A reference frame in the solar wind can often be found wherein the flow vector v is everywhere approximately parallel to the magnetic field vector B . This is the frame of the heliospheric magnetic structure moving relative to the plasma. Since $v \perp B$ is very small in this reference frame, the magnetic structure appears to have little temporal evolution. The structure moves outward away from the Sun faster than the plasma flow. Even for highly Alfvénic plasma, the structure does not move at the Alfvén speed relative to the proton plasma, rather it moves at $\sim 0.7 v_A$. This may be caused by the spread in the vector directions of the local magnetic field. The degree of inhomogeneity of the plasma is hypothesized to control the motion of the magnetic structure through the plasma. If so, non-Alfvénicity may be owed to an inability of Alfvénic perturbations to coherently propagate from Alfvénic injections at the Sun. Schemes that mathematically advect magnetic and plasma structure from upstream solar wind monitors to the Earth may be improved by calculating and including the motion of the structure relative to the solar wind velocity vector.

Some Properties of the Solar Wind Turbulence at 1 AU Statistically Examined in the Different Types of Solar Wind Plasma

Joseph E. **Borovsky**, Michael H. Denton, Charles W. Smith

JGR [Volume124, Issue4](#) April 2019 Pages 2406-2424

sci-hub.se/10.1029/2019JA026580

A four-plasma classification scheme is used to categorize the ACE solar wind data set into four types of plasma: (1) coronal-hole-origin plasma, (2) streamer-belt-origin plasma, (3) sector-reversal-region plasma, and (4) ejecta. The statistical properties of the solar wind fluctuations at 1 AU are analyzed for each of the four types of plasma in the years 1998–2008 using ACE magnetic field and plasma measurements. Between the four types of solar wind plasma there are subtle statistical differences in the spectral indices of (a) trace- B , (b) trace- v , (c) total energy, (d) magnetic intensity, and (e) plasma number density. Between the four types of plasma there are significant statistical differences (a) in the Elsässer inward and outward spectral indices, (b) in the outward imbalance, (c) in the Alfvénicity, (d) in the normalized vector- B , vector- v , magnetic intensity, and number density fluctuation amplitudes, (e) in the population of strong current sheets, (f) in the population of sudden velocity shears, (g) in the anisotropies of magnetic field and velocity fluctuations, and (h) in the parallel-to- B magnetic field fluctuation spectral index. It is argued that the four-plasma categorization scheme is superior to a slow-versus-fast categorization for the study of turbulence and fluctuations in the solar wind.

On the Origins of the Intercorrelations between Solar-Wind Variables

Joseph E. **Borovsky**

JGR Volume 123, Issue 1 January 2018 Pages 20–29

<http://sci-hub.tw/10.1002/2017JA024650>

sci-hub.se/10.1002/2017JA024650

It is well known that the time variations of the diverse solar-wind variables at 1 AU (e.g. solar-wind speed, density, proton temperature, electron temperature, magnetic-field strength, specific entropy, heavy-ion charge-state densities, electron strahl intensity) are highly intercorrelated with each other. In correlation studies of the driving of the Earth's magnetosphere-ionosphere-thermosphere system by the solar wind, these solar-wind intercorrelations make determining cause and effect very difficult. In this report analysis of solar-wind spacecraft measurements and compressible-fluid computer simulations are used to study the origins of the solar-wind intercorrelations. Two causes are found: (1) synchronized changes in the values of the solar-wind variables as the plasma types of the solar wind are switched by solar rotation and (2) dynamic interactions (compressions and rarefactions) in the solar wind between the Sun and the Earth. These findings provide an incremental increase in the understanding of how the Sun-Earth system operates.

Is the Dst Index Sufficient to Define All Geospace Storms?

Joseph E. **Borovsky**, Yuri Shprits

JGR 2017

<http://onlinelibrary.wiley.com/doi/10.1002/2017JA024679/pdf>

The purpose of this commentary is (1) to raise awareness about some shortcomings of the use of the Dst index to identify storms, to gauge storm intensity, and to represent stormtime space-weather phenomena and (2) to initiate discussions about different types of storms and about improved identifiers for different types of storms.

The trailing edges of high-speed streams at 1 AU

Joseph E. Borovsky, Michael H. Denton

JGR Volume 121, Issue 7 July 2016 Pages 6107–6140

The trailing-edge rarefactions of 54 high-speed streams at 1 AU are analyzed. The temporal durations of the trailing-edge rarefactions agree with ballistic calculations based on the observed speeds of the fast and slow wind bounding the rarefactions. A methodology is developed to measure solar-wind compression and rarefaction using the orientations of solar-wind current sheets. One focus is to determine the signature that best describes the location of the trailing-edge stream interface between coronal-hole-origin plasma and streamer-belt-origin plasma; based on the current-sheet orientations, on the magnetic-field strength, on the intensity of the electron strahl, and on the intensity of the negative vorticity, an inflection point in the temporal profile of the solar-wind velocity is taken as the best indicator of the trailing-edge stream interface. Computer simulations support this choice. Using superposed-epoch analysis, the plasma properties and turbulence properties of trailing-edge rarefactions are surveyed. Whereas the signatures of the coronal-hole/streamer-belt (slow-wind/fast-wind) boundary in the leading edge (corotating interaction region) stream interface are simultaneous, they are not simultaneous in the trailing edge, with ion-charge-state signatures occurring on average 13.7 h prior to the proton entropy signature. It is suggested that differences in the leading and trailing edges of coronal holes on the Sun might account for the differences in the leading and trailing edges of high-speed streams at 1 AU: the formation timescales, heating timescales, and charge-state-equilibration timescales of closed flux loops in the corona might be involved.

The differences between storms driven by helmet streamer CIRs and storms driven by pseudostreamer CIRs.

Borovsky JE, Denton MH

(2013) JGRA 118: 5506-5521

Differences between CME-driven storms and CIR-driven storms.

Borovsky, J. E., and Denton, M. H.

2006. J. Geophys. Res., 111, A07S08, doi:10.1029/2005JA011447.

sci-hub.se/10.1029/2005JA011447

Twenty one differences between CME-driven geomagnetic storms and CIR-driven geomagnetic storms are tabulated. (CME-driven includes driving by CME sheaths, by magnetic clouds, and by ejecta; CIR-driven includes driving by the associated recurring high-speed streams.) These differences involve the bow shock, the magnetosheath, the radiation belts, the ring current, the aurora, the Earth's plasma sheet, magnetospheric convection, ULF pulsations, spacecraft charging in the magnetosphere, and the saturation of the polar cap potential. CME-driven storms are brief, have denser plasma sheets, have strong ring currents and Dst, have solar energetic particle events, and can produce great auroras and dangerous geomagnetically induced currents; CIR-driven storms are of longer duration, have hotter plasmas and stronger spacecraft charging, and produce high fluxes of relativistic electrons. Further, the magnetosphere is more likely to be preconditioned with dense plasmas prior to CIR-driven storms than it is prior to CME-driven storms. CME-driven storms pose more of a problem for Earth-based electrical systems; CIR-driven storms pose more of a problem for space-based assets.

Propagation of Cosmic Rays in Heliosphere: the HelMod Model

M.J. Boschini, S. Della Torre, M. Gervasi, G. La Vacca, P. G. Rancoita

Advances in Space Research 62 (2018) 2859-2879

<https://arxiv.org/pdf/1704.03733.pdf>

The heliospheric modulation model \helmod{} is a two dimensional treatment dealing with the helio-colatitude and radial distance from Sun and is employed to solve the transport-equation for the GCR propagation through the heliosphere down to Earth. This work presents the current version 3 of the \helmod{} model and reviews how main processes involved in GCR propagation were implemented.~The treatment includes the so-called particle drift effects -- ~e.g., those resulting, for instance, from the extension of the neutral current sheet inside the heliosphere and from the curvature and gradient of the IMF --, which affect the transport of particles entering the solar cavity as a function of their charge sign.~The \helmod{} model is capable to provide modulated spectra which well agree within the experimental errors with those measured by AMS-01, BESS, PAMELA and AMS-02 during the solar cycles 23 and 24.~Furthermore, the counting rate measured by Ulysses at +/- 80degree of solar latitude and 1 to 5\,AU was also found in agreement with that expected by \helmod{} code version 3.

A Twenty-First Century View of the March 1989 Magnetic Storm

D.H. Boteler

Space Weather [Volume17, Issue10](#) Pages 1427-1441 2019

<https://doi.org/10.1029/2019SW002278>

<https://agupubs.onlinelibrary.wiley.com/doi/10.1029/2019SW002278>

sci-hub.se/10.1029/2019sw002278

On March 13, 1989, the largest magnetic storm of the last century caused widespread effects on power systems including a blackout of the Hydro-Québec system. Since then this event has become the archetypal disturbance for examining the geomagnetic hazard to power systems. However, even 30 years on from 1989, the story of exactly what happened in March 1989 is far from complete. This paper re-examines the information available about the March 1989 event and uses this to construct a timeline and description of the space weather phenomena and how they caused the power system effects. The evidence shows that the disturbance was caused by two coronal mass ejections (CMEs): the first associated with a X4.5 flare on March 10 and the second linked to a M7.3 flare on March 12. The arrival of the interplanetary coronal mass ejection (ICME) shock fronts caused storm sudden commencements (SSC) at 01.27 UT and 07.43 UT on March 13. The transit time and speed of the first (second) ICME shock are 54.5 hrs (31.5 hrs) and 760 km/sec (1320 km/sec). Empirical relations are used to estimate solar wind speed and southward IMF, B_s , and give values of $v=980$ km/sec, $B_s=40$ nT to 60nT at the peak of the storm. Key findings are that the second SSC occurred at the same time as the substorm that impacted the Hydro-Québec system and indicates that external triggering of the substorm may have contributed to a faster substorm onset than might otherwise have occurred. This caused the production of larger geomagnetically induced currents (GIC) that caused the Hydro-Québec blackout. The March 1989 storm had the largest recorded value of the Dst index representing the size of the magnetic storm main phase, but the Hydro-Québec blackout occurred early in the storm when the Dst value was less disturbed. Only later in the storm did Dst reach its peak value. At this time an expansion of the auroral oval brought disturbances to lower latitudes where they caused power system problems in the US, UK and Sweden.

Comparison of CME and ICME Structures Derived from Remote-Sensing and In Situ Observations

V. Bothmer, N. Mrotzek

[Solar Physics](#) November 2017, 292:157

<https://link.springer.com/article/10.1007/s11207-017-1171-7>

We present results from the comparison of the near-Sun and in situ analysis of two Earth-directed coronal mass ejections (CMEs) with different 3D orientations and solar source region characteristics. The CME on **14 July 2000**, the so-called Bastille Day storm, a well-studied event, was observed from a single-point perspective by the Large Angle and Spectrometric Coronagraph (LASCO) onboard the Solar and Heliospheric Observatory (SOHO). It caused a major geomagnetic storm with a peak K_p of 9. The CME originated from a magnetic bipolar photospheric source region with the polarity inversion line being oriented rather parallel to the heliographic equator. In contrast, the CME on **29 September 2013**, which caused a geomagnetic storm with a peak K_p intensity of 8-, originated from a magnetic quadrupolar photospheric source region with the polarity inversion line between the two bipoles almost vertically oriented with respect to the heliographic equator. The results of a graduated cylindrical shell (GCS) analysis of the CMEs near the Sun are compared with the minimum variance analysis (MVA) of the magnetic field structure of the interplanetary CME (ICME) measured in situ near Earth's orbit. The results are in good agreement for the September 2013 CME and ICME, whereas the July 2000 ICME appears substantially inclined near Earth's orbit. The discrepancy can likely be explained taking into account kinks in the CME's near-Sun structure of the CME that expands into the interplanetary medium.

Sources of magnetic helicity over solar cycle

Bothmer, V.

Proc. ISCS Symp. ESA-SP-535, 2003, File

The magnetic field characteristics of a sample set of helical magnetic flux rope ICMEs (magnetic clouds) observed by the Wind and ACE satellites in solar cycle 23 and their related space weather effects are investigated. The solar source regions of the magnetic clouds were identified using remote sensing observations of the SOHO, Yohkoh and TRACE spacecraft together with ground-based $H\alpha$ images. Each cloud observed at 1 AU could be uniquely associated with a well defined frontside halo CME some days before the cloud's arrival at 1 AU. The hemispheric origin is consistent with

the expected hemispheric helicity pattern. The space weather effects of the clouds were quite variable, depending on their internal magnetic field configuration and speed of propagation

The structure and origin of magnetic clouds in the solar wind

V. [Bothmer](#)^{1*} and R. Schwenn

Ann. Geophysicae 16, 1±24 (1998), [File](#)

Plasma and magnetic field data from the Helios 1/2 spacecraft have been used to investigate the structure of magnetic clouds (MCs) in the inner heliosphere. 46 MCs were identified in the Helios data for the period 1974-1981 between 0.3 and 1 AU. 85% of the MCs were associated with fast-forward interplanetary shock waves, supporting the close association between MCs and SMEs (solar mass ejections). Seven MCs were identified as direct consequences of Helios-directed SMEs, and the passage of MCs agreed with that of interplanetary plasma clouds (IPCs) identified as white-light brightness enhancements in the Helios photometer data. The total (plasma and magnetic field) pressure in MCs was higher and the plasma- β lower than in the surrounding solar wind. Minimum variance analysis (MVA) showed that MCs can best be described as large-scale quasi-cylindrical magnetic flux tubes. The axes of the flux tubes usually had a small inclination to the ecliptic plane, with their azimuthal direction close to the east-west direction. The large-scale flux tube model for MCs was validated by the analysis of multi-spacecraft observations. MCs were observed over a range of up to $\sim 60^\circ$ in solar longitude in the ecliptic having the same magnetic configuration. The Helios observations further showed that over-expansion is a common feature of MCs. From a combined study of Helios, Voyager and IMP data we found that the radial diameter of MCs increases between 0.3 and 4.2 AU proportional to the distance, R , from the Sun as $R^{0.8}$ (R in AU). The density decrease inside MCs was found to be proportional to $R^{-2.4}$, thus being stronger compared to the average solar wind. Four different magnetic configurations, as expected from the flux-tube concept, for MCs have been observed in situ by the Helios probes. MCs with left- and right-handed magnetic helicity occurred with about equal frequencies during 1974-1981, but surprisingly, the majority (74%) of the MCs had a south to north (SN) rotation of the magnetic field vector relative to the ecliptic. In contrast, an investigation of solar wind data obtained near Earth's orbit during 1984-1991 showed a preference for NS-clouds. A direct correlation was found between MCs and large quiescent filament disappearances (disappearance brusques, DBs). The magnetic configurations of the filaments, as inferred from the orientation of the prominence axis, the polarity of the overlying field lines and the hemispheric helicity pattern observed for filaments, agreed well with the in situ observed magnetic structure of the associated MCs. The results support the model of MCs as large-scale expanding quasi-cylindrical magnetic flux tubes in the solar wind, most likely caused by SMEs associated with eruptions of large quiescent filaments. We suggest that the hemispheric dependence of the magnetic helicity structure observed for solar filaments can explain the preferred orientation of MCs in interplanetary space as well as their solar cycle behavior. However, the white-light features of SMEs and the measured volumes of their interplanetary counterparts suggest that MCs may not simply be just $H<\alpha>$ -prominences, but that SMEs likely convect large-scale coronal loops overlying the prominence axis out of the solar atmosphere.

Eruptive prominences as sources of magnetic clouds in the solar wind,

Towards an AI-based understanding of the solar wind: A critical data analysis of ACE data.

[Bouriat](#) S, Vandame P, Barthélémy M and Chanutot J

(2022) Front. Astron. Space Sci. 9: 980759.

doi: 10.3389/fspas.2022.980759

<https://www.frontiersin.org/articles/10.3389/fspas.2022.980759/pdf>

All artificial intelligence models today require preprocessed and cleaned data to work properly. This crucial step depends on the quality of the data analysis being done. The Space Weather community increased its use of AI in the past few years, but a thorough data analysis addressing all the potential issues is not always performed beforehand. Here is an analysis of a largely used dataset: Level-2 Advanced Composition Explorer's SWEPAM and MAG measurements from 1998 to 2021 by the ACE Science Center. This work contains guidelines and highlights issues in the ACE data that are likely to be found in other space weather datasets: missing values, inconsistency in distributions, hidden information in statistics, etc. Amongst all specificities of this data, the following can seriously impact the use of algorithms: Histograms are not uniform distributions at all, but sometime Gaussian or Laplacian. Algorithms will be inconsistent in the learning samples as some rare cases will be underrepresented. Gaussian distributions could be overly brought by Gaussian noise from measurements and the signal-to-noise ratio is difficult to estimate.

Models will not be reproducible from year to year due to high changes in histograms over time. This high dependence on the solar cycle suggests that one should have at least 11 consecutive years of data to train the algorithm.

Rounding of ion temperatures values to different orders of magnitude throughout the data, (probably due to a fixed number of bits on which measurements are coded) will bias the model by wrongly over-representing or under-representing some values.

There is an extensive number of missing values (e.g., 41.59% for ion density) that cannot be implemented without pre-processing. Each possible pre-processing is different and subjective depending on one's underlying objectives

A linear model will not be able to accurately model the data. Our linear analysis (e.g., PCA), struggles to explain the data and their relationships. However, non-linear relationships between data seem to exist.

Data seem cyclic: we witness the apparition of the solar cycle and the synodic rotation period of the Sun when looking at autocorrelations.

Some suggestions are given to address the issues described to enable usage of the dataset despite these challenges.

Turbulence Characteristics of Switchback and Nonswitchback Intervals Observed by Parker Solar Probe

Sofiane [Bourouaine](#)^{1,2}, Jean C. Perez¹, Kristopher G. Klein³, Christopher H. K. Chen⁴, Mihailo Martinović³, Stuart D. Bale^{4,5,6,7}, Justin C. Kasper⁸, and Nour E. Raouafi²

<https://iopscience.iop.org/article/10.3847/2041-8213/abbd4a/pdf>

We use Parker Solar Probe (PSP) in situ measurements to analyze the characteristics of solar wind turbulence during the first solar encounter covering radial distances between 35.7R_☉ and 41.7R_☉. In our analysis we isolate so-called switchback (SB) intervals (folded magnetic field lines) from nonswitchback (NSB) intervals, which mainly follow the Parker spiral field. Using a technique based on conditioned correlation functions, we estimate the power spectra of Elsasser, magnetic, and bulk velocity fields separately in the SB and NSB intervals. In comparing the turbulent energy spectra of the two types of intervals, we find the following characteristics: (1) The decorrelation length of the backward-propagating Elsasser field z^- is larger in the NSB intervals than the one in the SB intervals; (2) the magnetic power spectrum in SB intervals is steeper, with spectral index close to $-5/3$, than in NSB intervals, which have a spectral index close to $-3/2$; (3) both SB and NSB turbulence are imbalanced with NSB having the largest cross-helicity, (4) the residual energy is larger in the SB intervals than in NSB, and (5) the analyzed fluctuations are dominated by Alfvénic fluctuations that are propagating in the sunward (antisunward) direction for the SB (NSB) turbulence. These observed features provide further evidence that the switchbacks observed by PSP are associated with folded magnetic field lines giving insight into their turbulence nature.

Inner-Heliosphere Signatures of Ion-Scale Dissipation and Nonlinear Interaction

We perform a statistical study of the turbulent power spectrum at inertial and kinetic scales observed during the first perihelion encounter of Parker Solar Probe. We find that often there is an extremely steep scaling range of the power spectrum just above the ion-kinetic scales, similar to prior observations at 1 AU, with a power-law index of around -4 . Based on our measurements, we demonstrate that either a significant ($>50\%$) fraction of the total turbulent energy flux is dissipated in this range of scales, or the characteristic nonlinear interaction time of the turbulence decreases dramatically from the expectation based solely on the dispersive nature of nonlinearly interacting kinetic Alfvén waves.

Ion Scale Electromagnetic Waves in the Inner Heliosphere

ApJ **2019**

<https://arxiv.org/pdf/1912.02361.pdf>

Understanding the physical processes in the solar wind and corona which actively contribute to heating, acceleration, and dissipation is a primary objective of NASA's **Parker Solar Probe (PSP)** mission. Observations of coherent electromagnetic waves at ion scales suggests that linear cyclotron resonance and non-linear processes are dynamically relevant in the inner heliosphere. A wavelet-based statistical study of coherent waves in the first perihelion encounter of PSP demonstrates the presence of transverse electromagnetic waves at ion resonant scales which are observed in 30-50% of radial field intervals. Average wave amplitudes of approximately 4 nT are measured, while the mean duration of wave events is of order 20 seconds; however long duration wave events can exist without interruption on hour-long timescales. Though ion scale waves are preferentially observed during intervals with a radial mean magnetic field, we show that measurement constraints, associated with single spacecraft sampling of quasi-parallel waves superposed with anisotropic turbulence, render the measured quasi-parallel ion-wave spectrum unobservable when the mean magnetic field is oblique to the solar wind flow; these results imply that the occurrence of coherent ion-scale waves is not limited to a radial field configuration. The lack of strong radial scaling of characteristic wave amplitudes and duration suggests that the waves are generated $\{\em{in-situ}\}$ through plasma instabilities. Additionally, observations of proton distribution functions indicate that temperature anisotropy may drive the observed ion-scale waves. **Oct 31- Nov 11, 2018**

THE SOLAR ERUPTION OF 2005 MAY 13 AND ITS EFFECTS: LONG-BASELINE INTERPLANETARY SCINTILLATION OBSERVATIONS OF THE EARTH-DIRECTED CORONAL MASS EJECTION

Data derived NARMAX Dst model

Boynton, R. J.; Balikhin, M. A.; Billings, S. A.; Sharma, A. S.; Amariutei, O. A.

Annales Geophysicae, Volume 29, Issue 6, **2011**, pp.965-971

<http://www.ann-geophys.net/29/965/2011/angeo-29-965-2011.pdf>

The NARMAX OLS-ERR methodology is applied to identify a mathematical model for the dynamics of the Dst index. The NARMAX OLS-ERR algorithm, which is widely used in the field of system identification, is able to identify a mathematical model for a wide class of nonlinear systems using input and output data. Solar wind-magnetosphere coupling functions, derived from analytical or data based methods, are employed as the inputs to such models and the outputs are geomagnetic indices. The newly deduced coupling function, $p1/2V4/3BT\sin6(\theta/2)$, has been implemented as an input to model the Dst dynamics. It was shown that the identified model has a very good forecasting ability, especially with the geomagnetic storms.

Inner Structure of CME Shock Fronts Revealed by the Electromotive Force and Turbulent Transport Coefficients in Helios-2 Observations

Philippe-A. **Bourdin** (1), **Bernhard Hofer** (1,2), **Yasuhito Narita** (1,2,3)

ApJ **855** 111 **2018**

<https://arxiv.org/pdf/1802.10111.pdf>

<http://sci-hub.tw/10.3847/1538-4357/aaae04>

Electromotive force is an essential quantity in dynamo theory. During a coronal mass ejection (CME), magnetic helicity gets decoupled from the Sun and advected into the heliosphere with the solar wind. Eventually, a heliospheric magnetic transient event might pass by a spacecraft, such as the Helios space observatories. Our aim is to investigate the electromotive force, the kinetic helicity effect (α term), the turbulent diffusion (β term) and the cross-helicity effect (γ term) in the inner heliosphere below 1 au. We set up a one-dimensional model of the solar wind velocity and magnetic field for a hypothetical interplanetary CME. Because turbulent structures within the solar wind evolve much slower than this structure needs to pass by the spacecraft, we use a reduced curl operator to compute the current density and vorticity. We test our CME shock-front model against an observed magnetic transient that passes by the Helios-2 spacecraft. At the peak of the fluctuations in this event we find strongly enhanced α , β and γ terms, as well as a strong peak in the total electromotive force. Our method allows us to automatically identify magnetic transient events from any in-situ spacecraft observations that contain magnetic field and plasma velocity data of the solar wind.

Scaling Laws for Dynamic Solar Loops

Stephen J. **Bradshaw**¹ and A. Gordon Emslie²

2020 ApJ 904 141

<https://doi.org/10.3847/1538-4357/abbf50>

The scaling laws that relate the peak temperature T_M and volumetric heating rate E_H to the pressure P and length L for static coronal loops were established over 40 yr ago; they have proved to be of immense value in a wide range of studies. Here we extend these scaling laws to dynamic loops, where enthalpy flux becomes important to the energy balance, and study impulsive heating/filling characterized by upward enthalpy flows. We show that for collision-dominated thermal conduction, the functional dependencies of the scaling laws are the same as for the static case, when the radiative losses scale as $T^{-1/2}$, but with a different constant of proportionality that depends on the Mach number M of the flow. The dependence on the Mach number is such that the scaling laws for low to moderate Mach number flows are almost indistinguishable from the static case. When thermal conduction is limited by turbulent processes, however, the much weaker dependence of the scattering mean free path (and hence thermal conduction coefficient) on temperature leads to a limiting Mach number for return enthalpy fluxes driven by thermal conduction between the corona and chromosphere.

Coronal mass ejection deformation at 0.1 au observed by WISPR

Carlos R. **Braga**, [Angelos Vourlidis](#), [Paulett C. Liewer](#), [Phillip Hess](#), [Guillermo Stenborg](#), [Pete Riley](#)

ApJ 938 13 2022

<https://arxiv.org/pdf/2209.13057.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac90bf/pdf>

Although coronal mass ejections (CMEs) resembling flux ropes generally expand self-similarly, deformations along their fronts have been reported in observations and simulations. We present evidence of one CME becoming deformed after a period of self-similarly expansion in the corona. The event was observed by multiple white-light imagers on **January 20-22, 2021**. The change in shape is evident in observations from the heliospheric imagers from the Wide-Field Imager for Solar Probe Plus (WISPR), which observe this CME for ~ 44 hours. We reconstruct the CME using forward-fitting models. In the first hours, observations are consistent with a self-similar expansion but later on the front flattens forming a dimple. Our interpretation is that the CME becomes deformed at ~ 0.1 au due to differences in the background solar wind speeds. The CME expands more at higher latitudes, where the background solar wind is faster. We consider other possible causes for deformations, such as loss of coherence and slow-mode shocks. The CME deformation seems to cause a time-of-arrival error of 16 hours at ~ 0.5 au. The deformation is clear only in the WISPR observations and, it thus, would have been missed by 1-AU coronagraphs. Such deformations may help explain the time-of-arrival errors in events where only coronagraph observations are available.

Coronal mass ejections observed by heliospheric imagers at 0.2 and 1 au

The events on April 1 and 2, 2019

Carlos R. **Braga**^{1,2} and Angelos Vourlidis

A&A 650, A31 (2021)

<https://arxiv.org/pdf/2011.05229.pdf>

<https://www.aanda.org/articles/aa/pdf/2021/06/aa39490-20.pdf>

<https://doi.org/10.1051/0004-6361/202039490>

Context. We study two coronal mass ejections (CMEs) observed between **April 1 to 2, 2019** by both the inner Wide-Field Imager for Parker Solar Probe (WISPR-I) onboard the Parker Solar Probe (PSP) spacecraft (located between about 46 and 38 solar radii during this period) and the inner heliospheric imager (HI-1) onboard the Solar Terrestrial Relations Observatory Ahead (STEREO-A) spacecraft, orbiting the Sun at about 0.96 au. This is the first study of CME observations from two viewpoints in similar directions but at considerably different solar distances.

Aims. Our objective is to derive CME kinematics from WISPR-I observations and to compare them with results from HI-1. This allows us to understand how the PSP observations affect the CME kinematics, especially due to its proximity to the Sun.

Methods. We estimated the CME positions, speeds, accelerations, propagation directions, and longitudinal deflections using imaging observations from two spacecrafts and a set of analytical expressions that consider the CME as a point structure and take the rapid change in spacecraft position into account. We derived the kinematics using each viewpoint independently and both viewpoints as a constraint.

Results. We found that both CMEs are slow (< 400 km s^{-1}), propagating eastward of the Sun-Earth line (westward of PSP and STEREO-A). The second CME seems to accelerate between ~ 0.1 and ~ 0.2 au and deflect westward with an angular speed consistent with the solar rotation speed. We found some discrepancies in the CME solar distance (up to

0.05 au, particularly for CME #1), latitude (up to $\sim 10^\circ$), and longitude (up to 24°) when comparing results from different fit cases (different observations or set of free parameters).

Conclusions. Discrepancies in longitude are likely due to the feature that is tracked visually, rather than instrumental biases or fit assumptions. For similar reasons, the CME #1 solar distance, as derived from WISPR-I observations, is larger than the HI-1 result, regardless of the fit parameters considered. Error estimates for CME kinematics do not show any clear trend associated with the observing instrument. The source region location and the lack of any clear in situ counterparts (both at near-Earth and at PSP) support our estimate of the propagation direction for both events.

Predicting the Time-of-Arrival of Coronal Mass Ejections at Earth From Heliospheric Imaging Observations

Carlos Roberto [Braga](#), [Angelos Vourlidis](#), [Guillermo Stenborg](#), [Alisson Dal Lago](#), [Rafael Rodrigues Souza de Mendonça](#), [Ezequiel Echer](#)

JGR [Volume125, Issue9](#) e2020JA027885 2020

<https://arxiv.org/pdf/2008.09005.pdf>

<https://doi.org/10.1029/2020JA027885>

The Time-of-Arrival (ToA) of coronal mass ejections (CME) at Earth is a key parameter due to the space weather phenomena associated with the CME arrival, such as intense geomagnetic storms. Despite the incremental use of new instrumentation and the development of novel methodologies, ToA estimated errors remain above 10 hours on average. Here, we investigate the prediction of the ToA of CMEs using observations from heliospheric imagers, i.e., from heliocentric distances higher than those covered by the existent coronagraphs. In order to perform this work we analyse 14 CMEs observed by the heliospheric imagers HI-1 onboard the twin STEREO spacecraft to determine their front location and speed. The kinematic parameters are derived with a new technique based on the Elliptical Conversion (ElCon) method, which uses simultaneous observations from the two viewpoints from STEREO. Outside the field of view of the instruments, we assume that the dynamics of the CME evolution is controlled by aerodynamic drag, i.e., a force resulting from the interaction with particles from the background solar wind. To model the drag force we use a physical model that allows us to derive its parameters without the need to rely on drag coefficients derived empirically. We found a CME ToA mean error of 1.6 ± 8.0 hours ToA and a mean absolute error of 6.9 ± 3.9 hours for a set of 14 events. The results suggest that observations from HI-1 lead to estimates with similar errors to observations from coronagraphs. **2010-03-19, 03-Apr-2010, 09-Apr-2010, 15-Feb-2011, 26-Mar-2011, 2011-06-14, 14-Sep-2011, 20-Apr-2012, 15-Jun-2012, 13-Jul-2012, 28-Sep-2012, 06-Oct-2012, 28-Oct-2012, 15-Mar-2013, 11-Apr-2013**

The Solar Eruption of 2005 May 13 and Its Effects: Long-Baseline Interplanetary Scintillation Observations of the Earth-Directed Coronal Mass Ejection

A. R. [Breen](#),¹ R. A. Fallows,¹ M. M. Bisi,² R. A. Jones,³ B. V. Jackson,² M. Kojima,⁴ G. D. Dorrian,¹ H. R. Middleton,¹ P. Thomasson,⁵ and G. Wannberg⁶

Astrophysical Journal, 683: L79–L82, 2008

<http://www.journals.uchicago.edu/toc/apjl/2008/683/1>

Long-baseline observations of interplanetary scintillation (IPS) provide a unique source of information on solar wind speed and meridional direction across the inner regions of the solar system. We report the results of a series of coordinated IPS observations of an Earth-directed CME. A significant development in the interpretation of these data is the use of 3D tomographic reconstructions of solar wind structure derived from STELab IPS data to better constrain the analysis of extremely long baseline observations from EISCAT and MERLIN. The combination of these two approaches leads to a significantly better understanding of the interaction of the CME with the background solar wind than would be possible with either technique alone, revealing a significant rotation in the meridional flow direction of the background wind associated with the passage of the CME. The CME itself is decelerated significantly between its emergence through the corona and its arrival in the IPS ray path, with comparatively little change in speed from then until arrival at ACE.

Gleissberg Cycle Dependence of Inner Zone Proton Flux

Emily J. [Bregou](#), [Mary K. Hudson](#), [Brian T. Kress](#), [Murong Qin](#), [Richard S. Selesnick](#)

Space Weather e2022SW003072 2022

<https://doi.org/10.1029/2022SW003072>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2022SW003072>

Inner zone proton flux from 1980 to mid-2021 is examined using NOAA POES satellite data, indicating a long-term increase corresponding to a one hundred year minimum in solar activity consistent with the Centennial Gleissberg Cycle. Variation of inner belt protons is correlated with decreasing F10.7 maxima over the 40-year period, serving as proxy for solar EUV input to Earth's atmosphere. Extending an earlier study (Qin et al., 2014) of > 70 MeV protons from 1980 – 2021 using the South Atlantic Anomaly (SAA) peak flux, and at fixed L = 1.3, a comparison is made between the > 35, > 70 and > 140 MeV energy channels on POES. All three energies show an increase in proton flux over the period 1998 – 2021 using a single spacecraft. The observed flux increase is correlated with decreasing F10.7 over the longer 40-year time interval, as with the ~11-year solar cycle. A phase lag during Solar Cycle 24 (January 2010 – June 2021) between the F10.7 minimum and proton flux maximum was determined to be ~500 days, the same at all energies studied. A model calculation of the inner zone proton flux is found to generally confirm the long-term trend examined both in absolute magnitude and phase lag. It is concluded that this long-term trend is a manifestation of the concurrent Gleissberg cycle minimum and accompanying decrease in solar EUV. Reduced EUV at solar maximum (F10.7 proxy) reduces proton loss to the atmosphere following solar maximum, thus explaining the long-term flux increase observed.

Formation, shape, and evolution of magnetic structures in CIRs at 1 AU

Broiles, T. W.; Desai, M. I.; McComas, D. J.

J. Geophys. Res., Vol. 117, No. A3, A03102, 2012, File

<http://dx.doi.org/10.1029/2011JA017288>

We have surveyed the properties of **153 co-rotating interaction regions (CIRs) observed at 1 AU from January, 1995 through December, 2008**. We identified that 74 of the 153 CIRs contain planar magnetic structures (PMSs). For planar and non-planar CIRs, we compared distributions of the bulk plasma and magnetic field parameters. Our identification of CIRs and their features yields the following results: (1) The different pressures within CIRs are strongly correlated. (2) There is no statistical difference between planar and non-planar CIRs in the distributions and correlations between bulk plasma and magnetic field parameters. (3) The mean observed CIR azimuthal tilt is within 1 σ of the predicted Parker spiral at 1 AU, while the mean meridional tilt is about 20°. (4) The meridional tilt of CIRs changes from one solar rotation to the next, with no relationship between successive reoccurrences. (5) The meridional tilt of CIRs in the ecliptic is not ordered by the magnetic field polarity of the parent coronal hole. (6) Although solar wind deflection is a function of CIR shape and speed, the relationship is not in agreement with that predicted by Lee (2000). We conclude the following: (1) PMSs in CIRs are not caused by a unique characteristic in the local plasma or magnetic field. (2) The lack of relationship between CIR tilt and its **parent coronal hole** suggests that coronal hole boundaries may be more complex than currently observed. (3) In general, further theoretical work is necessary to explain the observations of CIR tilt.

The Formation and Lifetime of Outflows in a Solar Active Region

David H. **Brooks**^{1,2}, Louise Harra^{3,4}, Stuart D. Bale⁵, Krzysztof Barczynski^{3,4}, Cristina Mandrini⁶, Vanessa Polito^{7,8}, and Harry P. Warren⁹

2021 ApJ 917 25

<https://doi.org/10.3847/1538-4357/ac0917>

Active regions are thought to be one contributor to the slow solar wind. Upflows in EUV coronal spectral lines are routinely observed at their boundaries, and provide the most direct way for upflowing material to escape into the heliosphere. The mechanisms that form and drive these upflows, however, remain to be fully characterized. It is unclear how quickly they form, or how long they exist during their lifetimes. They could be initiated low in the atmosphere during magnetic flux emergence, or as a response to processes occurring high in the corona when the active region is fully developed. On **2019 March 31** a simple bipolar active region (AR 12737) emerged and upflows developed on each side. We used observations from Hinode, SDO, IRIS, and Parker Solar Probe (PSP) to investigate the formation and development of the upflows from the eastern side. We used the spectroscopic data to detect the upflow, and then used the imaging data to try to trace its signature back to earlier in the active region emergence phase. We find that the upflow forms quickly, low down in the atmosphere, and that its initiation appears associated with a small field-opening eruption and the onset of a radio noise storm detected by PSP. We also confirmed that the upflows existed for the vast majority of the time the active region was observed. These results suggest that the contribution to the solar wind occurs even when the region is small, and continues for most of its lifetime.

The Drivers of Active Region Outflows into the Slow Solar Wind

David H. **Brooks**^{1,13}, Amy R. Winebarger², Sabrina Savage², Harry P. Warren³, Bart De Pontieu^{4,5}, Hardi Peter⁶, Jonathan W. Cirtain⁷, Leon Golub⁸, Ken Kobayashi², Scott W. McIntosh⁹Show full author list

2020 ApJ 894 144

<https://doi.org/10.3847/1538-4357/ab8a4c>

Plasma outflows from the edges of active regions have been suggested as a possible source of the slow solar wind. Spectroscopic measurements show that these outflows have an enhanced elemental composition, which is a distinct signature of the slow wind. Current spectroscopic observations, however, do not have sufficient spatial resolution to distinguish what structures are being measured or determine the driver of the outflows. The High-resolution Coronal Imager (Hi-C) flew on a sounding rocket in 2018 May and observed areas of active region outflow at the highest spatial resolution ever achieved (250 km). Here we use the Hi-C data to disentangle the outflow composition signatures observed with the Hinode satellite during the flight. We show that there are two components to the outflow emission: a substantial contribution from expanded plasma that appears to have been expelled from closed loops in the active region core and a second contribution from dynamic activity in active region plage, with a composition signature that reflects solar photospheric abundances. The two competing drivers of the outflows may explain the variable composition of the slow solar wind.

Full-Sun observations for identifying the source of the slow solar wind

David H. [Brooks](#), Ignacio Ugarte-Urra, Harry P. Warren

Nature Communications **2015**

<http://arxiv.org/pdf/1605.09514v1.pdf>

Fast (>700 km/s) and slow (~400 km/s) winds stream from the Sun, permeate the heliosphere and influence the near-Earth environment. While the fast wind is known to emanate primarily from polar coronal holes, the source of the slow wind remains unknown. Here we identify possible sites of origin using a slow solar wind source map of the entire Sun, which we construct from specially designed, full-disk observations from the Hinode satellite, and a magnetic field model. Our map provides a full-Sun observation that combines three key ingredients for identifying the sources: velocity, plasma composition and magnetic topology and shows them as solar wind composition plasma outflowing on open magnetic field lines. The area coverage of the identified sources is large enough that the sum of their mass contributions can explain a significant fraction of the mass loss rate of the solar wind.

Attention-based machine vision models and techniques for solar wind speed forecasting using solar EUV images

Edward J. E. [Brown](#), [Filip Svoboda](#), [Nigel P. Meredith](#), [Nicholas Lane](#), [Richard B. Horne](#)

Space Weather **Volume 20, Issue 3** e2021SW002976 **2022**

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2021SW002976>

<https://doi.org/10.1029/2021SW002976>

Extreme ultraviolet images taken by the Atmospheric Imaging Assembly on board the Solar Dynamics Observatory make it possible to use deep vision techniques to forecast solar wind speed - a difficult, high-impact, and unsolved problem. At a four day time horizon, this study uses attention-based models and a set of methodological improvements to deliver an 11.1% lower RMSE and a 17.4% higher prediction correlation compared to the previous work testing on the period from 2010 to 2018. Our analysis shows that attention-based models combined with our pipeline consistently outperform convolutional alternatives. Our study shows a large performance improvement by using a 30 minute as opposed to a daily sampling frequency. Our model has learned relationships between coronal holes' characteristics and the speed of their associated high speed streams, agreeing with empirical results. Our study finds a strong dependence of our best model on the phase of the solar cycle, with the best performance occurring in the declining phase. **2011-06-07**

The low-frequency break observed in the slow solar wind magnetic spectra★

R. [Bruno](#)¹, D. Telloni², L. Sorriso-Valvo^{3,4}, R. Marino⁵, R. De Marco¹ and R. D'Amicis¹

A&A 627, A96 (2019)

[sci-hub.se/10.1051/0004-6361/201935841](https://doi.org/10.1051/0004-6361/201935841)

Fluctuations of solar wind magnetic field and plasma parameters exhibit a typical turbulence power spectrum with a spectral index ranging between $\sim 5/3$ and $\sim 3/2$. In particular, at 1 AU, the magnetic field spectrum, observed within fast corotating streams, also shows a clear steepening for frequencies higher than the typical proton scales, of the order of $\sim 3 \times 10^{-1}$ Hz, and a flattening towards $1/f$ at frequencies lower than $\sim 10^{-3}$ Hz. However, the current literature reports observations of the low-frequency break only for fast streams. Slow streams, as observed to date, have not shown a clear break, and this has commonly been attributed to slow wind intervals not being long enough. Actually, because of the longer transit time from the Sun, slow wind turbulence would be older and the frequency break would be shifted to lower frequencies with respect to fast wind. Based on this hypothesis, we performed a careful search for long-lasting

slow wind intervals throughout 12 years of Wind satellite measurements. Our search, based on stringent requirements not only on wind speed but also on the level of magnetic compressibility and Alfvénicity of the turbulent fluctuations, yielded 48 slow wind streams lasting longer than 7 days. This result allowed us to extend our study to frequencies sufficiently low and, for the first time in the literature, we are able to show that the $1/f$ magnetic spectral scaling is also present in the slow solar wind, provided the interval is long enough. However, this is not the case for the slow wind velocity spectrum, which keeps the typical Kolmogorov scaling throughout the analysed frequency range. After ruling out the possible role of compressibility and Alfvénicity for the $1/f$ scaling, a possible explanation in terms of magnetic amplitude saturation, as recently proposed in the literature, is suggested.

Forecasting high-speed solar wind streams based on solar extreme-ultraviolet images

X. Bu , B. Luo, C. Shen , S. Liu, J. Gong, Y. Cao , H. Wang

Space Weather **Volume17, Issue7** Pages 1040-1058 **2019**

[sci-hub.se/10.1029/2019SW002186](https://doi.org/10.1029/2019SW002186)

High-speed solar wind streams that originate from coronal holes play an important role in space weather disturbances, especially during the declining phase of the solar cycle. Space weather forecasters attempt to find good coronal hole indices that can be used to predict high speed streams days in advance. Several indices related to the coronal hole area, brightness, or magnetic field expansion factor have been reported in the literature. Empirical solar wind forecast models have been developed and used in operational service by several organizations by constructing prediction functions that relate the coronal hole index to the solar wind speed. In this paper, we present a new empirical modeling method, and test its validity by comparing it with a previously reported method when applied to different coronal hole indices. In total, six empirical models are tested for a long period of time (2011--2018), with a 27-day persistence model as a comparison benchmark. The results show that while all these empirical models can capture the temporal patterns of the solar wind observations well, the new modeling method and utilization of a composite coronal hole index PCH as an input parameter indeed improves the forecast accuracy. The high speed streams can be predicted approximately 3 days in advance, with a probability of detection (POD) of 0.78, a positive predictive value (PPV) of 0.73, and a threat score (TS) of 0.61. The uncertainty of the high-speed stream arrival time is approximately 1 day and the uncertainty of the peak speed is approximately 80 km/s. **February 28, 2011**

Extended Cosmic Ray Decreases with Strong Anisotropy after Passage of Interplanetary Shocks

Nutthawara **Buatthaisong**¹, David Ruffolo¹, Alejandro Sáiz¹, Chanoknan Banglieng², Warit

Mitthumsiri¹, Tanin Nutaro³, and Waraporn Nuntiyakul⁴

2022 ApJ 939 99

<https://iopscience.iop.org/article/10.3847/1538-4357/ac96ea/pdf>

The passage of an interplanetary shock and/or interplanetary coronal mass ejection often causes a rapid decrease in the Galactic cosmic-ray (GCR) flux, known as a Forbush decrease, followed by a recovery of the flux over some days. These local effects are of short duration and strongly rigidity dependent, with higher-rigidity particles exhibiting much weaker effects. In contrast, we present data for two events in which the cosmic-ray flux gradually decreased for about 1 week after shock passage, then recovering over the following week, with the highest anisotropy levels observed throughout Solar Cycle 24. These extended decreases have a weak rigidity dependence and are much more prominent in observations at higher cutoff rigidity, where the initial Forbush decrease is not clearly detected and other variations are generally weak, as we demonstrate using data from the Princess Sirindhorn Neutron Monitor at Doi Inthanon, Thailand with a cutoff rigidity of about 17 GV. We propose that these extended decrease events were initiated upon the passage of an interplanetary shock that inhibited the inflow of GCRs along the interplanetary magnetic field, possibly due to magnetic mirroring at the shock. We also discuss the general behavior of GCR anisotropy as observed at this high cutoff rigidity.

Abundances of Suprathermal Heavy Ions in CIRs During the Minimum of Solar Cycle 23

R. **Bučík**, U. Mall, A. Korth, G. M. Mason

Solar Physics, November **2012**, Volume 281, Issue 1, pp 411-422

In this paper we examine the elemental composition of the 0.1 – 1 MeV nucleon⁻¹ interplanetary heavy ions from H to Fe in corotating interaction regions (CIRs) measured by the SIT (Suprathermal Ion Telescope) instrument. We use observations taken on board the STEREO spacecraft from January 2007 through December 2010, which included the unusually long solar minimum following Solar Cycle 23. During this period instruments on STEREO observed more than 50 CIR events making it possible to investigate CIR ion abundances during solar minimum conditions with unprecedented high statistics. The observations reveal annual variations of relative ion abundances in the CIRs during

the 2007–2008 period as indicated by the He/H, He/O and Fe/O elemental ratios. We discuss possible causes of the variability in terms of the helium focusing cone passage and heliolatitude dependence. The year 2009 was very quiet in CIR-event activity. In 2010 the elemental composition in CIRs were influenced by sporadic solar energetic particle (SEP) events. The 2010 He/H and He/O abundance ratios in CIRs show large event-to-event variations with values resembling the SEP-like composition. This finding suggests that the suprathermal SEPs could be the source population for CIR acceleration.

An Empirical Relationship Between Coronal Density and Solar Wind Velocity in the Middle Corona With Applications to Space Weather

Kaine A. [Bunting](#), [Huw Morgan](#)

Space Weather [Volume21, Issue3](#) e2023SW003448 2023

<https://doi.org/10.1029/2023SW003448>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2023SW003448>

Accurate predictions of ambient solar wind conditions are a central component of space weather forecasting. A recent advancement is to use the distribution of electron density at a heliocentric distance of $8 R_{\odot}$, gained by applying coronal rotational tomography to coronagraph data, as an inner boundary condition for the time-dependent Heliospheric Upwind eXtrapolation solar wind model. This approach requires conversion of densities into solar wind velocity at the inner boundary. Based on comparison of the distribution of in situ measurements of density and velocities, this work finds a scaled exponential equation relating the density and outflow velocity at $8 R_{\odot}$, with three key parameters found as a function of time between years 2007–2021. Based on this relationship, comparison of modeled and in situ measurements of velocities at Earth, STEREO A and STEREO B over the past solar cycle give a mean absolute error of 61.2, 69.0, and 66.1 km s⁻¹ respectively. An analysis of thousands of events (defined as solar wind streams above 450 km s⁻¹) gives an accuracy score of 76%. This agreement validates the density-velocity relationship, and shows that an inner boundary based on coronagraph observations is a robust complement, or alternative, to commonly-used magnetic model constraints for solar wind modeling and forecasting.

Heliocentric Distance and Solar Activity Dependence of Sustained Quasi-radial Interplanetary Magnetic Field Occurrence

Brandon L. [Burkholder](#)^{1,2}, Li-Jen Chen², Norberto Romanelli^{2,3}, +

2023 ApJ 953 85

<https://iopscience.iop.org/article/10.3847/1538-4357/ace328/pdf>

Planets close to their stars experience an interplanetary magnetic field (IMF) that is dominantly quasi-radial. Our solar system serves as a laboratory to study how the occurrence of quasi-radial IMF varies away from the star and under different stellar activities. Furthermore, on time and spatial scales relevant to magnetospheric physics, solar wind variability prevails in the form of structures generated both at the Sun and locally in the interplanetary space. The stationary Parker spiral model only approximates the large-scale structure of the IMF. Deviations from the Parker spiral often result in strongly radial magnetic fields that give rise to kinetic foreshock turbulence, which in turn can impact planetary magnetospheres. The relative significance of this type of interaction can be estimated statistically based on the occurrence rate of cases where the IMF is directed along the radial direction, leading to the entire day-side magnetosphere being downstream of the ion foreshock. We use observations covering radial distances from 0.1 to 10 au and more than 2 solar cycles to quantify the prevalence of radial IMFs throughout the heliosphere. Near Earth's orbit, it is found that the occurrence rates of quasi-radial and southward IMF orientations are similar, and that the Pearson correlation coefficient is $R_{xy} \sim -0.7$ calculated between quasi-radial IMF occurrence rate and solar activity. A negative correlation is demonstrated for radial distances extending to at least Mars but not to Saturn.

Magnetic Reconnection of Solar Flux Tubes and Coronal Reconnection Signatures in the Solar Wind at 1 AU

B. L. [Burkholder](#), [A. Otto](#)

JGR [Volume124, Issue11](#) November 2019 Pages 8227-8254

<https://doi.org/10.1029/2019JA027114>

The origin of interplanetary magnetic field that is frozen-in to the solar wind plasma flow is clearly magnetic flux from the Sun's corona. However, the filamented structure of magnetic fields observed in the solar wind cannot be accounted for quite so simply. Given the 2 days or more for solar wind to travel from the Sun to 1 AU, some argue that many current sheets are present due to turbulence and other in-transit effects in the dynamic plasma outflow. Alternatively, it is postulated that a “flux tube texture” of the solar wind exists as fossil structure of the corona. In this paper we examine the possible influence of magnetic reconnection occurring close to the Sun or in the solar wind on the character of

current sheets observed by Magnetospheric Multiscale at 1 AU. Photospheric convection is used to perturb a magnetic carpet-like configuration, which has well-segmented open flux tubes defined by topological elements of the magnetic field. Flux tube boundaries in the model are defined by magnetic separatrix surfaces which are a preferential location for strong currents and magnetic reconnection. Reconnection is associated with signatures in the magnetic field and plasma that may advect with the solar wind all the way to 1 AU. Aided by three-dimensional coronal modeling and two-dimensional simulation examples of reconnection layers, we examine properties of current sheets observed by Magnetospheric Multiscale and how these solar wind boundaries may relate to reconnection operating earlier in the solar wind or corona.

Propagation of an Earth-directed coronal mass ejection in three dimensions

Jason P. **Byrne** 1 , Shane A. Maloney 1 , R.T. James McAteer 1 , 3 , Jose M. Refojo 2 & Peter T. Gallagher 1
Nature Communications 1 , Article number: 74 doi:10.1038/ncomms1077, **2010**, **File**

Solar coronal mass ejections (CMEs) are the most significant drivers of adverse space weather on Earth, but the physics governing their propagation through the heliosphere is not well understood. Although stereoscopic imaging of CMEs with NASA's Solar Terrestrial Relations Observatory (STEREO) has provided some insight into their three-dimensional (3D) propagation, the mechanisms governing their evolution remain unclear because of difficulties in reconstructing their true 3D structure. In this paper, we use a new elliptical tie-pointing technique to reconstruct a full CME front in 3D, enabling us to quantify its deflected trajectory from high latitudes along the ecliptic, and measure its increasing angular width and propagation from 2 to 46 R_{\odot} (~ 0.2 AU). Beyond 7 R_{\odot} , we show that its motion is determined by an aerodynamic drag in the solar wind and, using our reconstruction as input for a 3D magnetohydrodynamic simulation, we determine an accurate arrival time at the Lagrangian L1 point near Earth.

Probabilistic Drag-Based Ensemble Model (DBEM) Evaluation for Heliospheric Propagation of CMEs

Jaša Čalogović, [Mateja Dumbović](#), [Davor Sudar](#), [Bojan Vršnak](#), [Karmen Martinić](#), [Manuela Temmer](#), [Astrid Veronig](#)

Solar Phys. **296**, Article number: 114 **2021**

<https://arxiv.org/pdf/2107.06684.pdf>

<https://link.springer.com/content/pdf/10.1007/s11207-021-01859-5.pdf>

<https://doi.org/10.1007/s11207-021-01859-5>

The Drag-based Model (DBM) is a 2D analytical model for heliospheric propagation of Coronal Mass Ejections (CMEs) in ecliptic plane predicting the CME arrival time and speed at Earth or any other given target in the solar system. It is based on the equation of motion and depends on initial CME parameters, background solar wind speed, w and the drag parameter γ . A very short computational time of DBM ($< 0.01s$) allowed us to develop the Drag-Based Ensemble Model (DBEM) that takes into account the variability of model input parameters by making an ensemble of n different input parameters to calculate the distribution and significance of the DBM results. Thus the DBEM is able to calculate the most likely CME arrival times and speeds, quantify the prediction uncertainties and determine the confidence intervals. A new DBEMv3 version is described in detail and evaluated for the first time determining the DBEMv3 performance and errors by using various CME-ICME lists as well as it is compared with previous DBEM versions. The analysis to find the optimal drag parameter γ and ambient solar wind speed w showed that somewhat higher values ($\gamma \approx 0.3 \times 10^{-7} \text{ km}^{-1}$, $w \approx 425 \text{ km s}^{-1}$) for both of these DBEM input parameters should be used for the evaluation compared to the previously employed ones. Based on the evaluation performed for 146 CME-ICME pairs, the DBEMv3 performance with mean error (ME) of -11.3 h, mean absolute error (MAE) of 17.3 h was obtained. There is a clear bias towards the negative prediction errors where the fast CMEs are predicted to arrive too early, probably due to the model physical limitations and input errors (e.g. CME launch speed).

Analysis of an Interplanetary Coronal Mass Ejection by a Spacecraft Radio Signal: A Case Study

G. Molera **Calvés**, E. Kallio, G. Cimo, J. Quick, D. A. Duev, T. Bocanegra Bahamón, M. Nickola, M. A. Kharinov, A. G. Mikhailov

Space Weather 16 November 2017 Vol: 15, Pages: 1523–1534

<http://sci-hub.tw/10.1002/2017SW001701>

Tracking radio communication signals from planetary spacecraft with ground-based telescopes offers the possibility to study the electron density and the interplanetary scintillation of the solar wind. Observations of the telemetry link of planetary spacecraft have been conducted regularly with ground antennae from the European Very Long Baseline Interferometry Network, aiming to study the propagation of radio signals in the solar wind at different solar elongations and distances from the Sun. We have analyzed the Mars Express spacecraft radio signal phase fluctuations while, based on a 3-D heliosphere plasma simulation, an interplanetary coronal mass ejection (ICME) crossed the radio path during one of our observations on **6 April 2015**. Our measurements showed that the phase scintillation indices increased by a factor of 4 during the passage of the ICME. The method presented here confirms that the phase scintillation technique based on spacecraft signals provides information of the properties and propagation of the ICMEs in the heliosphere.

Using Mutual Information to Determine Geoeffectiveness of Solar Wind Phase Fronts With Different Front Orientations

T. G. **Cameron**, B. Jackel, D. M. Oliveira

JGR [Volume 124, Issue 3](#) March 2019 Pages 1582-1592

sci-hub.se/10.1029/2018JA026080

The geoeffectiveness of solar wind shocks depends on angle with respect to the Sun-Earth line, with highly angled solar wind shocks being less geoeffective than nearly frontal solar wind shocks. However, it is unclear whether this holds for the orientation of structures in nonshocked solar wind. In this paper, we perform a mutual information analysis of 18 years of in situ solar wind and ground magnetometer data in order to investigate the effects of solar wind phase front orientation on solar wind geoeffectiveness (indicated by SuperMAG SME, the SuperMAG enhanced version of the AE index). Since geomagnetic response is strongly influenced by interplanetary magnetic field (IMF) B_z , and IMF B_z affects phase front orientation, we use conditional mutual information to account for the effect of B_z on geomagnetic activity. In contrast to what has been found for solar wind shocks, we find that during times of IMF $B_z > 0$, phase fronts aligned with the average Parker spiral direction (45° azimuth, 0° inclination) tend to be associated with higher geomagnetic activity (SME > 500 nT) than would be expected if IMF B_z and phase front orientation quantities were unrelated. During times of IMF $B_z < 0$, there is no connection between solar wind phase front orientation and geomagnetic activity (SME). We believe that Parker spiral-aligned phase fronts being associated with higher geomagnetic activity during times of IMF $B_z > 0$ is due to constant phase front orientation allowing for more efficient energy transfer either through viscous interaction or high-latitude reconnection.

Classification of Solar Wind With Machine Learning

Enrico **Camporeale**, Algo Carè, Joseph E. Borovsky

JGR November 2017 Vol: 122, Pages: 10,910–10,920

<http://sci-hub.tw/10.1002/2017JA024383>

We present a four-category classification algorithm for the solar wind, based on Gaussian Process. The four categories are the ones previously adopted in Xu and Borovsky (2015): ejecta, coronal hole origin plasma, streamer belt origin plasma, and sector reversal origin plasma. The algorithm is trained and tested on a labeled portion of the OMNI data set. It uses seven inputs: the solar wind speed V_{sw} , the temperature standard deviation σ_T , the sunspot number R , the F10.7 index, the Alfvén speed v_A , the proton specific entropy S_p , and the proton temperature T_p compared to a velocity-dependent expected temperature. The output of the Gaussian Process classifier is a four-element vector containing the probabilities that an event (one reading from the hourly averaged OMNI database) belongs to each category. The probabilistic nature of the prediction allows for a more informative and flexible interpretation of the results, for instance, being able to classify events as “undecided.” The new method has a median accuracy larger than 90% for all categories, even using a small set of data for training. The Receiver Operating Characteristic curve and the reliability diagram also demonstrate the excellent quality of this new method. Finally, we use the algorithm to classify a large portion of the OMNI data set, and we present for the first time transition probabilities between different solar wind categories. Such probabilities represent the “climatological” statistics that determine the solar wind baseline.

Interplanetary coronal mass ejections in the near-Earth solar wind during 1996–2002

H. V. [Cane](#)¹ and I. G. Richardson

JOURNAL OF GEOPHYSICAL RESEARCH, VOL. 108, NO. A4, 1156, 2003, [File](#)

We summarize the occurrence of interplanetary coronal mass ejections (ICMEs) in the near-Earth solar wind during 1996–2002, corresponding to the increasing and maximum phases of solar cycle 23. In particular, we give a detailed list of such events. This list, based on in situ observations, is not confined to subsets of ICMEs, such as “magnetic clouds” or those preceded by “halo” coronal mass injections (CMEs) observed by the Solar and Heliospheric Observatory/Large Angle and Spectrometric Coronagraph, and provides an overview of 214 ICMEs in the near-Earth solar wind during this period. The ICME rate increases by about an order of magnitude from solar minimum to solar maximum (when the rate is ~ 3 ICMEs per solar rotation period). The rate also shows a temporary reduction during 1999 and another brief, deeper reduction in late 2000 to early 2001, which only approximately track variations in the solar 10-cm flux. In addition, there are occasional periods of several rotations duration when the ICME rate is enhanced in association with high solar activity levels. We find an indication of a periodic variation in the ICME rate, with a prominent period of ~ 165 days similar to that previously reported in various solar phenomena. It is found that the fraction of ICMEs that are magnetic clouds has a solar cycle variation, the fraction being larger near solar minimum. For the subset of events that we could associate with a CME at the Sun the transit speeds from the Sun to the Earth were highest after solar maximum.

CORONAL MASS EJECTIONS AND FORBUSH DECREASES

Review

HILARY V. [CANE](#)

Space Science Reviews 93: 41–62, 2000, [File](#)

Coronal Mass Ejections (CMEs) are plasma eruptions from the solar atmosphere which involve previously closed field regions which are expelled into the interplanetary medium. Such regions and the shocks which they may generate, have pronounced effects on cosmic ray densities both locally and at some distance away. These energetic particle effects can often be used to identify CMEs in the interplanetary medium, where they are usually called “ejecta”. When both the ejecta and shock effects are present the resulting cosmic ray event is called a “classical, two-step” Forbush decrease. This paper will summarize the characteristics of CMEs, their effects on particles and the present understanding of the mechanisms involved which cause the particle effects. The role of CMEs in long term modulation will also be discussed.

Cosmic ray decreases: 1964-1994

[Cane](#), H. V.; Richardson, I. G.; von Roseninge, T. T.

Journal of Geophysical Research, Volume 101, Issue A10, p. 21561-21572, 1996

We have studied 30 years (1964-1994) of neutron monitor data in order to understand the principle mechanisms causing short-term (<20-day duration) cosmic ray decreases seen at Earth. By examining the characteristics of associated low energy (<200 MeV) particle enhancements in combination with the neutron monitor data, we have determined the responsible solar wind disturbances for 153 of the 180 $\geq 4\%$ decreases. The vast majority (86% of the 153 events) are caused by coronal mass ejections and the shocks that they generate. The ejecta is intercepted only when the solar event

originates within 50° of the Sun's central meridian. For more distant events, only the shock is intercepted at Earth. We present a list of all 180 events seen in the years 1964-1994 together with the associated solar event, when this can be determined, and some details about the solar wind structures based on in situ solar wind data, if available. This list represents a compendium of major solar wind disturbances affecting a large section of the inner heliosphere over this time period. We also discuss enhanced daily variations in some events which are related to radial gradients caused by strong disturbances inside the Earth's orbit.

Unveiling the Journey of a Highly Inclined CME: Insights from the March 13, 2012 Event with 110° Longitudinal Separation

F. Carcaboso, M. Dumbovic, C. Kay, D. Lario, L. K. Jian, L. B. Wilson III, R. Gómez-Herrero, M. Temmer, S. G. Heinemann, T. Nieves-Chinchilla, A. M. Veronig

A&A 2024

<https://arxiv.org/pdf/2401.17501.pdf>

A fast and wide Coronal Mass Ejection (CME) erupted from the Sun on **2012-03-13**. Its interplanetary counterpart was detected in situ two days later by STEREO-A and near-Earth spacecraft. We suggest that at 1 au the CME extended at least 110° in longitude, with Earth crossing its east flank and STEREO-A crossing its west flank. Despite their separation, measurements from both positions showed very similar in situ CME signatures. The solar source region where the CME erupted was surrounded by three coronal holes (CHs). Their locations with respect to the CME launch site were east (negative polarity), southwest (positive polarity) and west (positive polarity). The solar magnetic field polarity of the area covered by each CH matches that observed at 1 au in situ. Suprathermal electrons at each location showed mixed signatures with only some intervals presenting clear counterstreaming flows as the CME transits both locations. The strahl population coming from the shortest magnetic connection of the structure to the Sun showed more intensity. The study presents important findings regarding the in situ measured CME on **2012-03-15**, detected at a longitudinal separation of 110° in the ecliptic plane despite its initial inclination being around 45° when erupted. This suggests that the CME may have deformed and/or rotated, allowing it to be observed near its legs with spacecraft at a separation angle greater than 100° . The CME structure interacted with high-speed streams generated by the surrounding CHs. The piled-up plasma in the sheath region exhibited an unexpected correlation in magnetic field strength despite the large separation in longitude. In situ observations reveal that at both locations there was a flank encounter, where the spacecraft crossed the first part of the CME, then encountered ambient solar wind, and finally passed near the legs of the structure.

Characterisation of suprathermal electron pitch-angle distributions

*Bidirectional and isotropic periods in solar wind**

Fernando Carcaboso, Raúl Gómez-Herrero, Francisco Espinosa Lara, Miguel A. Hidalgo, Ignacio Cernuda and Javier Rodríguez-Pacheco

A&A 635, A79 (2020)

<https://doi.org/10.1051/0004-6361/20193660>

Context. Suprathermal electron pitch-angle distributions (PADs) contain substantial information about the magnetic topology of the solar wind. Their characterisation and quantification allow us to automatically identify periods showing certain characteristics.

Aims. This work presents a robust automatic method for the identification and statistical study of two different types of PADs: bidirectional suprathermal electrons (BDE, often associated with closed magnetic structures) and isotropic (likely corresponding to solar-detached magnetic field lines or highly scattered electrons).

Methods. Spherical harmonics were fitted to the observed suprathermal PADs of the 119–193 eV energy channel of STEREO/SWEA from March 2007 to July 2014, and they were characterised using signal processing analysis in order to identify periods of isotropic and bidirectional PADs. The characterisation has been validated by comparing the results obtained here with those of previous studies.

Results. Interplanetary coronal mass ejections (ICMEs) present longer BDE periods inside the magnetic obstacles. A significant amount of BDE remain after the end of the ICME. Isotropic PADs are found in the sheath of the ICMEs, and at the post-ICME region likely due to the erosion of the magnetic field lines. Both isotropy and BDE are solar-cycle dependent. The isotropy observed by STEREO shows a nearly annual periodicity, which requires further investigation. There is also a correspondence between the number of ICMEs observed and the percentage of time showing BDE.

Conclusions. A method to characterise PADs has been presented and applied to the automatic identification of two relevant distributions that are commonly observed in the solar wind, such as BDE and isotropy. Four catalogues (STEREO-A and STEREO-B for isotropic and BDE periods of at least 10 min) based on this identification are provided for future applications.

ACE SWICS observations of solar cycle variations of the solar wind

A. Cardenas-O'Toole, [E. Landi](#)

ApJ 2022

<https://arxiv.org/pdf/2201.05535.pdf>

In the present work we utilize ACE/SWICS in-situ measurements of the properties of the solar wind outside ICMEs in order to determine whether, and to what extent are the solar wind properties affected by the solar cycle. We focus on proton temperatures and densities, ion temperatures and differential speeds, charge state distributions and both relative and absolute elemental abundances. We carry out this work dividing the wind in velocity bins to investigate how winds at different speeds react to the solar cycle. We also repeat this study, when possible, to the subset of SWICS measurements less affected by Coulomb collisions. We find that with the only exception of differential speeds (for which we do not have enough measurements) all wind properties change as a function of the solar cycle. Our results point towards a scenario where both the slow and fast solar wind are accelerated by waves, but originate from different sources (open/closed magnetic structures for the fast/slow wind, respectively) whose relative contribution changes along the solar cycle. We also find that the signatures of heating and acceleration on one side, and of the FIP effect on the other, indicate that wave-based plasma heating, acceleration and fractionation remain active throughout the solar cycle, but decrease their effectiveness in all winds, although the slow wind is much affected than the fast one.

Space storm measurements of the July 2005 solar extreme events from the low corona to the Earth

[Caroubalos](#), C.; Preka-Papadema, P.; Mavromichalaki, H.; Moussas, X.; Papaioannou, A.; Mitsakou, E.; Hillaris, A.

Advances in Space Research, Volume 43 , Issue 4, p. 600-604, 2009.

<http://arxiv.org/pdf/1009.3579v1.pdf>

The Athens Neutron Monitor Data Processing (ANMODAP) Center recorded an unusual Forbush decrease with a sharp enhancement of cosmic ray intensity right after the main phase of the Forbush decrease on 16 July 2005, followed by a second decrease within less than 12 h. This exceptional event is neither a ground level enhancement nor a geomagnetic effect in cosmic rays. It rather appears as the effect of a special structure of interplanetary disturbances originating from a group of coronal mass ejections (CMEs) in the **13-14 July 2005** period. The initiation of the CMEs was accompanied by type IV radio bursts and intense solar flares (SFs) on the west solar limb (AR 786); this group of energetic phenomena appears under the label of Solar Extreme Events of July 2005. We study the characteristics of these events using combined data from Earth (the ARTEMIS IV radioheliograph, the Athens Neutron Monitor (ANMODAP)), space (WIND/WAVES) and data archives. We propose an interpretation of the unusual Forbush profile in terms of a magnetic structure and a succession of interplanetary shocks interacting with the magnetosphere.

Space Storm Measurements of 17 and 21 April 2002 Forbush Effects from Artemis-IV Solar Radio-Spectrograph, Athens Neutron Monitor Station and Coronas-F Satellite

Sarlanis, G. Souvatzoglou, M. Gerontidou, C. Plainaki, S. Tatsis, S. N. Kuznetsov, I.N. Myagkova, K. Kudela

<http://arxiv.org/abs/1009.3650>

In this report we present two complex eruptive solar events and the associated Cosmic Ray effects (Forbush decrease). We use combined recordings from a number of Earthbound Receivers, Space Experiments and data archives (such as the ARTEMIS-IV Radio spectrograph, the Athens NEUTRON MONITOR, the LASCO CME Lists, the SONG of the {CORONAS-F} satellite, etc.). The influence of solar transients on the interplanetary medium conditions and the cosmic ray flux is analysed and discussed. The observed time sequence of events of this time period indicates that the initiation of CMEs is closely related to the appearance of type II and IV radio bursts and strong solar flares. Their effects extend from the lower corona to the near Earth vicinity affecting Cosmic Ray measurements and space weather. As regards the Forbush decrease our data indicate significant amplification at the presence of a MHD shock.

Portuguese eyewitness accounts of the great space weather event of 1582

Víctor Manuel Sánchez [Carrasco](#)^{1,2*} and José Manuel Vaquero^{2,3}

J. Space Weather Space Clim. 2020, 10, 4

<https://www.swsc-journal.org/articles/swsc/pdf/2020/01/swsc190083.pdf>

Newly discovered descriptions about the great aurora observed in March 1582 are presented in this work. These records were made by Portuguese observers from Lisbon. Both records described the aurora like a great fire in the northern part of the sky. It was observed during three consecutive nights, according to one of the sources. Thus, we present a discussion of these auroral records in order to complement other works that studied the aurora sighted in March 1582.

Validation of an operational product to determine L1 to Earth propagation time delays

Authors

M. D. **Cash**, S. Witters Hicks, D. A. Biesecker, A. A. Reinard, C. A. de Koning, D. R. Weimer

Space Weather 2016

We describe the development and validation of an operational space weather tool to forecast propagation delay times between L1 and Earth using the Weimer and King (2008) tilted phase front technique. A simple flat plane convection delay method is currently used by the NOAA Space Weather Prediction Center (SWPC) to propagate the solar wind from a monitoring satellite located at L1 to a point upstream of the magnetosphere. This technique assumes that all observed solar wind discontinuities, such as interplanetary shocks and interplanetary coronal mass ejection boundaries, are in a flat plane perpendicular to the Sun-Earth line traveling in the GSE X direction at the observed solar wind velocity. In reality, these phase plane fronts can have significantly tilted orientations, and by relying on a ballistic propagation method, delay time errors of ± 15 min are common. In principle, the propagation time delay product presented here should more accurately predict L1 to Earth transit times by taking these tilted phase plane fronts into account. This algorithm, which is based on the work of Weimer and King (2008), is currently running in real time in test mode at SWPC as part of the SWPC test bed. We discuss the current algorithm performance, and via our detailed validation study, show that there is no significant difference between the two propagation methods when run in a real-time operational environment.

Space Weather Volume 13, Issue 10 (pages 611–625) 2015

On 23 July 2012 a significant and rapid coronal mass ejection (CME) was detected in situ by the Solar Terrestrial Relations Observatory (STEREO) A. This CME was unusual due to its extremely brief Sun-to-1 AU transit time of less than 21 h and its exceptionally high impact speed of 2246 km/s. If this CME had been Earth directed, it would have produced a significant geomagnetic storm with potentially serious consequences. To protect our ground- and space-based assets, there is a clear need to accurately forecast the arrival times of such events using realistic input parameters and models run in near real time. Using Wang-Sheely-Arge (WSA)-Enlil, the operational model currently employed at the NOAA Space Weather Prediction Center, we investigate the sensitivity of the 23 July CME event to model input parameters. Variations in the initial CME speed, angular width, and direction, as well as the ambient solar wind background, are investigated using an ensemble approach to study the effect on the predicted arrival time of the CME at STEREO A. Factors involved in the fast transit time of this large CME are discussed, and potential improvements to modeling such events with the WSA-Enlil model are presented.

Characterizing interplanetary shocks for development and optimization of an automated solar wind shock detection algorithm

M. D. **Cash**^{1,2,*}, J. S. Wrobel³, K. C. Cosentino⁴ and A. A. Reinard

JGR, Volume 119, Issue 6, pages 4210–4222, June 2014

Human evaluation of solar wind data for interplanetary (IP) shock identification relies on both heuristics and pattern recognition, with the former lending itself to algorithmic representation and automation. Such detection algorithms can potentially alert forecasters of approaching shocks, providing increased warning of subsequent geomagnetic storms.

However, capturing shocks with an algorithmic treatment alone is challenging, as past and present work demonstrates. We present a statistical analysis of 209 IP shocks observed at L1, and we use this information to optimize a set of shock identification criteria for use with an automated solar wind shock detection algorithm. In order to specify ranges for the threshold values used in our algorithm, we quantify discontinuities in the solar wind density, velocity, temperature, and magnetic field magnitude by analyzing 8 years of IP shocks detected by the SWEPAM and MAG instruments aboard the ACE spacecraft. Although automatic shock detection algorithms have previously been developed, in this paper we conduct a methodical optimization to refine shock identification criteria and present the optimal performance of this and similar approaches. We compute forecast skill scores for over 10,000 permutations of our shock detection criteria in order to identify the set of threshold values that yield optimal forecast skill scores. We then compare our results to previous automatic shock detection algorithms using a standard data set, and our optimized algorithm shows improvements in the reliability of automated shock detection.

A New Method Linking the Solar Wind Speed to the Coronal Magnetic Field

Marta **Casti**^{1,2}, Charles N. Arge¹, Alessandro Bemporad³, Rui F. Pinto^{4,5}, and Carl J. Henney⁶
2023 ApJ 949 42

<https://iopscience.iop.org/article/10.3847/1538-4357/acc85d/pdf>

The release and acceleration of the solar wind is still an outstanding question. There are several aspects related to this phenomenon that still need to be investigated, and one of these is the identification of the region within the inner corona where the larger fraction of acceleration occurs. To address this matter, it is necessary to have reliable measurements of the solar wind speed between 1 and 10 solar radii (R_{\odot}). Moreover, in order to describe the coronal plasma behavior, it is important to consider its interaction with the magnetic field. Within this context, our intent is to investigate a method to combine measurements of the solar wind with the extrapolated magnetic field in the corona to derive how the solar wind velocity evolves along the magnetic field lines, aiming at better understanding the sources, origins, and acceleration of the solar wind. To this purpose, we used outflow speed measurements of the coronal plasma derived by applying the Doppler dimming technique, as well as the global magnetic field configuration derived from the measured photospheric magnetic field by using the Wang–Sheeley–Arge model. These two sets of data are then combined for heliocentric distances between 2.6 and 5 R_{\odot} . This paper presents the proposed method and the results obtained over two different Carrington rotations (CR 1923 and CR 1924), demonstrating the applicability of the method and the capability to link measured solar wind velocity to the extrapolated coronal magnetic field in order to derive the velocity profile.

Relating 27-Day Averages of Solar, Interplanetary Medium Parameters, and Geomagnetic Activity Proxies in Solar Cycle 24

Yvelice **Castillo**, [Maria Alexandra Pais](#), [João Fernandes](#), [Paulo Ribeiro](#), [Anna L. Morozova](#) & [Fernando J. G. Pinheiro](#)

[Solar Physics](#) volume 296, Article number: 115 (2021)

<https://link.springer.com/content/pdf/10.1007/s11207-021-01856-8.pdf>

<https://doi.org/10.1007/s11207-021-01856-8>

Correlations between solar, interplanetary-medium parameters, and geomagnetic-activity proxies in 27-day averages (a Bartels rotation) were analyzed for the 2009 – 2016 time interval. In this analysis, two new proxies were considered: i) BzsBzs GSM (Geocentric Solar Magnetic), calculated as the daily percentage of the IMF southward component along the GSM zz-axis and then averaged every 27 days; ii) four magnetospheric indices (T-indices), calculated from the local north–south (xx) contributions of the magnetosphere’s cross-tail (TAIL), the symmetric ring current (SRC), the partial ring current (PRC), and the Birkeland current (FAC), derived from the Tsyanenko and Sitnov (J. Geophys. Res. 110, A03208, [2005](#); TS05) semi-empirical magnetospheric model. Our results suggest that, among the parameters tested in this study, solar facular areas, interplanetary magnetic-field intensity and new proxies derived from the TS05 model could be taken into account in an empirical model, with a 27-day resolution, to explain geomagnetic activity felt on the Earth’s surface in terms of solar-surface features and the IMF condition. We further retrieve a clear annual oscillation in series of 27-day-mean values of toward/away asymmetries of geomagnetic-activity indices, which can be interpreted in the light of the Russell–McPherron hypothesis for the semiannual variation of geomagnetic activity.

Solar and interplanetary triggers of the largest Dst variations of the solar cycle 23

Y. **Cerrato**, E. Saiz, C. Cid, , , W.D. Gonzalez, J. Palacios

Journal of Atmospheric and Solar-Terrestrial Physics, Voume 80, May 2012, Pages 111–123, **File**

We present the results of an investigation from the Sun to the Earth of the sequence of events that caused major Dst decreases ($\Delta Dst \leq -100$ nT during 1 h) that occurred during 1996–2005. These events are expected to be better related to

geomagnetic induced current (GIC) events than those events where any geomagnetic index is far from its quiet time value. At least one full halo CME with a speed on the plane of sky above 900 km/s participates in every studied event. The seven events were triggered by interplanetary signatures, which arise as a consequence of interaction among different solar ejections. The interaction arises at different stages from the solar surface, between segments of a filament, to the interplanetary medium, appearing as ejecta or multiple-magnetic clouds (MultiMCs). In other cases, shock waves overtake or compress previous ICMEs and at other times the interaction also appears between magnetic clouds (MCs) and streams.

Ionospheric response to Strong Geomagnetic Storms during 2000-2005: An IMF clock angle perspective

[Sumanjit Chakraborty](#), [Sarbani Ray](#), [Abhirup Datta](#), [Ashik Paul](#)

Radio Science **2020**

<https://arxiv.org/pdf/2008.06765.pdf>

This paper presents the equatorial ionospheric response to eleven strong-to-severe geomagnetic storms that occurred during the period 2000-2005, the declining phase of the solar cycle 23. The analysis has been performed using the global ion density plots of Defense Meteorological Satellite Program (DMSP). Observations show that for about 91% of the cases, post-sunset equatorial irregularities occurred within 3h from the time of northward to southward transition of the Interplanetary Magnetic Field (IMF) clock angle, thus bringing out the importance of the role played by IMF By in the process of Prompt Penetration of Electric Field (PPEF) in addition to the IMF Bz. This is an improvement from the previously reported (Ray et al., 2015) 4h window of ESF generation from the southward IMF Bz crossing -10 nT. **April 05-07, 2000, May 29-31, 2005**

Probabilistic prediction of geomagnetic storms and the Kp index

Shibaji [Chakraborty](#) and Steven Karl Morley

J. Space Weather Space Clim. **2020**, 10, 36

<https://www.swsc-journal.org/articles/swsc/pdf/2020/01/swsc190086.pdf>

Geomagnetic activity is often described using summary indices to summarize the likelihood of space weather impacts, as well as when parameterizing space weather models. The geomagnetic index K_p in particular, is widely used for these purposes. Current state-of-the-art forecast models provide deterministic K_p predictions using a variety of methods – including empirically-derived functions, physics-based models, and neural networks – but do not provide uncertainty estimates associated with the forecast. This paper provides a sample methodology to generate a 3-hour-ahead K_p prediction with uncertainty bounds and from this provide a probabilistic geomagnetic storm forecast. Specifically, we have used a two-layered architecture to separately predict storm (K_p ≥ 5-) and non-storm cases. As solar wind-driven models are limited in their ability to predict the onset of transient-driven activity we also introduce a model variant using solar X-ray flux to assess whether simple models including proxies for solar activity can improve the predictions of geomagnetic storm activity with lead times longer than the L1-to-Earth propagation time. By comparing the performance of these models we show that including operationally-available information about solar irradiance enhances the ability of predictive models to capture the onset of geomagnetic storms and that this can be achieved while also enabling probabilistic forecasts. **22-28 July 2004**

Table 3. List of storm events (2001-2006)

Probabilistic forecasting of the disturbance storm time index: An autoregressive Gaussian process approach

M. [Chandorkar](#), E. Camporeale, S. Wing

Space Weather Volume 15, Issue 8 August **2017** Pages 1004–1019

<http://sci-hub.cc/10.1002/2017SW001627>

We present a methodology for generating probabilistic predictions for the Disturbance Storm Time(Dst) geomagnetic activity index. We focus on the One Step Ahead prediction task and use the OMNI hourly resolution data to build our models. Our proposed methodology is based on the technique of Gaussian Process Regression. Within this framework we develop two models; Gaussian Process Autoregressive (GP-AR) and Gaussian Process Autoregressive with exogenous inputs (GP-ARX). We also propose a criterion to aid model selection with respect to the order of autoregressive inputs. Finally, we test the performance of the GP-AR and GP-ARX models on a set of 63 geomagnetic storms between 1998 and 2006 and illustrate sample predictions with error bars for some of these events. **2003/11/20-22**

How can a Negative Magnetic Helicity Active Region Generate a Positive Helicity Magnetic Cloud ?

R. **Chandra** · E. Pariat · B. Schmieder · C.H. Mandrini · W. Uddin ·

Solar Phys., 261(1), 127-148, **2010**, **File**

The geoeffective magnetic cloud (MC) of **20 November 2003**, has been associated to the **18 November 2003**, solar active events in previous studies. In some of these, it was estimated that the magnetic helicity carried by the MC had a positive sign, as well as its solar source, active region (AR) NOAA 10501. In this paper we show that the large-scale magnetic field of AR 10501 had a negative helicity sign. Since coronal mass ejections (CMEs) are one of the means by which the Sun ejects magnetic helicity excess into the interplanetary space, the signs of magnetic helicity in the AR and MC should agree. Therefore, this finding contradicts what is expected from magnetic helicity conservation. However, using for the first time correct helicity density maps to determine the spatial distribution of magnetic helicity injection, we show the existence of a localized flux of positive helicity in the southern part of AR 10501. We conclude that positive helicity was ejected from this portion of the AR leading to the observed positive helicity MC.

Over-expansion of a coronal mass ejection generates sub-Alfvénic plasma conditions in the solar wind at Earth

E. **Chané**¹, B. Schmieder^{1,2}, S. Dasso^{3,4}, C. Verbeke¹, B. Grison⁵, P. Démoulin^{2,6} and S. Poedts^{1,7}

A&A 647, A149 (**2021**)

<https://doi.org/10.1051/0004-6361/202039867>

<https://www.aanda.org/articles/aa/pdf/2021/03/aa39867-20.pdf>

Context. From **May 24–25, 2002**, four spacecraft located in the solar wind at about 1 astronomical unit (au) measured plasma densities one to two orders of magnitude lower than usual. The density was so low that the flow became sub-Alfvénic for four hours, and the Alfvén Mach number was as low as 0.4. Consequently, the Earth lost its bow shock, and two long Alfvén wings were generated.

Aims. This is one of the lowest density events ever recorded in the solar wind at 1 au, and the least documented one. Our goal is to understand what caused the very low density.

Methods. Large Angle and Spectrometric Coronagraph (LASCO) and in situ data were used to identify whether something unusual occurred that could have generated such low densities

Results. The very low density was recorded inside a large interplanetary coronal mass ejection (ICME), which displayed a long, linearly declining velocity profile, typical of expanding ICMEs. We deduce a normalised radial expansion rate of 1.6. Such a strong expansion, occurring over a long period of time, implies a radial size expansion growing with the distance from the Sun to the power 1.6. This can explain a two-orders-of-magnitude drop in plasma density. Data from LASCO and the Advanced Composition Explorer show that this over-expanding ICME was travelling in the wake of a previous ICME.

Conclusions. The very low densities measured in the solar wind in May 2002 were caused by the over-expansion of a large ICME. This over-expansion was made possible because the ICME was travelling in a low-density and high-velocity environment present in the wake of another ICME coming from a nearby region on the Sun and ejected only three hours previously. Such conditions are very unusual, which explains why such very low densities are almost never observed.

Observations of interplanetary scintillation of the 2005 May 13 coronal mass ejection: numerical models

O **Chang**, R F **González**, M M **Bisi**, R A **Fallows**

MNRAS, Volume 508, Issue 1, **2021**, Pages 1314–1320,

<https://doi.org/10.1093/mnras/stab2664>

The 2005 May 13 eruption was an Earth-directed coronal mass ejection (CME) observed using the Multi-Element Radio-Linked Interferometer Network telescope system in the UK as it traversed the Interplanetary Medium on 2005 May 14. Observations of interplanetary scintillation (IPS) provide information on the solar wind conditions, which include velocities and density. In addition, it is also possible to calculate other parameters related to the turbulence and geometry of density irregularities in the solar wind from observations of IPS. Previous analyses have shown that IPS information can be difficult to interpret when a complex structure is crossing the line of sight since the physical properties of the plasma may change quite drastically with distance from the Sun. In order to compare and relate the internal structure of a CME and its physical changes, with the results from observations of IPS obtained previously, we

carried out a numerical simulation of the 2005 May 13 eruptive event as it propagates into the IPM, adapting the geometrical properties derived by IPS analysis. In this work, we give a possible explanation of some signatures of CME sub-structure from the point of view of the IPS technique combined with what the modelling reveals. **13-14 May 2005**

Multiple-point Modeling the Parker Spiral Configuration of the Solar Wind Magnetic Field at the Solar Maximum of Solar Cycle 24

Qing [Chang](#)¹, Xiaojun Xu¹, Qi Xu¹, Jun Zhong², Jiaying Xu¹, Jing Wang¹, and Tielong Zhang^{3,4}
2019 ApJ 884 102

<https://doi.org/10.3847/1538-4357/ab412a>

By assuming that the solar wind flow is spherically symmetric and that the flow speed becomes constant beyond some critical distance $r = R_0$ (neglecting solar gravitation and acceleration by high coronal temperature), the large-scale solar wind magnetic field lines are distorted into a Parker spiral configuration, which is usually simplified to an Archimedes spiral. Using magnetic field observations near Mercury, Venus, and Earth during solar maximum of Solar Cycle 24, we statistically surveyed the Parker spiral angles and obtained the empirical equations of the Archimedes and Parker spirals by fitting the multiple-point results. We found that the solar wind magnetic field configurations are slightly different during different years. Archimedes and Parker spiral configurations are quite different from each other within 1 au. Our results provide empirical Archimedes and Parker spiral equations that depend on the solar wind velocity and the critical distance (R_0). It is inferred that R_0 is much larger than that previously assumed. In the near future, the statistical survey of the near-Sun solar wind velocity by Parker Solar Probe can help verify this result.

Single-Site IPS Power Spectra Analysis for Space-Weather Products Using Cross Correlation Function Results from EISCAT and MERLIN IPS Data

O. [Chang](#) [M.M. Bisi](#) [E. Aguilar-Rodriguez](#) [R.A. Fallows](#) [J.A. Gonzalez-Esparza](#) [I. Chashei](#) [S. Tyulbashev](#)

Space Weather **Volume17, Issue7** Pages 1114-1130 **2019**

sci-hub.se/10.1029/2018SW002142

Interplanetary scintillation (IPS) manifests itself as a variation in the radio signal received from a distant, compact radio source on the sky. The intensity fluctuations of the radio waves are caused by density inhomogeneities in the outflowing solar plasma across the heliosphere. IPS allows us to infer solar wind speed and density variations along the line of sight (LOS). There are two types of techniques in the literature to infer solar wind speed using IPS data sets: single-site analysis (SSA), where the power spectra from single time series' are analysed to obtain solar wind parameters; and multi-site analysis, where the cross-correlation function (CCF) of data from two or more widely-separated sites is used. The selection of the analysis technique depends on the number of sites available to each IPS system. In order to combine and complement solar wind speed determinations from different instruments, it is important to validate results and methodologies of the two techniques. In this paper, we analysed previously well-studied European Incoherent SCATter (EISCAT) and Multi-Element Radio-Linked Interferometer Network (MERLIN) observations of IPS with well-known results from the CCF methodology. We applied the SSA technique to each of the individual EISCAT and MERLIN IPS power spectra. This work shows the capabilities of the SSA to describe complex events and seeks to obtain improved parameter fits using the SSA methodology.

Comparison of solar wind speed estimates from nearly simultaneous IPS observations at 327 and 111 MHz

I.V. [Chashei](#), [V.R. Lukmanov](#), [S.A. Tyulbashev](#), [M. Tokumaru](#)

Solar Phys. **296**, Article number: 63 **2021**

<https://arxiv.org/ftp/arxiv/papers/2102/2102.08767.pdf>

<https://link.springer.com/content/pdf/10.1007/s11207-021-01804-6.pdf>

<https://doi.org/10.1007/s11207-021-01804-6>

Results are presented of a comparison between solar wind speed estimates made using the time delays between 3 pairs of 327 MHz antennas at ISEE and estimates made by modeling the temporal power spectra observed with the 111 MHz BSA antenna at LPI. The observations were made for 6 years in the descending phase of solar cycle 24. More than 100 individual records were obtained for the compact source 3C48 and the extended and anisotropic source 3C298. The correlation between the daily speed estimates from 3C48 is 50%. Their annual averages agree within the error estimates and show the expected solar cycle variation. However the correlation between speeds from 3C298 is only 25% and their annual averages do not agree well. We investigate possible causes of this bias in the 3C298 estimated speeds.

Coronal Mass Ejections in September 2017 from Monitoring of Interplanetary Scintillations with the Large Phased Array of the Lebedev Institute of Physics

I. V. **Chashei**, S. A. Tyul'bashev, V. I. Shishov & I. A. Subaev
[Astronomy Reports](#) May 2018, Volume 62, [Issue 5](#), pp 346–351
Astronomicheskii Zhurnal, 2018, Vol. 95, No. 5, pp. 366–371.

<https://link.springer.com/content/pdf/10.1134%2FS1063772918050025.pdf>

Results of monitoring of interplanetary scintillations with the Large Phased Array of the Pushchino Radio Astronomy Observatory at 111 MHz during a period of flare activity of the Sun in the first ten days of September 2017 are presented. Enhancements of scintillations associated with interplanetary coronal mass ejections propagating after limb flares have been recorded. The propagation velocities are estimated to be about 2000 km/s for an ejection on September 7 and about 1000 km/s for an ejection on September 6. It is shown that, during the propagation from the Sun, the lateral part of the ejections decelerates faster than its leading part. Night-time enhancements of second-timescale scintillations during periods of high geomagnetic activity have an ionospheric origin.

Interplanetary and ionosphere scintillation produced by ICME 20 December 2015

Observational data of scintillation monitoring with typical time about 1 s at the frequency 111 MHz are presented for the period between 18 and 23 December when interplanetary coronal mass ejection (ICME) of flare origin resulted in the geomagnetic storm on **20–21 December 2015** with $Dst \approx -200$ nT. Our estimates show that the mean ICME speed between the solar corona and the start of interplanetary scintillation enhancement is close to the mean speed between the corona and the Earth. The strong increase of the nighttime scintillation level is observed after ICME coming to the Earth. Scintillation analysis of the individual radio sources shows that the 1 s night scintillation is of ionospheric origin and can be explained by an order increase of irregularity drift speed in the disturbed ionosphere.

Global Structure of the Turbulent Solar Wind during 24 Solar Activity Maxima from IPS Observations with the Multibeam Radio Telescope BSA LPI at 111 MHz

Study of a Large Forbush Decrease of July 2017

D.M.L. **Chauhan**, V. Chaudhary and M.K. Richharia
[PoS\(ICRC2019\) id.047](#) **2019**

<https://pos.sissa.it/358/047/pdf>

A large Forbush decrease (Fd) has been recorded by Moscow neutron monitoring station on 17th July 2017. An attempt has been made to understand the probable causes which have contributed for the occurrence of the large Fd. During the period of investigation extreme solar and interplanetary events i.e. sun spot numbers, disturbance storm time (Dst) index and Ap index has been investigated. The Dst index is suddenly increased during the event period indicating high geomagnetic activity during event time. The rise in sun spot numbers earlier the onset of forbush decrease reveals that it should have some connection with the occurrence of solar flares which further effects the cosmic ray variation. Probably this decrease is a result of high activity on the sun. The forbush decrease under investigation is probably due to the solar flare generated shock wave magnetic perturbation.

Interplanetary Magnetic Field Parameters Affecting Cosmic Ray Forbush Decrease

D.M.L. **Chauhan**, M.K. Richharia and B. Soni
PoS(ICRC2019) , id.045 , **2019**

<https://pos.sissa.it/358/045/pdf>

Coronal mass ejections (CMEs) hurl huge volumes of magnetized plasma into interplanetary space often referred to as ICMEs or ejecta. They are an important component of solar wind and can cause enhanced geomagnetic activity when they interact with the Earth's magnetosphere. When the ejecta have an average speed greater than the upstream solar wind speed they create a shock. The large IMF variations due to interplanetary shocks cause depression in the cosmic ray intensity (CRI) called Forbush Decrease (FD). Large Fds caused by fast CMEs are specifically associated with energetic X-ray flares. In the present paper, the author has studied seven largest Forbush decrease events selected from Moscow Neutron Monitor Station during a period of twelve years (1996- 2008), i.e., 23rd solar cycle. The analysis of CRI data with interplanetary magnetic field $|B|$, its southward component B_z , solar wind velocity, Kp and Dst indices

shows that all the three phenomena- solar, interplanetary and geomagnetic are connected to FD. The relationship between interplanetary parameters and FDs is discussed in detail. Moreover the solar cycle effect is found to be slightly shifted for large FDs as the frequency of occurrence of major FD events is more in the descending phase of the solar cycle. **9-15 April 2001, 4-10 November 2001, 22-28 November 2001, 28 October-3 November 2003, 24-30 July 2004, 13- 19 May 2005 & 9-15 September 2005**

How Nanoflares Produce Kinetic Waves, Nano-Type III Radio Bursts, and Non-Thermal Electrons in the Solar Wind

H. **Che**

Proceedings of 17th Annual International Astrophysics Conference, Santa Fe, 2018 **2018**

<https://arxiv.org/pdf/1807.10942.pdf>

Observations of the solar corona and the solar wind discover that the solar wind is unsteady and originates from the impulsive events near the surface of the Sun's atmosphere. How solar coronal activities affect the properties of the solar wind is a fundamental issue in heliophysics. We report a simulation and theoretical investigation of how nanoflare accelerated electron beams affect the kinetic-scale properties of the solar wind and generate coherent radio emission. We show that nanoflare-accelerated electron beams can trigger a nonlinear electron two stream instability, which generates kinetic Alfvén and whistler waves, as well as a non-Maxwellian electron velocity distribution function, consistent with observations of the solar wind. The plasma coherent emission produced in our model agrees well with the observations of Type III, J and V solar radio bursts. Open questions in the kinetic solar wind model are also discussed.

Formation of a Magnetic Cloud from the Merging of Two Successive Coronal Mass Ejections

Chong **Chen**, [Ying D. Liu](#), [Bei Zhu](#), [Huidong Hu](#), [Rui Wang](#)

ApJ **969** L4 **2024**

<https://arxiv.org/pdf/2406.13603>

<https://iopscience.iop.org/article/10.3847/2041-8213/ad53ca/pdf>

On **2022 March 28** two successive coronal mass ejections (CMEs) were observed by multiple spacecraft and resulted in a magnetic cloud (MC) at 1 AU. We investigate the propagation and interaction properties of the two CMEs correlated with the MC using coordinated multi-point remote sensing and in situ observations from Solar Orbiter, STEREO A, SOHO, and Wind. The first CME was triggered by a filament eruption with a high inclination angle. Roughly 9 hr later, the second CME originating from the same active region erupted with a smaller tilt angle and faster speed compared to the first one. The second CME overtook the preceding CME and formed a merged front at approximately $75 r_{\text{sun}}$, which developed into a complex ejecta at 1 AU. The descending speed and low proton temperature inside the complex ejecta suggest that the two CMEs have fully merged before reaching 1 AU, leading them to begin expanding rather than compressing against each other. The complex ejecta appears to have the magnetic field and plasma signatures of an MC, although there is a discontinuity in the magnetic field implying previous interactions. The cross section of the complex ejecta, reconstructed from in situ data using a Grad-Shafranov technique, exhibits a right-handed flux rope structure. These results highlight that an MC-like complex ejecta lacking interaction features could arise from the complete merging of two CMEs.

The effect of continuous geomagnetic storms on enhancements of ultrarelativistic electrons in the Earth's outer radiation belt

Jingrun **Chen**, Jingrun Chen, Chaoling Tang, and Xinxin Chu

Front. Astron. Space Sci. **11**: 1381764. **2024**

<https://doi.org/10.3389/fspas.2024.1381764>

<https://www.frontiersin.org/articles/10.3389/fspas.2024.1381764/full>

Ultrarelativistic electrons ($E_k > 3$ MeV) are the most energetic electrons in the Earth's outer radiation belt, which can cause serious damage to equipments on satellites. The evolutions of ultrarelativistic electrons during geomagnetic storm have been well understood, but the effects of continuous geomagnetic storm on ultrarelativistic electrons are still unclear. Using the data of the Van Allen Probes, we study the evolutions of ultrarelativistic electrons in the Earth's outer radiation belt during the three continuous geomagnetic storm events. These continuous geomagnetic storm events include the two geomagnetic storms. During the recovery phase of the first geomagnetic storm, enhanced relativistic and ultrarelativistic electrons with lower energies (≥ 3.4 MeV) are observed. These enhanced relativistic electrons could be the source of ultrarelativistic electrons and contribute to ultrarelativistic electron acceleration during the second geomagnetic storm. While 3.4 MeV electrons could be further enhanced during the second geomagnetic storm. During the recovery phase of the second small or moderate geomagnetic storm, ultrarelativistic electrons with higher cutoff energies (≥ 5.2 MeV) and higher fluxes are observed. Compared to an isolated geomagnetic storm with similar solar

wind and geomagnetic conditions, ultrarelativistic electrons with higher cutoff energies and higher fluxes are observed during the recovery phase of the second geomagnetic storm. We also find that continuous geomagnetic storm events may contribute even more to enhancements of ultrarelativistic electrons in the outer radiation belt if the second geomagnetic storm is a small or moderate storm with a low solar wind dynamic pressure and short-duration main phase. These can help us to further understand the evolutions of ultrarelativistic electrons in the Earth's outer radiation belt during geomagnetic storms. **18-25 May 2013, 1-7 June 2013, 20-25 April 2017**

Parallel Diffusion Coefficient of Energetic Charged Particles in the Inner Heliosphere from the Turbulent Magnetic Fields Measured by Parker Solar Probe

Xiaohang **Chen**¹, Joe Giacalone¹, Fan Guo², and Kristopher G. Klein¹

2024 ApJ 965 61

<https://iopscience.iop.org/article/10.3847/1538-4357/ad33c3/pdf>

Diffusion coefficients of energetic charged particles in turbulent magnetic fields are a fundamental aspect of diffusive transport theory but remain incompletely understood. In this work, we use quasi-linear theory to evaluate the spatial variation of the parallel diffusion coefficient κ_{\parallel} from the measured magnetic turbulence power spectra in the inner heliosphere. We consider the magnetic field and plasma velocity measurements from Parker Solar Probe made during Orbits 5–13. The parallel diffusion coefficient is calculated as a function of radial distance from 0.062 to 0.8 au, and the particle energy from 100 keV to 1 GeV. We find that κ_{\parallel} increases exponentially with both heliocentric distance and energy of particles. The fluctuations in κ_{\parallel} are related to the episodes of large-scale magnetic structures in the solar wind. By fitting the results, we also provide an empirical formula of $\kappa_{\parallel} = (5.16 \pm 1.22) \times 10^{18} r^{1.17 \pm 0.08} E^{0.71 \pm 0.02} \text{ (cm}^2 \text{ s}^{-1}\text{)}$ in the inner heliosphere, which can be used as a reference in studying the transport and acceleration of solar energetic particles as well as the modulation of cosmic rays.

Earth's Alfvén wings driven by the April 2023 Coronal Mass Ejection

Li-Jen **Chen**, [Daniel Gershman](#), [Brandon Burkholder](#), [Yuxi Chen](#), + + +

2024

<https://arxiv.org/ftp/arxiv/papers/2402/2402.08091.pdf>

In this paper, we report Magnetospheric Multiscale (MMS) observations of the dayside magnetosphere when the upstream Alfvén speed rises above the solar wind speed (sub-Alfvénic), causing the windsock-like magnetosphere to transform into Alfvén wings. The event occurred in the magnetic cloud of a Coronal Mass Ejection (CME) on April 24, 2023. We highlight the following outstanding features: (1) a layer of accelerated cold CME flow directly adjacent to the wing and to the magnetopause, which represents a rare regime of the terrestrial magnetosphere interaction with unshocked CME plasma; (2) moving filaments of the Alfvén wing created by magnetic reconnection, which represent new channels of connection between Earth's magnetosphere and the foot points of the Sun's erupted flux rope; (3) cold CME ion deceleration with little heating across the magnetopause. The reported MMS measurements advance our knowledge of CME interaction with planetary magnetospheres, and open new opportunities to further understand how sub-Alfvénic plasma flows impact astrophysical bodies such as Mercury, moons of Jupiter, and exoplanets that are close to their host stars. **24 Apr 2023**

Small-scale Magnetic Flux Ropes in Stream Interaction Regions from Parker Solar Probe and Wind Spacecraft Observations

Yu **Chen**¹, Qiang Hu^{1,2}, Robert C. Allen³, and Lan K. Jian⁴

2023 ApJ 943 33

<https://iopscience.iop.org/article/10.3847/1538-4357/aca894/pdf>

Using in situ measurements from the Parker Solar Probe and Wind spacecraft, we investigate the small-scale magnetic flux ropes (SFRs) and their properties inside stream interaction regions (SIRs). Within SIRs from ~ 0.15 to 1 au, SFRs are found to exist in a wide range of solar wind speeds with more frequent occurrences after the stream interface, and the Alfvénicity of these structures decreases significantly with increasing heliocentric distances. Furthermore, we examine the variation of five corresponding SIRs from the same solar sources. The enhancements of suprathermal electrons within these SIRs persist at 1 au and are observed multiple times. An SFR appears to occur repeatedly with the recurring SIRs and is traversed by the Wind spacecraft at least twice. This set of SFRs has similarities in variations of the magnetic field components, plasma bulk properties, density ratio of solar wind alpha and proton particles, and unidirectional suprathermal electrons. We also show, through the detailed time-series plots and Grad–Shafranov reconstruction results, that they possess the same chirality and carry comparable amounts of magnetic flux. Lastly, we discuss the possibility for these recurring SFRs to be formed via interchange reconnection, maintain the connection with the Sun, and survive up to 1 au. **2018 Aug 14-16, 2018 Sep 10-11, 2018 Oct 7, 2018 Nov 4-5, 2019 August 24**

Multispacecraft Remote Sensing and In Situ Observations of the 2020 November 29 Coronal Mass Ejection and Associated Shock: From Solar Source to Heliospheric Impacts

[Chong Chen](#), [Ying D. Liu](#), [Bei Zhu](#)

ApJ **937** 44 **2022**

<https://arxiv.org/pdf/2207.07534.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac7ff6/pdf>

We investigate the source eruption, propagation and expansion characteristics, and heliospheric impacts of the **2020 November 29** coronal mass ejection (CME) and associated shock, using remote sensing and in situ observations from multiple spacecraft. A potential--field source--surface model is employed to examine the coronal magnetic fields surrounding the source region. The CME and associated shock are tracked from the early stage to the outer corona using extreme ultraviolet and white light observations. Forward models are applied to determine the structures and kinematics of the CME and the shock near the Sun. The shock shows an ellipsoidal structure, expands in all directions, and encloses the whole Sun as viewed from both SOHO and STEREO A, which results from the large expansion of the CME flux rope and its fast acceleration. The structure and potential impacts of the shock are mainly determined by its radial and lateral expansions. The CME and shock arrive at Parker Solar Probe and STEREO A. Only based on the remote sensing observations, it is difficult to predict whether and when the CME/shock would arrive at the Earth. Combining Wind in situ measurements and WSA-ENLIL simulation results, we confirm that the far flank of the CME (or the CME leg) arrives at the Earth with no shock signature. These results highlight the importance of multipoint remote sensing and in situ observations for determining the heliospheric impacts of CMEs.

RU-net: A Residual U-net for Automatic Interplanetary Coronal Mass Ejection Detection

Jun [Chen](#)^{1,2}, Hao Deng^{6,1}, Shuxin Li^{3,4,5}, Weifu Li¹, Hong Chen^{6,1}, Yanhong Chen^{3,5}, and Bingxian Luo^{3,4,5}

2022 ApJS 259 8

<https://iopscience.iop.org/article/10.3847/1538-4365/ac4587/pdf>

Detection methods for interplanetary coronal mass ejections (ICMEs) from in situ spacecraft measurements are mostly manual, which are labor-intensive and time-consuming, being prone to the inconsistencies of identification criteria and the incompleteness of the existing catalogs. Therefore, the automatic detection of ICMEs has aroused the interest of the astrophysical community. Of these automatic methods, the convolutional neural network--based methods show the advantages of fast speed and high precision. To further improve the computing feasibility and detection performance, this paper proposes a method called residual U-net (RU-net), from the perspective of time-series segmentation. With the help of U-net architecture, we design an encoder--decoder network with skip connection to capture multiscale information, where the end-to-end architecture with an embedded residual element is formulated to accelerate the algorithmic convergence. For the in situ data from 1997 October 1 to 2016 January 1 collected by the Wind spacecraft, the results of our experiments demonstrate the competitive performance of the proposed RU-net in terms of accuracy and efficiency (178 of 230 ICMEs are detected in the test set, and the F1 score is 80.18%). **1997 October 10-13**

Small-scale magnetic flux ropes and their properties based on in-situ measurements from Parker Solar Probe

Yu [Chen](#), [Qiang Hu](#)

ApJ **924** 43 **2022**

<https://arxiv.org/pdf/2111.09261.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac3487/pdf>

We report small-scale magnetic flux ropes via the Parker Solar Probe in situ measurements during the first six encounters and present additional analyses to supplement our prior work in [Chen et al. 2021](#). These flux ropes are detected by the Grad-Shafranov-based algorithm with the duration and scale size ranging from 10 seconds to $\lesssim 1$ hour and from a few hundred kilometers to 10^{-3} au, respectively. They include both static structures and those with significant field-aligned plasma flows. Most structures tend to possess large cross helicity, while the residual energy distributes in wide ranges. We find that these dynamic flux ropes mostly propagate anti-sunward, with no preferential sign of magnetic helicity. The magnetic flux function follows a power law and is proportional to scale size. We also present case studies showing reconstructed two-dimensional (2D) configurations, which confirm that the static and dynamic flux ropes have the common configuration of spiral magnetic field lines (also streamlines). Moreover, the existence of such events hints at the interchange reconnection as a possible mechanism to generate flux rope-like structures near the Sun. Lastly, we summarize the major findings and discuss the possible correlation between these flux

rope-like structures and turbulence due to the process of local Alfvénic alignment. **2019 Mar 30-Apr 11, 2020 Jan 23-Feb 8**

Macro Magnetic Holes Caused by Ripples in Heliospheric Current Sheet from Coordinated Imaging and Parker Solar Probe Observations

Chong **Chen**^{1,2}, Ying D. Liu^{1,2}, and Huidong Hu¹

2021 ApJ 921 15

<https://doi.org/10.3847/1538-4357/ac1b2b>

Macro magnetic holes (MMHs), which are significant magnetic field decreases in the solar wind lasting tens of minutes, were found during the first four orbits of the Parker Solar Probe (PSP). We performed a detailed analysis of the **2020 January 30** event and found the possible cause of the MMH using coordinated remote sensing observations from STEREO A and PSP in situ measurements. The results indicate that an MMH represents a brief encounter with the rippled heliospheric current sheet (HCS). Out of the data from the first four orbits of PSP, we identified 17 MMHs and carried out a statistical analysis. Basic characteristics of MMHs include (1) MMHs usually last tens of minutes; (2) the magnetic field strength inside the events is much lower than that in the ambient solar wind; (3) enhanced plasma density, radial velocity, and plasma β are usually found inside the MMHs; and (4) the radial magnetic field has the same polarity before and after an MMH. Based on potential field-source surface and magnetohydrodynamics models, for each of the events we roughly estimate the radial size and the lower limit of the vertical size (i.e., the separation distance between PSP and the HCS), which are $2 R_{\odot}$ and $10 R_{\odot}$ on average, respectively. These results suggest that MMHs are a frequent phenomenon that may shed light on the dynamics of the HCS and the origins and evolutions of the solar wind structures in the heliosphere.

Small-scale Magnetic Flux Ropes with Field-aligned Flows via the PSP In Situ Observations

Yu **Chen**¹, Qiang Hu^{1,2}, Lingling Zhao^{1,2}, Justin C. Kasper^{3,4}, and Jia Huang⁴

2021 ApJ 914 108

<https://doi.org/10.3847/1538-4357/abfd30>

Magnetic flux rope, formed by the helical magnetic field lines, can sometimes maintain its shape while carrying significant plasma flow that is aligned with the local magnetic field. We report the existence of such structures and static flux ropes by applying the Grad-Shafranov-based algorithm to the Parker Solar Probe in situ measurements in the first five encounters. These structures are detected at heliocentric distances, ranging from 0.13 to 0.66 au, in a 4-month time period. We find that flux ropes with field-aligned flows, although they occur more frequently, have certain properties similar to those of static flux ropes, such as the decaying relations of the magnetic fields within structures with respect to heliocentric distances. Moreover, these events are more likely with magnetic pressure dominating over the thermal pressure. About one-third of events are detected in the relatively fast solar wind. Taking into account the high Alfvénicity, we also compare with switchback spikes identified during three encounters and interpret their interrelations. We find that some switchbacks can be detected when the spacecraft traverses flux-rope-like structures. The cross-section maps for selected events are presented via the new Grad-Shafranov-type reconstruction. Finally, the possible evolution of the magnetic flux rope structures in the inner heliosphere is discussed.

Small-scale Magnetic Flux Ropes in the First two Parker Solar Probe Encounters

ApJ **903** 76 **2020**

<https://arxiv.org/pdf/2007.04551.pdf>

<https://doi.org/10.3847/1538-4357/abb820>

Small-scale magnetic flux ropes (SFRs) are a type of structures in the solar wind that possess helical magnetic field lines. In a recent report (Chen & Hu 2020), we presented the radial variations of the properties of SFR from 0.29 to 8 au using in situ measurements from the Helios, ACE/Wind, Ulysses, and Voyager spacecraft. With the launch of the Parker Solar Probe (PSP), we extend our previous investigation further into the inner heliosphere. We apply a Grad-Shafranov-based algorithm to identify SFRs during the first two PSP encounters. We find that the number of SFRs detected near the Sun is much less than that at larger radial distances, where magnetohydrodynamic (MHD) turbulence may act as the local source to produce these structures. The prevalence of Alfvénic structures significantly suppresses the detection of SFRs at closer distances. We compare the SFR event list with other event identification methods, yielding a dozen well-matched events. The cross-section maps of two selected events confirm the cylindrical magnetic flux rope configuration.

The power-law relation between the SFR magnetic field and heliocentric distances seems to hold down to 0.16 au. **2018 November 13**

Effects of Radial Distances on Small-scale Magnetic Flux Ropes in the Solar Wind

Yu **Chen**¹ and Qiang Hu²

2020 ApJ 894 25

<https://doi.org/10.3847/1538-4357/ab8294>

Small-scale magnetic flux ropes (SFRs) in the solar wind have been studied for decades. Statistical analysis utilizing various in situ spacecraft measurements is the main observational approach to investigating the generation and evolution of these small-scale structures. Based on the Grad–Shafranov reconstruction technique, we use the automated detection algorithm to build the databases of these small-scale structures via various spacecraft measurements at different heliocentric distances. We present the SFR properties, including the magnetic field and plasma parameters at different radial distances from the Sun near the ecliptic plane. It is found that the event occurrence rate is still of the order of a few hundreds per month, the duration and scale-size distributions follow power laws, and the flux-rope axis orientations are approximately centered around the local Parker spiral directions. In general, most SFR properties exhibit radial decays. In addition, with various databases established, we derive scaling laws for the changes in average field magnitude, event counts, and SFR scale sizes, with respect to the radial distances, ranging from ~ 0.3 au for Helios to ~ 7 au for the Voyager spacecraft. The implications of our results for comparisons with the relevant theoretical works and for applications to the Parker Solar Probe mission are discussed.

The Evolution and Role of Solar Wind Turbulence in the Inner Heliosphere

ApJ **2019**

<https://arxiv.org/pdf/1912.02348.pdf>

The first two orbits of the Parker Solar Probe (PSP) spacecraft have enabled the first in situ measurements of the solar wind down to a heliocentric distance of 0.17 au (or 36 Rs). Here, we present an analysis of this data to study solar wind turbulence at 0.17 au and its evolution out to 1 au. While many features remain similar, key differences at 0.17 au include: increased turbulence energy levels by more than an order of magnitude, a magnetic field spectral index of $-3/2$ matching that of the velocity and both Elsasser fields, a lower magnetic compressibility consistent with a smaller slow-mode kinetic energy fraction, and a much smaller outer scale that has had time for substantial nonlinear processing. There is also an overall increase in the dominance of outward-propagating Alfvénic fluctuations compared to inward-propagating ones, and the radial variation of the inward component is consistent with its generation by reflection from the large-scale gradient in Alfvén speed. The energy flux in this turbulence at 0.17 au was found to be $\sim 10\%$ of that in the bulk solar wind kinetic energy, becoming $\sim 40\%$ when extrapolated to the Alfvén point, and both the fraction and rate of increase of this flux towards the Sun is consistent with turbulence-driven models in which the solar wind is powered by this flux. **6th October 2018 to 18th April 2019**

Characteristics of a Gradual Filament Eruption and Subsequent CME Propagation in Relation to a Strong Geomagnetic Storm

Chong **Chen**, [Ying D. Liu](#), [Rui Wang](#), [Xiaowei Zhao](#), [Huidong Hu](#), [Bei Zhu](#)

ApJ **884** 90 **2019**

<https://arxiv.org/pdf/1908.11100.pdf>

<https://doi.org/10.3847/1538-4357/ab3f36>

An unexpected strong geomagnetic storm occurred on **2018 August 26**, which was caused by a slow coronal mass ejection (CME) from a gradual eruption of a large quiet-region filament. We investigate the eruption and propagation characteristics of this CME in relation to the strong geomagnetic storm with remote sensing and in situ observations. Coronal magnetic fields around the filament are extrapolated and compared with EUV observations. We determine the propagation direction and tilt angle of the CME flux rope near the Sun using a graduated cylindrical shell (GCS) model and the Sun-to-Earth kinematics of the CME with wide-angle imaging observations from STEREO A. We reconstruct the flux-rope structure using a Grad-Shafranov technique based on the in situ measurements at the Earth and compare it with those from solar observations and the GCS results. Our conclusions are as follows: (1) the eruption of the filament was unusually slow and occurred in the regions with relatively low critical heights of the coronal field decay index; (2)

the axis of the CME flux rope rotated in the corona as well as in interplanetary space, which tended to be aligned with the local heliospheric current sheet; (3) the CME was bracketed between slow and fast solar winds, which enhanced the magnetic field inside the CME at 1 AU; (4) the geomagnetic storm was caused by the enhanced magnetic field and a southward orientation of the flux rope at 1 AU from the rotation of the flux rope.

Analysis of Small-scale Magnetic Flux Ropes Covering the Whole Ulysses Mission

Yu **Chen**, **Qiang Hu**, **Jakobus le Roux**

ApJ **881** 58 **2019**

<https://arxiv.org/pdf/1905.00986.pdf>

sci-hub.se/10.3847/1538-4357/ab2ccf

Small-scale magnetic flux ropes, in the solar wind, have been studied for decades via the approach of both simulation and observation. Statistical analysis utilizing various in-situ spacecraft measurements is the main observational approach. In this study, we extend the automated detection of small-scale flux ropes based on the Grad-Shafranov reconstruction to the complete dataset of *Ulysses* spacecraft in-situ measurements. We first discuss the temporal variation of the bulk properties of 22,719 flux ropes found through our approach, namely, the average magnetic field and plasma parameters, etc., as functions of the heliographical latitudes and heliocentric radial distances. We then categorize all identified events into three groups based on event distributions in different latitudes separated at 30°, at different radial distances, and under different solar activities, respectively. By the detailed statistical analysis, we conclude as follows. (1) The properties of flux ropes, such as the duration, scale size, etc., follow the power-law distributions, but with different slope indices, especially for distributions at different radial distances. (2) Also, they are affected by the solar wind speed which has different distributions under the different solar activities, which is manifested as the latitudinal effect. (3) The main difference in flux rope properties between the low and high latitudes is attributed to possible Alfvénic structures or waves. (4) Flux ropes with longer duration and larger scale sizes occur more often at larger radial distances. (5) With more strict Walén slope threshold, more events are excluded at higher latitudes. The entire database is published online at [this http URL](#).

Enhanced energy input from the magnetosphere to the upper atmosphere during geomagnetic storms has a profound effect on thermospheric density and consequently near-Earth satellite orbit decay. These geomagnetic storms are caused by two different processes. The first is coronal mass ejections (CMEs) and the second is corotating interaction regions (CIRs). CME-driven storms are characterized by large maximum energy input but relatively short duration, whereas CIR-driven storms have relatively small maximum energy input but are of a considerably longer duration. In this paper we carried out a statistical study to assess the relative importance of each kind of storm to satellite orbital decay. The results demonstrate that CIR storms have a slightly larger effect on total orbital decay than CME storms do in a statistical sense. During the declining phase and the minimum years of a solar cycle, CIR storms occur frequently and quasiperiodically. These storms have a large effect on thermospheric densities and satellite orbits because of their relatively long duration. Thus, it is important to fully understand their behavior and impact.

Bayesian prediction of geomagnetic storms: Wind data, 1996–2010,

Chen, J., S. P. Slinker, and I. Triandaf

(2012), Space Weather, 10, S04005,

The feature-based Bayesian method previously developed by Chen et al. (1996, 1997) to predict the occurrence, severity, and duration of large geomagnetic storms has been run on a daily basis on the Wind/Magnetic Fields Investigation (MFI) data from January 1996 until March 2010. The algorithm uses as input real-time solar wind magnetic field data obtained **at the L1 Lagrange point**, and the output is the probability prediction of the magnetic field structure of the upstream solar wind that has yet to arrive, and its geoeffectiveness, where geoeffectiveness is measured by the traditional Dst index. The performance characteristics of the method are evaluated using a four-level contingency table: nonstorm disturbances ($-80 \text{ nT} < \text{Dst} \leq -50 \text{ nT}$), weak storms ($-120 \text{ nT} < \text{Dst} \leq -80 \text{ nT}$), moderate storms ($-160 \text{ nT} < \text{Dst} \leq -120 \text{ nT}$), and strong storms ($\text{Dst} \leq -160 \text{ nT}$). It is found that the greater the level of disturbances, the more accurate the prediction is. With moderate and strong storms combined, the algorithm correctly predicted 30 out of 37 storms (81%). The false negatives are caused by solar wind structures with short durations ($\leq 1\text{--}2$ hrs) of strong southward magnetic field (say, $B_z \leq -30 \text{ nT}$), which are sparsely represented in the probability distribution functions constructed using prior solar wind data (OMNI data set from 1973–1981). The algorithm does not predict the storm onset time, but the results of the present and previous tests show that the average warning time ranges from a few hours to a maximum of 10–15 hours.

Key Signatures of Prominence Materials and Category of Cold Materials Identified by Random Forest Classifier

Zexin **Cheng**¹, Shuo Yao¹, and Shuyi Meng¹

2023 ApJS 268 25

<https://iopscience.iop.org/article/10.3847/1538-4365/ace447/pdf>

The origin of cold materials identified by different criteria is unclear. They are highly suspected to be erupted prominences. However, some cold materials defined by charge depletion exist in both quiet solar wind and interplanetary coronal mass ejections (ICMEs). Recently, solar observations show failed prominence eruption in coronal mass ejections (CMEs) that the prominence sometimes did not propagate into interplanetary space. This work uses Random Forest Classifier (RFC), which is an interpretable supervised machine-learning algorithm to study the distinct signatures of prominence cold materials (PCs) compared to quiet solar wind (QSW) and ICMEs excluding cold materials (ICMEEs). Twelve physical features measured by ACE at 1 au and the monthly averaged sunspot number are used in this study. The measurements from ACE are proton moments, magnetic field component B_z , He/H, He/O, Fe/O, mean charge of oxygen and carbon, $C6+/C5$, $C6+/C4+$, and $O7+/O6+$. According to the returned weights from RFC that are checked by support vector machine classifier, the most important in situ signatures of PCs are obtained. Next, the trained RFC is used to check the category of the cold materials not related to CME observations. The results show that most segments of the cold materials are from prominences, but four of them are possibly from ICMEEs; another one segment is possibly from QSW. The most distinct signatures of PCs are lower ($C6+/C5+$)/($O7+/O6+$), proton temperature, and He/O. Considering the obvious overlaps on key physical features between QSW, ICMEEs, and PCs, the multifeature classifier shows an advantage in identifying them than solid criteria.

Using Stereoscopic Observations of Cometary Plasma Tails to Infer Solar Wind Speed

Long **Cheng**^{1,2,3}, Quanhao Zhang^{1,2,3}, Yuming Wang^{1,2,3}, Xiaolei Li^{1,2,3}, and Rui Liu

2020 ApJ 897 87

<https://sci-hub.tw/https://iopscience.iop.org/article/10.3847/1538-4357/ab93b6>

Detection of the solar wind speed near the Sun is significant in understanding the heating and acceleration of the solar wind. Cometary plasma tails have long been used as natural probes for solar wind speed; previous solar wind speed estimates via plasma tails, however, were based on comet images from a single viewpoint, and the projection effect may influence the result. Using stereoscopic observations from the Solar Terrestrial Relations Observatory and the Solar and Heliospheric Observatory, we three-dimensionally reconstruct the plasma tails of three comets C/2012 S1 (ISON), C/2010 E6, and C/2011 W3 (Lovejoy) and infer the ambient solar wind speed. The first comet is located between 3.5 and 6 solar radii (R_s) away from the Sun at high latitudes; the estimated solar wind speed is about 300–500 km s^{-1} . The second comet is located within 10 R_s and about 20° away from the ecliptic; the estimated solar wind speed is about 200–320 km s^{-1} . The third comet is also located at low latitudes but farther ($>20 R_s$) away from the Sun; the estimated solar wind speed is about 100–600 km s^{-1} . For comets near the ecliptic, our results are close to those predicted by MHD models, whereas for the comet at high latitudes, the deviation between our estimate and the model results is notable. This consistency and difference could be used to constrain and improve solar wind models. We will seek opportunities to apply the method to comet 322P, whose tail may sweep the Parker Solar Probe. **2010 March 12, 2011 December 18, 2013 November 28**

Sun-Earth connection Event of Super Geomagnetic Storm on **March 31, 2001**: the Importance of Solar Wind Density

Li-Bin [Cheng](#), [Gui-Ming Le](#), [Ming-Xian Zhao](#)

Research in Astronomy and Astrophysics

2019

<https://arxiv.org/pdf/1910.07932.pdf>

An X1.7 flare at 10:15 UT and a halo CME with a projected speed of 942 km/s erupted from NOAA solar active region 9393 located at N20W19, were observed on **2001 March 29**. When the CME reached the Earth, it triggered a super geomagnetic storm (hereafter super storm). We find that the CME always moved towards the Earth according to the intensity-time profiles of protons with different energies. The solar wind parameters responsible for the main phase of the super storm occurred on March 31, 2001 is analyzed taking into account the delayed geomagnetic effect of solar wind at the L1 point and using the SYM-H index. According to the variation properties of SYM-H index during the main phase of the super storm, the main phase of the super storm is divided into two parts. A comparative study of solar wind parameters responsible for the two parts shows the evidence that the solar wind density plays a significant role in transferring solar wind energy into the magnetosphere, besides the southward magnetic field and solar wind speed.

Tracking the Evolution of A Coherent Magnetic Flux Rope Continuously from the Inner to the Outer Corona

X. [Cheng](#), M. D. Ding, Y. Guo, J. Zhang, A. Vourlidis, Y. D. Liu, O. Olmedo, J. Q. Sun, and C. Li

E-print, Oct 2013, File; 2014 ApJ 780 28

http://sprg.ssl.berkeley.edu/~liuxying/pubs/2014_apj_cheng.pdf

The magnetic flux rope (MFR) is believed to be the underlying magnetic structure of coronal mass ejections (CMEs). However, it remains unclear how an MFR evolves into and forms the multi-component structure of a CME. In this paper, we perform a comprehensive study of an extreme-ultraviolet (EUV) MFR eruption on **2013 May 22** by tracking its morphological evolution, studying its kinematics, and quantifying its thermal property. As EUV brightenings begin, the MFR starts to rise slowly and shows helical threads winding around an axis. Meanwhile, cool filamentary materials descend spirally down to the chromosphere. These features provide direct observational evidence of intrinsically helical structure of the MFR. Through detailed kinematical analysis, we find that the MFR evolution experiences two distinct phases: a slow rise phase and an impulsive acceleration phase. We attribute the first phase to the magnetic reconnection within the quasi-separatrix-layers surrounding the MFR, and the much more energetic second phase to the fast magnetic reconnection underneath the MFR. We suggest that the transition between these two phases be caused by the torus instability. Moreover, we identify that the MFR evolves smoothly into the outer corona and appears as a coherent structure within the white light CME volume. The MFR in the outer corona was enveloped by bright fronts that originated from plasma pile-up in front of the expanding MFR. The fronts are also associated with the preceding sheath region followed the outmost MFR-driven shock.

On the Relationship Between Transit Time of ICMEs and Strength of the Initiated Geomagnetic Storms

I.M. [Chertok](#)

Solar Phys. 295, Article number: 74 2020

<https://arxiv.org/abs/2004.14894>

<https://arxiv.org/ftp/arxiv/papers/2004/2004.14894.pdf>

More than 140 isolated non-recurrent geomagnetic storms (GMSs) of various intensities from extreme to weak are considered, which are reliably identified with solar eruptive sources (coronal mass ejections, CMEs). The analysis aims to obtain a possibly complete picture of the relationship between the transit time of propagation of CMEs and interplanetary coronal mass ejections (ICMEs) from the Sun to the Earth (more precisely, the time interval dtp from the moment of an eruption until the peak of the corresponding GMS) and the maximum intensity of this GMS, as measured by the disturbance storm time geomagnetic index Dst. Two groups of events are singled out: one includes GMSs, the source of which was an eruption from an active region (AR events), the other GMSs caused by filament eruptions from quiescent areas of the Sun located outside ARs (QS events). The distribution of the large number of the analyzed events on a dtp - Dst plane confirms and substantially clarifies the known regularities. The AR events are characterized by a shorter transit time ($\text{dtp} \sim 1\text{-}4$ days) and much stronger GMSs (Dst up to -600 nT mainly) in comparison with the QS events ($\text{dtp} \sim 3\text{-}5$ days, Dst > -200 nT). For events of both groups, the shorter transit time of CMEs/ICMEs, the more intense GMSs; in particular, for AR events when dtp declines from 4 to 1 day, Dst decreases on average from -100 to -470 nT and can reach -900 nT. From the point of view of the nature of GMSs and their sources on the Sun, the obtained results mean that both the speed of CMEs/ICMEs and the strength of the magnetic field transferred by them are largely

determined by the parameters of the corresponding eruptions, in particular, by the eruptive magnetic flux and the released energy.

Solar Eruptions, Forbush Decreases and Geomagnetic Disturbances from Outstanding Active Region 12673

I.M. **Chertok**, [A.V. Belov](#), [A.A. Abunin](#)

Space Weather, [Volume 16, Issue 10](#) Pages 1549-1560, 2018

<https://doi.org/10.1029/2018SW001899>

<https://arxiv.org/ftp/arxiv/papers/1809/1809.07961.pdf>

Based on our tool for the early diagnostics of solar eruption geoeffectiveness (EDSEG tool; Chertok et al., 2013, 2015, 2017), we have analyzed space weather disturbances that occurred in early September 2017. Two flares, SOL2017-09-04T20:33 (M5.5) and SOL2017-09-06T12:02 (X9.3), accompanied by Earth-directed halo coronal mass ejections (CMEs) were found to be geoeffective. We extracted the associated EUV dimmings and arcades and calculated their total unsigned magnetic flux. This calculation allowed us to estimate the possible scales of the Forbush decreases (FDs) and geomagnetic storms (GMSs) in the range from moderate to strong, and they are close to the observed scales. More precisely, after the first eruption, an FD approximately equal to 2% and almost no GMS occurred because the Bz magnetic field component in front of the corresponding interplanetary CME (ICME) was northern. The stronger second eruption produced somewhat larger composite disturbances (FD ~ 9.3% and GMS with indexes Dst ~ -144 nT, Ap ~ 235) than expected (FD ~ 4.4%, Dst ~ -135 nT, Ap ~ 125) because the second ICME overtook the trailing part of the first ICME near Earth, and the resulting Bz component was more intense and southern. Both ICMEs arrived at Earth earlier than expected because they propagated in the high-speed solar wind emanated from an extended coronal hole adjacent to AR12673 along their entire path. Overall, the presented results provide further evidence that the EDSEG tool can be used for the earliest diagnostics of actual solar eruptions to forecast the scale of the corresponding geospace disturbances.

An Early Diagnostics of the Geoeffectiveness of Solar Eruptions from Photospheric Magnetic Flux Observations: The Transition from SOHO to SDO

I.M. **Chertok** (1), V.V. Grechnev (2), A.A. Abunin

Solar Physics **292**: 62.

2017 doi:10.1007/s11207-017-1081-8

<https://arxiv.org/pdf/1702.05905.pdf>

<http://link.springer.com/content/pdf/10.1007%2Fs11207-017-1081-8.pdf>

In our previous articles (Chertok et al.: 2013, Solar Phys. 282, 175, and 2015, Solar Phys. 290, 627), we presented a preliminary tool for the early diagnostics of the geoeffectiveness of solar eruptions based on the estimate of the total unsigned line-of-sight photospheric magnetic flux in accompanying extreme-ultraviolet arcades and dimmings. This tool was based on the analysis of eruptions observed in 1996-2005 with SOHO/EIT and MDI. Empirical relationships were obtained to estimate the probable importance of upcoming space weather disturbances caused by an eruption, which just occurred, without data on the associated coronal mass ejections. It was possible to estimate the intensity of a non-recurrent geomagnetic storm (GMS) and Forbush decrease (FD), as well as their onset and peak times. After 2010-2011, data on solar eruptions are obtained with SDO/AIA and HMI. We use relatively short intervals of overlapping EIT-AIA and MDI-HMI detailed observations and a number of large eruptions over the next five years with the 12-hour cadence EIT images to adapt the SOHO diagnostic tool to SDO data. The adopted brightness thresholds select from the EIT 195 \AA and AIA 193 \AA image practically the same areas of arcades and dimmings with a cross-calibration factor of 3.6-5.8 (5.0-8.2) for the AIA exposure time of 2.0 s (2.9 s). For the same photospheric areas, the MDI magnetic flux systematically exceeds the HMI flux by a factor of 1.4. Based on these results, the empirical diagnostic relationships obtained from SOHO data are adjusted to SDO instruments. Examples of a post-diagnostics based on SDO data are presented. As before, the tool is applicable to non-recurrent GMSs and FDs caused by nearly central eruptions from active regions, provided that the southern component of the interplanetary magnetic field near the Earth is predominantly negative, which is not predicted by this tool.

Relationship between the Magnetic Flux of Solar Eruptions and the Ap Index of Geomagnetic Storms

I. M. **Chertok**, M. A. Abunina, A. A. Abunin, A. V. Belov, V. V. Grechnev

Solar Phys. February 2015, Volume 290, [Issue 2](#), pp 627-633

<http://arxiv.org/pdf/1410.1646v1.pdf>

Solar coronal mass ejections (CMEs) are main drivers of the most powerful non-recurrent geomagnetic storms. In the extreme-ultraviolet range, CMEs are accompanied by bright post-eruption arcades and dark dimmings. The analysis of events of the Solar Cycle 23 (Chertok et al., 2013, Solar Phys. 282, 175) revealed that the summarized unsigned magnetic flux in the arcades and dimming regions at the photospheric level, Φ , is significantly related to the intensity (Dst index) of geomagnetic storms. This provides the basis for the earliest diagnosis of geoeffectiveness of solar eruptions. In the present article, using the same data set, we find that a noticeable correlation exists also between the eruptive magnetic flux, Φ , and another geomagnetic index, Ap. As the magnetic flux increases from tens to approx. 500 (in units of 10^{20} Mx), the geomagnetic storm intensity measured by the 3-hour Ap index, enhances in average from Ap approx. 50 to a formally maximum value of 400 (in units of 2 nT). The established relationship shows that in fact the real value of the Ap index is not limited and during the most severe magnetic storms may significantly exceed 400.

Magnetic Flux of EUV Arcade and Dimming Regions as a Relevant Parameter for Early Diagnostics of Solar Eruptions – Sources of Non-recurrent Geomagnetic Storms and Forbush Decreases

I. M. [Chertok](#), V. V. Grechnev, A. V. Belov, A. A. Abunin
Solar Physics, January 2013, Volume 282, Issue 1, pp 175-199

<http://arxiv.org/pdf/1209.2208v1.pdf>

This study aims at the early diagnostics of the geoeffectiveness of coronal mass ejections (CMEs) from quantitative parameters of the accompanying EUV dimming and arcade events. We study events of the 23th solar cycle, in which major non-recurrent geomagnetic storms (GMS) with $Dst < -100$ nT are sufficiently reliably identified with their solar sources in the central part of the disk. Using the SOHO/EIT 195 Å images and MDI magnetograms, we select significant dimming and arcade areas and calculate summarized unsigned magnetic fluxes in these regions at the photospheric level. The high relevance of this eruption parameter is displayed by its pronounced correlation with the Forbush decrease (FD) magnitude, which, unlike GMSs, does not depend on the sign of the Bz component but is determined by global characteristics of ICMEs. Correlations with the same magnetic flux in the solar source region are found for the GMS intensity (at the first step, without taking into account factors determining the Bz component near the Earth), as well as for the temporal intervals between the solar eruptions and the GMS onset and peak times. The larger the magnetic flux, the stronger the FD and GMS intensities are and the shorter the ICME transit time is. The revealed correlations indicate that the main quantitative characteristics of major non-recurrent space weather disturbances are largely determined by measurable parameters of solar eruptions, in particular, by the magnetic flux in dimming areas and arcades, and can be tentatively estimated in advance with a lead time from 1 to 4 days. For GMS intensity, the revealed dependencies allow one to estimate a possible value, which can be expected if the Bz component is negative.

Dependence of Forbush-decrease characteristics on parameters of solar eruptions

I M [Chertok](#)¹, A A Abunin¹, A V Belov¹ and V V Grechnev
2013 J. Phys.: Conf. Ser. 409 012150

We analyze relations between characteristics of an extended ensemble of Forbush decreases (FDs) caused by CMEs from the central zone of the solar disk during the 23rd solar cycle, on the one hand, and such solar eruption parameter as a summarized unsigned magnetic flux of CME-associated EUV dimmings and arcades, on the other hand. This eruption parameter is shown to have a pronounced direct correlation with the FD magnitude and a conspicuous reverse correlation with the ICME transit time from the Sun to the Earth. The revealed correlations indicate that main quantitative characteristics of major non-recurrent FDs (and geomagnetic storms as well) are largely determined by parameters of solar eruptions, in particular such as the summarized magnetic flux of dimmings and arcades.

First measurement of interplanetary scintillation with the ASKAP radio telescope: implications for space weather

Rajan [Chhetri](#), [John Morgan](#), [Vanessa Moss](#), [Ron Ekers](#), [Danica Scott](#), [Keith Bannister](#), [Cherie K. Day](#), [Adam T. Deller](#), [Ryan M. Shannon](#)

Advances in Space Research (ASR) entitled "COSPAR Space Weather Roadmap 2022: Scientific Research and Applications" 2022

<https://arxiv.org/pdf/2208.04981.pdf>

We report on a measurement of interplanetary scintillation (IPS) using the Australian Square Kilometre Array Pathfinder (ASKAP) radio telescope. Although this proof-of-concept observation utilised just 3 seconds of data on a single source, this is nonetheless a significant result, since the exceptional wide field of view of ASKAP, and this validation of its ability to observe within 10 degrees of the Sun, mean that ASKAP has the potential to observe an interplanetary coronal mass ejection (CME) after it has expanded beyond the field of view of white light coronagraphs, but long before it has reached the Earth. We describe our proof of concept observation and extrapolate from the measured noise parameters to determine what information could be gleaned from a longer observation using the full field of view. We demonstrate that, by adopting a 'Target Of Opportunity' (TOO) approach, where the telescope is triggered by the detection of a CME in white-light coronagraphs, the majority of interplanetary CMEs could be observed by ASKAP while in an elongation range <30 degrees. It is therefore highly complementary to the colocated Murchison Widefield Array, a lower-frequency instrument which is better suited to observing at elongations >20 degrees.

Large-scale Structure and Turbulence Transport in the Inner Solar Wind: Comparison of Parker Solar Probe's First Five Orbits with a Global 3D Reynolds-averaged MHD Model

Rohit [Chhiber](#)^{1,2}, Arcadi V. Usmanov^{1,2}, William H. Matthaeus¹, and Melvyn L. Goldstein^{2,3}

2021 ApJ 923 89

<https://doi.org/10.3847/1538-4357/ac1ac7>

Simulation results from a global magnetohydrodynamic model of the solar corona and solar wind are compared with Parker Solar Probe (PSP) observations during its first five orbits. The fully three-dimensional model is based on Reynolds-averaged mean-flow equations coupled with turbulence-transport equations. The model includes the effects of electron heat conduction, Coulomb collisions, turbulent Reynolds stresses, and heating of protons and electrons via a turbulent cascade. Turbulence-transport equations for average turbulence energy, cross helicity, and correlation length are solved concurrently with the mean-flow equations. Boundary conditions at the coronal base are specified using solar synoptic magnetograms. Plasma, magnetic field, and turbulence parameters are calculated along the PSP trajectory. Data from the first five orbits are aggregated to obtain trends as a function of heliocentric distance. Comparison of simulation results with PSP data shows good agreement, especially for mean-flow parameters. Synthetic distributions of magnetic fluctuations are generated, constrained by the local rms turbulence amplitude given by the model. Properties of this computed turbulence are compared with PSP observations.

Random Walk and Trapping of Interplanetary Magnetic Field Lines: Global Simulation, Magnetic Connectivity, and Implications for Solar Energetic Particles

Rohit [Chhiber](#), [David Ruffolo](#), [William H. Matthaeus](#), [Arcadi V. Usmanov](#), [Paisan Tooprakai](#), [Piyanate Chuychai](#), [Melvyn L. Goldstein](#)

ApJ 2020

<https://arxiv.org/pdf/2011.06620.pdf>

The random walk of magnetic field lines is an important ingredient in understanding how the connectivity of the magnetic field affects the spatial transport and diffusion of charged particles. As solar energetic particles (SEPs) propagate away from near-solar sources, they interact with the fluctuating magnetic field, which modifies their distributions. We develop a formalism in which the differential equation describing the field line random walk contains both effects due to localized magnetic displacements and a non-stochastic contribution from the large-scale expansion. We use this formalism together with a global magnetohydrodynamic simulation of the inner-heliospheric solar wind, which includes a turbulence transport model, to estimate the diffusive spreading of magnetic field lines that originate in different regions of the solar atmosphere. We first use this model to quantify field line spreading at 1 au, starting from a localized solar source region, and find rms angular spreads of about 20° - 60° . In the second instance, we use the model to estimate the size of the source regions from which field lines observed at 1 au may have originated, thus quantifying the uncertainty in calculations of magnetic connectivity; the angular uncertainty is estimated to be about 20° . Finally, we estimate the filamentation distance, i.e., the heliocentric distance up to which field lines originating in magnetic islands can remain strongly trapped in filamentary structures. We emphasize the key role of slab-like fluctuations in the transition from filamentary to more diffusive transport at greater heliocentric distances. 2012 May 12

Clustering of Intermittent Magnetic and Flow Structures near Parker Solar Probe's First Perihelion -- A Partial-Variance-of-Increments Analysis

Rohit [Chhiber](#), [M. Goldstein](#), [B. Maruca](#), [A. Chasapis](#), [W. Matthaeus](#), [D. Ruffolo](#), [R. Bandyopadhyay](#), [T. Parashar](#), [R. Qudsi](#), [T. Dudok de Wit](#), [S. Larson](#), [R. Livi](#), [M. Velli](#), [N. Raouafi](#)

ApJ 2019

<https://arxiv.org/pdf/1912.03608.pdf>

During the Parker Solar Probe's (PSP) first perihelion pass, the spacecraft reached within a heliocentric distance of $\sim 37 R_{\odot}$ and observed numerous magnetic and flow structures characterized by sharp gradients. To better understand these intermittent structures in the young solar wind, an important property to examine is their degree of correlation in time and space. To this end, we use the well-tested Partial Variance of Increments (PVI) technique to identify intermittent events in FIELDS and SWEAP observations of magnetic and proton-velocity fields (respectively) during PSP's first solar encounter, when the spacecraft was within 0.25 au from the Sun. We then examine distributions of waiting times between events with varying separation and PVI thresholds. We find power-law distributions for waiting times shorter than a characteristic scale comparable to the correlation time, suggesting a high degree of correlation that may originate in a clustering process. Waiting times longer than this characteristic time are better described by an exponential, suggesting a random memory-less Poisson process at play. These findings are consistent with near-Earth observations of solar wind turbulence. The present study complements the one by Dudok de Wit et al. (2020, present volume), which focuses on waiting times between observed "switchbacks" in the radial magnetic field.

Contextual Predictions for Parker Solar Probe II: Turbulence Properties and Taylor

Hypothesis

Rohit [Chhiber](#), [Arcadi V. Usmanov](#), [William H. Matthaeus](#), [Tulasi N. Parashar](#), [Melvyn L. Goldstein](#)

2019

<https://arxiv.org/pdf/1902.03340.pdf>

The Parker Solar Probe (PSP) primary mission extends seven years and consists of 24 orbits of the Sun with descending perihelia culminating in a closest approach of ($\sim 9.8 R_{\odot}$). In the course of these orbits PSP will pass through widely varying conditions, including anticipated large variations of turbulence properties such as energy density, correlation scales and cross helicities. Here we employ global magnetohydrodynamics simulations with self-consistent turbulence transport and heating [\citep{usmanov2018}](#) to preview likely conditions that will be encountered by PSP, by assuming suitable boundary conditions at the coronal base. The code evolves large-scale parameters -- such as velocity, magnetic field, and temperature -- as well as turbulent energy density, cross helicity, and correlation scale. These computed quantities provide the basis for evaluating additional useful parameters that are derivable from the primary model outputs. Here we illustrate one such possibility in which computed turbulence and large-scale parameters are used to evaluate the accuracy of the Taylor "frozen-in" hypothesis along the PSP trajectory. Apart from the immediate purpose of anticipating turbulence conditions that PSP will encounter, as experience is gained in comparisons of observations with simulated data, this approach will be increasingly useful for planning and interpretation of subsequent observations.

Contextual Predictions for Parker Solar Probe I: Critical Surfaces and Regions

Rohit [Chhiber](#), [Arcadi V. Usmanov](#), [William H. Matthaeus](#), [Melvyn L. Goldstein](#)

2018 *ApJS* 241 11

<https://arxiv.org/pdf/1806.00570.pdf>

<https://doi.org/10.3847/1538-4365/ab0652>

The solar corona and young solar wind may be characterized by critical surfaces -- the sonic, Alfvén, and first plasma- β unity surfaces -- that demarcate regions where the solar wind flow undergoes certain crucial transformations. Global numerical simulations and remote sensing observations offer a natural mode for the study of these surfaces at large scales, thus providing valuable context for the high-resolution in-situ measurements expected from the soon-to-be-launched Parker Solar Probe (PSP). The present study utilizes global three-dimensional magnetohydrodynamic simulations of the solar wind to characterize the critical surfaces and investigate the flow in propinquitous regions. Effects of solar activity are incorporated by varying source magnetic dipole tilts and employing magnetogram-based boundary conditions. A magnetohydrodynamic turbulence model is self-consistently coupled to the bulk flow equations, enabling investigation of turbulence properties of the flow in the vicinity of critical regions. The simulation results are compared with a variety of remote sensing observations. A simulated PSP trajectory is used to provide contextual predictions for the spacecraft in terms of the computed critical surfaces. Broad agreement is seen in the interpretation of the present results in comparison with existing remote sensing results, both from heliospheric imaging and from radio scintillation studies. The trajectory analyses show that the period of time that PSP is likely to spend inside the $\beta=1$, sonic and Alfvén surfaces depends sensitively on the degree of solar activity and the tilt of the solar dipole and location of the heliospheric current sheet.

Direct Observations of a Shock Traversing Preceding Two Coronal Mass Ejections: Insights from Solar Orbiter, Wind, and STEREO Observations

The three successive coronal mass ejections (CMEs) that erupted from **2023 November 27–28**, provide the first opportunity to shed light on the entire process of a shock propagating through, sequentially compressing, and modifying two preceding CMEs using in situ data from Solar Orbiter, Wind, and STEREO-A. We describe the interaction of the three CMEs as follows: CME-1 and CME-2 interacted with each other at distances close to the Sun. Subsequently, the shock (S3) driven by CME-3 caught up with and compressed ICME-2 before 0.83 au, forming a typical shock–ICME interaction event observed by the Solar Orbiter. The S3 continued to propagate, crossing ICME-2 and propagating into ICME-1 as observed by Wind, and completely overtaking both ICME-1 and ICME-2 at STEREO-A. The interaction between S3 and the preceding two ICMEs leads to a clear compression of preceding ICMEs including an increase in magnetic field (~150%) and a reduction in the interval of ICMEs. It presents direct and compelling evidence that a shock can completely traverse two preceding CMEs, accompanied by a significant decrease in shock strength (magnetic compression ratio decrease from 1.74 to 1.49). Even though the three ICMEs interact significantly in the heliosphere, their magnetic field configurations exhibit coherence at different observation points, especially for ICME-3. Those results highlight the significant implications of shock–CME interactions for CME propagation and space weather forecasting.

The Dynamic Evolution of Multipoint Interplanetary Coronal Mass Ejections Observed with BepiColombo, Tianwen-1, and MAVEN

<https://iopscience.iop.org/article/10.3847/2041-8213/acd7e7/pdf>

We present two multipoint interplanetary coronal mass ejections (ICMEs) detected by the Tianwen-1 and Mars Atmosphere and Volatile Evolution spacecraft at Mars and the BepiColombo (0.56 au ~0.67 au) upstream of Mars from 2021 December 5 to 31. This is the first time that BepiColombo is used as an upstream solar wind monitor ahead of Mars and that Tianwen-1 is used to investigate the magnetic field characteristics of ICMEs at Mars. The Heliospheric Upwind Extrapolation time model was used to connect the multiple in situ observations and the coronagraph observations from STEREO/SECCHI and SOHO/LASCO. The first fast coronal mass ejection event (~761.2 km s⁻¹), which erupted on December 4, impacted Mars centrally and grazed BepiColombo by its western flank. The ambient slow solar wind decelerated the west flank of the ICME, implying that the ICME event was significantly distorted by the solar wind structure. The second slow ICME event (~390.7 km s⁻¹) underwent an acceleration from its eruption to a distance within 0.69 au and then traveled with the constant velocity of the ambient solar wind. These findings highlight the importance of background solar wind in determining the interplanetary evolution and global morphology of ICMEs up to Mars distance. Observations from multiple locations are invaluable for space weather studies at Mars and merit more exploration in the future. **2021 December 4–8, 2021 December 28–31**

Interplanetary Coronal Mass Ejections and Stream Interaction Regions Observed by Tianwen-1 and MAVEN at Mars

Yutian **Chi**¹, Chenglong Shen^{2,3}, Long Cheng⁴, Bingkun Yu¹, Bin Miao^{2,3}, Yuming Wang^{2,3,5}, Tielong Zhang^{6,7}, Zhuxuan Zou⁴, Mengjiao Xu¹, Zonghao Pan

2023 ApJS 267 3

<https://iopscience.iop.org/article/10.3847/1538-4365/acd191/pdf>

The Tianwen-1 spacecraft is China's first Mars exploration mission. The Mars Orbiter Magnetometer (MOMAG) is a scientific instrument on board the Tianwen-1 mission that is designed to study magnetic fields at Mars, including the solar wind to the magnetosheath and the ionosphere. Using the first Tianwen-1/MOMAG data that is publicly available, we present an interplanetary coronal mass ejection (ICME) and stream interaction region (SIR) list based on in situ observations at Mars between 2021 November 16 and 2021 December 31. We compared the magnetic field intensity and vector magnetic field measurements from Tianwen-1/MOMAG and Mars Atmospheric Volatile Evolution (MAVEN)/Magnetometer (MAG) during the ICME and SIR interval and found a generally good consistency between them. Due to MAVEN's orbital adjustment since 2019, the Tianwen-1/MOMAG instrument is almost unique in its status as an interplanetary magnetic field monitor currently at Mars. The observations indicate that the MOMAG instrument on

Tianwen-1 is performing well and can provide accurate measurements of the vector magnetic field in the near-Mars solar wind space. The multipoint observations combining MOMAG, MINPA, and MEPA on board Tianwen-1 with MAG, SWIA, and STATIC on board MAVEN will help develop systematic studies of the characteristics of ICMEs and SIRs at Mars, and their influences on the Martian atmosphere and ionosphere.

Predictive Capabilities of Corotating Interaction Regions using STEREO and Wind in-situ observations

Yutian [Chi](#), [Chenglong Shen](#), [Christopher Scott](#), [Mengjiao Xu](#), [Mathew Owens](#), [Yuming Wang](#), [Mike Lockwood](#)

Space Weather **Volume20, Issue7** e2022SW003112 **2022**

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2022SW003112>

<https://doi.org/10.1029/2022SW003112>

Solar wind stream interaction regions (SIRs) and corotating interaction regions (CIRs) can cause geomagnetic storms and change energetic particle environment, ionospheric composition on Earth. Therefore advanced warning of SIRs/CIRs is vital for mitigating the effect of space weather on critical infrastructures in modern society. Recently, several solar missions, e.g., Vigil mission (Luntama et al., 2020) and Solar Ring mission (Wang et al., 2020), that can be served as a space weather monitor, have been proposed. To evaluate the capabilities of these future missions of predicting SIRs/CIRs, the STEREO-B spacecraft is used to investigate the correlation between SIRs/CIRs detected by STEREO-B and Wind spacecraft. The correlation coefficients of solar wind velocity in SIRs/CIRs are significantly higher than that of magnetic field intensity or plasma density. It indicates that the velocity structure of solar wind is more persistent than magnetic field and ion density. By assuming the SIR/CIR structures are stable and ideal corotation, 58.9% of SIRs/CIRs in the STEREO-B CIR catalogue can be used to predict CIR arrival time in near-Earth space. With increasing longitudinal and latitudinal separations between STEREO-B and Wind, the percentage of accurately predicted CIRs decreases gradually from 100% to 20%. If the separation angle between STEREO-B and Wind is within 30° in longitude and approximately ± 5° in latitude, more than 93.2% of SIRs/CIRs can be accurately predicted several days in advance. This demonstrates that a spacecraft situated 30° trailing Earth in its orbit, can optimize our space weather-predicting capabilities for the Earth and lessen the risk of missing or “false alarms” CIRs. **May 1–3, 2010**

Using the "Ghost Front" to Predict the Arrival Time and Speed of CMEs at Venus and Earth

<https://iopscience.iop.org/article/10.3847/1538-4357/aba95a/pdf>

Using in situ measurements and remote-sensing observations, we study two coronal mass ejections (CMEs) that left the Sun on **2012 June 13–14** and impacted both Venus and Earth while the planets were in close radial alignment. The two CMEs generate multiple fronts in Solar Terrestrial Relations Observatory (STEREO)/Heliospheric Imager (HI) images, which can also be observed in the "J-map" as bifurcated features. We present the "ghost front" model to combine remote observations from STEREO/SECCHI and in situ observations from the Wind and Venus Express (VEX) spacecraft, and to derive the kinematics and propagation directions of the CMEs. By fitting the observations of multiple fronts to a kinematically evolving flux rope model and assuming the CMEs undergo deceleration through frictional drag with a steady-state solar wind, we confirm that the outer and inner fronts of the CMEs as detected in HI images are consistent with peaks in Thomson scattered light returned from the flank and nose of a single front for each CME. An interaction takes place between CME-1 and CME-2 that can be observed in the HI-1 field of view (FOV) before CME-1 encounters Venus. The multipoint in situ observations of the shock–CME interaction event serve as further evidence of the interaction between CMEs. The arrival times calculated from the ghost front model are within 2.5 hr of those observed at VEX and Wind. Our analysis indicates that ghost fronts could provide information about the longitudinally extended shape of the CME in the FOV of HI-1, which can be used to improve the forecast of interplanetary CME arrival time at Earth.

Geoeffectiveness of Stream Interaction Regions From 1995 to 2016

Yutian [Chi](#) [Chenglong Shen](#) [Bingxian Luo](#) [Yuming Wang](#) [Mengjiao Xu](#)

Space Weather 16?, 12, 1960-1971 **2018**

<http://sci-hub.tw/10.1029/2018SW001894>

Stream interaction regions (SIRs) are important sources of geomagnetic storms. In this work, we first extend the end time of the widely used SIR catalog developed by Jian et al. (2006, <https://doi.org/10.1007/s11207-006-0132-3>), which covered the period from 1995 to 2009, to the end of 2016. Based on this extended SIR catalog, the geoeffectiveness of

SIRs is discussed in detail. It was found that 52% of the SIRs caused geomagnetic storms with $Dst_{min} \leq -30$ nT, but only 3% of them caused intense geomagnetic storms with $Dst_{min} \leq -100$ nT. Furthermore, we found that 10 of the intense geomagnetic storms caused by SIRs were associated with complex structures due to interactions between SIRs and interplanetary coronal mass ejections (ICMEs). In such a structure, an ICME is embedded in the SIR and located between the slow and fast solar wind streams. In addition, we found that the geoeffectiveness of SIRs interacting with ICMEs is enhanced. The possibility of SIR-ICME interaction structures causing geomagnetic storms is markedly higher than that of isolated SIRs or isolated ICMEs. In particular, the geoeffectiveness of SIR-ICME interaction structures is similar to that of the Shock-ICME interaction structures, which have been demonstrated to be the main causes of geomagnetic storms.

Statistical Study of the Interplanetary Coronal Mass Ejections from 1995 to 2014

Yutian **Chi**, Chenglong Shen, Yuming Wang, Pinzhong Ye, S. Wang

Solar Phys. **2015**

<http://arxiv.org/pdf/1504.07849v1.pdf>

In this work, we establish an ICME list from 1996 to 2014 based on the in-situ observations from the WIND and ACE satellites. Based on this ICME list, we extend the statistical analysis of the ICMEs to the solar maximum phase of solar cycle 24th. The analysis of the annual variations of the properties of ICMEs show that the number of ICMEs, the number of shocks, the percentage of ICMEs drove shocks, the magnetic field and plasma properties of ICMEs are well correlated with the solar cycle variation. The number of MCs do not show any correlation with sunspot number. But, the percentage of the MCs in ICMEs show good anti-correlation with the sunspot number. By comparison the parameters of MCs with None-MC ICMEs, we found that the MCs are stronger than the None-MC ICMEs. In addition, we compare the parameters of ICMEs with and without shocks. It is found that the ICMEs with shocks are much stronger than the ICME without shocks. Meanwhile, we discuss the distribution of the magnetic field and solar wind plasmas parameters of the sheath regions of ICMEs at first time. We find that the magnetic field and solar wind velocity in the sheath region are higher than them in the ejecta of ICMEs from statistical point of view.

GENESIS OF INTERPLANETARY INTERMITTENT TURBULENCE: A CASE STUDY OF ROPE-ROPE MAGNETIC RECONNECTION

Abraham C.-L. **Chian**^{1,2,9,10}, Heng Q. Feng³, Qiang Hu⁴, Murray H. Loew¹, Rodrigo A. Miranda⁵, Pablo R. Muñoz⁶, David G. Sibeck⁷, and De J. Wu

2016 ApJ 832 179

In a recent paper, the relation between current sheet, magnetic reconnection, and turbulence at the leading edge of an interplanetary coronal mass ejection was studied. We report here the observation of magnetic reconnection at the interface region of two interplanetary magnetic flux ropes. The front and rear boundary layers of three interplanetary magnetic flux ropes are identified, and the structures of magnetic flux ropes are reconstructed by the Grad-Shafranov method. A quantitative analysis of the reconnection condition and the degree of intermittency reveals that rope-rope magnetic reconnection is the most likely site for genesis of interplanetary intermittency turbulence in this event. The dynamic pressure pulse resulting from this reconnection triggers the onset of a geomagnetic storm.

Observation of the Solar Corona Using Radio Scintillation with the Akatsuki Spacecraft: Difference Between Fast and Slow Wind

[Shota Chiba](#), [Takeshi Imamura](#), [Munetoshi Tokumaru](#), [Daikou Shiota](#), [Takuma Matsumoto](#), [Hiroki Ando](#), [Hiroshi Takeuchi](#), [Yasuhiro Murata](#), [Atsushi Yamazaki](#), [Bernd Häusler](#) & [Martin Pätzold](#)
[Solar Physics](#) volume 297, Article number: 34 (2022)

<https://link.springer.com/content/pdf/10.1007/s11207-022-01968-9.pdf>

The properties of the coronal plasma at heliocentric distances of 1.5 – 8.9 R_{\odot} (solar radii) were studied with radio-occultation observations using JAXA's Akatsuki spacecraft in 2016. Physical parameters that characterize the solar wind were retrieved from the intensity-scintillation time series by fitting a theoretical spectrum to the observed power spectra. The derived solar-wind velocity clearly shows a difference between the fast wind and the slow wind, which was identified based on IPS observations. The inner scale, at which fluid motions dissipate and kinetic energy is converted to heat, increases with the heliocentric distance, and the fast wind has larger inner scales than the slow wind. By applying wavelet analysis to the frequency time series, we detected quasi-periodic fluctuations in the electron density. The density oscillations are considered to be manifestations of acoustic waves, which were generated from Alfvén waves originating from the photosphere, and the energy fluxes of those acoustic waves were estimated. The relative density-amplitude

peaks around $4 - 6 R_{\odot}$ and the wave-energy flux decreases beyond $\approx 6 R_{\odot}$, implying that the acoustic waves dissipate to heat the corona. The phase-scintillation spectrum that we obtained cannot be expressed by a single power law. A break is seen around the frequency of $0.5 - 2$ Hz beyond $\approx 6 R_{\odot}$, suggesting an excess power other than turbulence at lower frequencies. The enhancement of the relative density amplitude around $6 R_{\odot}$ found by the wavelet analysis might explain this excess power. The acoustic wave-energy flux in the fast solar wind tends to exceed that in the slow wind, suggesting that the fast wind is powered by a larger injection of Alfvén-wave energy than the slow wind.

DETECTION OF CURRENT SHEETS AND MAGNETIC RECONNECTIONS AT THE TURBULENT LEADING EDGE OF AN INTERPLANETARY CORONAL MASS EJECTION

Abraham C.-L. [Chian](#)^{1,2} and Pablo R. Muñoz

2011 ApJ 733 L34

The relation between current sheets, turbulence, and magnetic reconnections at the leading edge of an interplanetary coronal mass ejection detected by four Cluster spacecraft on **2005 January 21** is studied. We report the observational evidence of two magnetically reconnected current sheets in the vicinity of a front magnetic cloud boundary layer with the following characteristics: (1) a Kolmogorov power spectrum in the inertial subrange of the magnetic turbulence, (2) the scaling exponent of structure functions of magnetic fluctuations exhibiting multi-fractal scaling predicted by the She-Leveque magnetohydrodynamic model, and (3) bifurcated current sheets with the current density computed by both single-spacecraft and multi-spacecraft techniques.

A Bayesian approach to the drag-based modelling of ICMEs

Simone [Chierichini](#)^{1,2*}, Gregoire Francisco^{2,3}, Ronish Mugatwala^{1,2}, Raffaello Foldes^{4,5}, +++
J. Space Weather Space Clim. **2024**, 14, 1

<https://www.swsc-journal.org/articles/swsc/pdf/2024/01/swsc230044.pdf>

Coronal Mass Ejections (CMEs) are huge clouds of magnetised plasma expelled from the solar corona that can travel towards the Earth and cause significant space weather effects. The Drag-Based Model (DBM) describes the propagation of CMEs in an ambient solar wind as analogous to an aerodynamic drag. The drag-based approximation is popular because it is a simple analytical model that depends only on two parameters, the drag parameter γ and the solar wind speed w . DBM thus allows us to obtain reliable estimates of CME transit time at low computational cost. Previous works proposed a probabilistic version of DBM, the Probabilistic Drag Based Model (P-DBM), which enables the evaluation of the uncertainties associated with the predictions. In this work, we infer the “a-posteriori” probability distribution functions (PDFs) of the γ and w parameters of the DBM by exploiting a well-established Bayesian inference technique: the Monte Carlo Markov Chains (MCMC) method. By utilizing this Bayesian method through two different approaches, an ensemble and an individual approach, we obtain specific DBM parameter PDFs for two ensembles of CMEs: those travelling with fast and slow solar wind, respectively. Subsequently, we assess the operational applicability of the model by forecasting the arrival time of CMEs. While the ensemble approach displays notable limitations, the individual approach yields promising results, demonstrating competitive performances compared to the current state-of-the-art, with a Mean Absolute Error (MAE) of 9.86 ± 4.07 h achieved in the best-case scenario.

Direct observations of a complex coronal web driving highly structured slow solar wind

L. P. [Chitta](#), [D. B. Seaton](#), [C. Downs](#), [C. E. DeForest](#), [A. K. Higginson](#)

Nature Astronomy **2022**

<https://arxiv.org/ftp/arxiv/papers/2211/2211.13283.pdf>

<https://www.nature.com/articles/s41550-022-01834-5.pdf>

The solar wind consists of continuous streams of charged particles that escape into the heliosphere from the Sun, and is split into fast and slow components, with the fast wind emerging from the interiors of coronal holes. Near the ecliptic plane, the fast wind from low-latitude coronal holes is interspersed with a highly structured slow solar wind, the source regions and drivers of which are poorly understood. Here we report extreme-ultraviolet observations that reveal a spatially complex web of magnetized plasma structures that persistently interact and reconnect in the middle corona. Coronagraphic white-light images show concurrent emergence of slow wind streams over these coronal web structures. With advanced global MHD coronal models, we demonstrate that the observed coronal web is a direct imprint of the magnetic separatrix web (S-web). By revealing a highly dynamic portion of the S-web, our observations open a window into important middle-coronal processes that appear to play a key role in driving the structured slow solar wind.

2D solar wind speeds from 6 to 26 solar radii in solar cycle 24 by using Fourier filtering

Il-Hyun [Cho](#), [Yong-Jae Moon](#), [Valery M. Nakariakov](#), [Su-Chan Bong](#), [Jin-Yi Lee](#), [Donguk Song](#), [Harim Lee](#), [Kyung-Suk Cho](#)

<https://arxiv.org/pdf/1806.08540.pdf>

Measurement of the solar wind speed near the Sun is important for understanding the acceleration mechanism of the solar wind. In this study, we determine 2D solar wind speeds from 6 to 26 solar radii by applying Fourier motion filters to \textit{SOHO}/LASCO C3 movies observed from 1999 to 2010. Our method successfully reproduces the original flow speeds in the artificially generated data as well as streamer blobs. We measure 2D solar wind speeds from 1-day to 1-year timescales and their variation in solar cycle 24. We find that the solar wind speeds at timescales longer than a month in the solar maximum period are relatively uniform in the azimuthal direction, while they are clearly bimodal in the minimum period, as expected from the \textit{Ulysses} observations and IPS reconstruction. The bimodal structure appears at around 2006, becomes most distinctive in 2009, and abruptly disappears in 2010. The radial evolution of the solar wind speeds resembles the Parker's solar wind solution.

Comparison of Helicity Signs in Interplanetary CMEs and Their Solar Source Regions

K.-S. **Cho**, S.-H. Park, K. Marubashi, N. Gopalswamy, S. Akiyama, S. Yashiro, R.-S. Kim, E.-K. Lim
Solar Physics, May 2013, Volume 284, Issue 1, pp 105-127; **File**

If all coronal mass ejections (CMEs) have flux ropes, then the CMEs should keep their helicity signs from the Sun to the Earth according to the helicity conservation principle. This study presents an attempt to answer the question from the Coordinated Data Analysis Workshop (CDAW), "Do all CMEs have flux ropes?", by using a qualitative helicity sign comparison between interplanetary CMEs (ICMEs) and their CME source regions. For this, we select 34 CME-ICME pairs whose source active regions (ARs) have continuous SOHO/MDI magnetogram data covering more than 24 hr without data gap during the passage of the ARs near the solar disk center. The helicity signs in the ARs are determined by estimation of cumulative magnetic helicity injected through the photosphere in the entire source ARs. The helicity signs in the ICMEs are estimated by applying the cylinder model developed by Marubashi (Adv. Space. Res., 26, 55, 2000) to 16 second resolution magnetic field data from the MAG instrument onboard the ACE spacecraft. It is found that 30 out of 34 events (88 %) are helicity sign-consistent events, while four events (12 %) are sign-inconsistent. Through a detailed investigation of the source ARs of the four sign-inconsistent events, we find that those events can be explained by the local helicity sign opposite to that of the entire AR helicity (**28 July 2000 ICME**), incorrectly reported solar source region in the CDAW list (**20 May 2005 ICME**), or the helicity sign of the pre-existing coronal magnetic field (**13 October 2000** and **20 November 2003 ICMEs**). We conclude that the helicity signs of the ICMEs are quite consistent with those of the injected helicities in the AR regions from where the CMEs erupted.

An empirical relationship between coronal mass ejection initial speed and solar wind dynamic pressure

Cho, K.-S.; Bong, S.-C.; Moon, Y.-J.; Dryer, M.; Lee, S.-E.; Kim, K.-H.

J. Geophys. Res., Vol. 115, No. A10, A10111, 2010

Interplanetary shocks that precede coronal mass ejections (CMEs) are mainly responsible for sudden impulses, which are characterized by a simple step-like increase in the horizontal H component. Such a magnetic field change has been explained as a compression of the magnetosphere by the passage of a sudden increase in the solar wind dynamic pressure. Strong compression of the dayside magnetopause could cause geosynchronous satellites to be exposed to solar wind environments where large fluctuations of the interplanetary magnetic field and highly energetic particles are present. In this study, we chose 26 event pairs consisting of a type II burst/CME occurring in conjunction with a sudden commencement/sudden impulse (SC/SI) whose solar wind, and Earth magnetic field data are available. We then investigated relationships among three physical properties (kinetic energy, directional parameter, and speed) of near-Sun CMEs, solar wind dynamic pressure, and SC/SI amplitude. As a result, we found that (1) the CME speed is more highly correlated with SC/SI amplitude than its kinetic energy and direction parameter; (2) by adopting the empirical relationship between solar wind dynamic pressure and amplitude of symmetric H (a step-like increase in the horizontal H component at low latitude), we could derive an empirical formula for the relationship between solar wind dynamic pressure near the Earth and the CME speed; (3) the CME speed has a linear relationship with the difference of magnetopause locations derived by using the model of Shue et al. (1998) at the subsolar point before and after the shock arrivals; (4) a fast CME greater than 1600 km s⁻¹ could be a driver of the magnetopause crossing of a spacecraft at geosynchronous orbit. Our results show that the CME speed is an important parameter for early prediction of geosynchronous magnetopause crossing.

Series of Small-scale Low Plasma β Magnetic Flux Ropes Originating from the Same Longitudinal Region: Parker Solar Probe Observations

Kyung-Eun **Choi**¹, Dae-Young Lee², Sung-Jun Noh³, and Oleksiy Agapitov

2024 ApJ 961 3

<https://iopscience.iop.org/article/10.3847/1538-4357/ad02f6/pdf>

In this study, we report on small-scale magnetic flux ropes (SMFRs) observed as a compact series in a narrow Carrington longitudinal range during three Parker Solar Probe (PSP) encounters. First, during ~ 1.5 days of PSP's inbound part of Encounter 4, we identified a series of 11 SMFRs within $1^\circ 4'$ in longitude over the radial distance of $\sim 8.4 R_\odot$ (from ~ 44 to $35 R_\odot$). The identified SMFRs lasted from ~ 0.5 to 1.8 hr, and adjacent events were separated mostly by a few hours and up to ~ 6.5 hr at the longest, but some events were very closely spaced with intervals of a few \sim tens of minutes or less apart. Most of the identified SMFRs are successfully fitted to the force-free model. The SMFRs are clearly distinguished from the surroundings by a notable reduction in plasma β , which itself was comparably low (less than unity) in the background plasma. Furthermore, the magnetic field and plasma flow within the SMFRs fluctuated significantly less than the more turbulent surroundings. The fluctuations in the surrounding medium exhibited occasional Br polarity reversal (possibly switchbacks) and were Alfvénic to a large extent with far weaker compressional components. The majority of these key features with some differences have also been found in the series of SMFRs and their surroundings identified within $1^\circ 3'$ or less in longitude during Encounters 1 and 5. We speculate that these SMFRs were repetitively generated by successive reconnection within a very narrow angular zone located close to the Sun but not necessarily at the same radial position. **2-3 Nov 2018, 3-4 Jun 2020, 2020-01-25-26**

Near-orthogonal Orientation of Small-scale Magnetic Flux Ropes Relative to the Background Interplanetary Magnetic Field

Kyung-Eun [Choi](#)¹, Dae-Young Lee¹, Katsuhide Marubashi², and Seunguk Lee¹

2022 ApJ 931 98

<https://iopscience.iop.org/article/10.3847/1538-4357/ac69d3/pdf>

Small-scale magnetic flux ropes (SMFRs) have been identified at a large range of heliospheric distances from the Sun. Their features are somewhat similar to those of larger-scale flux rope structures such as magnetic clouds (MCs), while their occurrence rate is far higher. In this work, we examined the orientations of a large number of SMFRs that were identified at 1 au by fitting to the force-free model. We find that, while most of the SMFRs lie mostly close to the ecliptic plane, as previously known, their azimuthal orientations relative to the Sun–Earth line are found largely at two specific angles (slightly less than 45° and 225°). This latter feature in turn leads to a strong statistical trend in which the axis of SMFRs lies at a large tilt angle relative to (most often nearly orthogonal to) the corresponding background interplanetary magnetic field directions in the ecliptic plane. This feature is different from previous reports on SMFRs—and in stark contrast to the cases of MCs. This is an important observational constraint that should be considered for understanding SMFR generation and propagation. **6-7 Aug 1999, 21 Feb 2006**

Characteristics of Suprathermal Electrons in Small-Scale Magnetic Flux Ropes and Their Implications on the Magnetic Connection to the Sun

Kyung-Eun [Choi](#), [Dae-Young Lee](#), [Hee-Eun Wang](#), [Seunguk Lee](#), [Kyung-Chan Kim](#) & [Kyung Sun Park](#)

Solar Physics volume 296, Article number: 148 (2021)

<https://link.springer.com/content/pdf/10.1007/s11207-021-01888-0.pdf>

<https://doi.org/10.1007/s11207-021-01888-0>

Small-scale magnetic flux ropes (SMFRs) are observed more frequently than larger-scale magnetic flux ropes (e.g., magnetic clouds) in interplanetary space. We selected 235 SMFRs by applying cylindrical linear force-free fitting to 20-year observations of the Wind satellite, which meets the criteria of low beta, low temperature, an enhanced magnetic field, and a rotation feature. By examining the pitch angle distribution of suprathermal electrons for these events, we found that approximately 45.1% of the SMFRs were accompanied by unidirectional beams (strahl). A much smaller percentage of SMFRs ($\sim 10.7\%$) were associated with bidirectional beams. We also found a small percentage ($\sim 7.2\%$) of (sunward) conic distributions during SMFR events. Last, the remaining $\sim 37.0\%$ of SMFRs were associated with complex electron distributions. The unidirectional beams and most of the conics (together corresponding to $\sim 50\%$ of the total 235 SMFRs) imply open-field SMFRs with only one end connected to the Sun. For $\sim 37.7\%$ of the unidirectional beam SMFRs, the local IMF field polarity was orthogonal or inverted (possibly due to interchange reconnection). Based on the solar wind conditions around the bidirectional beams, we suggest that more than half of the bidirectional beams were not necessarily closed-field-line SMFRs. **2 Dec 1995, 16 Jun 1996, 12 Aug 1998, 10 Oct 1999, 14 September 2004, 8 Jul 2011,**

Solar Physics April 2019, 294:44

<https://link.springer.com/content/pdf/10.1007%2Fs11207-019-1433-7.pdf>

Periodic variations in solar-wind and geomagnetic parameters have long been recognized. In this work, we examine the periodic properties in the interplanetary magnetic field (IMF) near the Earth using satellite observations from 1996 to 2017. We pay particular attention to short-term periodicities (solar rotational period and its harmonics) of IMF Bz by distinguishing between the geocentric solar ecliptic (GSE) and the geocentric solar magnetospheric (GSM) coordinates. We find that, for nearly all of the years in Solar Cycles 23 and 24, IMF Bz exhibits periodic changes with a period of the solar rotation or its harmonics or both. We emphasize that these changes are far more pronounced in the GSM coordinates than in the GSE coordinates and during the northern hemisphere spring and fall seasons than the other two seasons. We attribute this result to an exquisite harmony between the Russell–McPherron effect and a well-defined IMF polarity that shows either a two- or four-sector structure for a long period of time.

Statistical properties and geoeffectiveness of southward interplanetary magnetic field with emphasis on weakly southward Bz events

Kyung-Eun **Choi**, Dae-Young Lee, Kyu-Cheol Choi, Jaehun Kim

JGR 2017

<http://onlineibrary.wiley.com/doi/10.1002/2016JA023836/pdf>

In this work we analyze the statistical properties and geoeffectiveness of southward IMF Bz (Bs) events measured near the Earth from 1996 to 2015. We classify the Bs events into six contrasting classes according to the duration and intensity of Bs: two subclasses of long-lasting major-intensity, two subclasses of long-lasting weak-intensity and two subclasses of short-lasting weak-intensity. We find the following results. (1) The occurrence rate of Bs events is lowest for the long-lasting major-intensity Bs classes, and increases toward shorter-lasting and weaker-intensity Bs classes. (2) Many of the Bs events in nearly all classes are associated with regions other than interplanetary coronal mass ejections and coronal-hole high-speed streams. (3) Alfvén waves account for a significant fraction of the Bs events (e.g., ~60% for the short-lasting and weak-intensity Bs classes). (4) There are clear differences in solar cycle dependence of Bs events among the different Bs classes. (5) Even either the long-lasting or short-lasting weak-intensity class Bs events can often be geoeffective by triggering substorms of weak-to-medium intensity and by enhancing geosynchronous relativistic electron fluxes. In conclusion, we emphasize that even the weakly (in terms of either intensity or duration) southward IMF Bz should be considered significant from the viewpoint of their high occurrence rate and their geoeffectiveness compared to those of long-lasting major-intensity.

Statistical Analysis of the Relationships among Coronal Holes, Corotating Interaction Regions, and Geomagnetic Storms

Yunhee **Choi** · Y.-J. Moon · Seonghwan Choi · Ji-Hye Baek · Sungsoo S. Kim · K.-S. Cho · G.S. Choe

Solar Phys (2009) 254: 311–323; **File**

We have examined the relationships among coronal holes (CHs), corotating interaction regions (CIRs), and geomagnetic storms in the period 1996 – 2003. We have identified 123 CIRs with forward and reverse shock or wave features in ACE and *Wind* data and have linked them to coronal holes shown in National Solar Observatory/Kitt Peak (NSO/KP) daily He I 10 830 Å maps considering the Sun – Earth transit time of the solar wind with the observed wind speed.

A sample of 107 CH – CIR pairs is thus identified. We have examined the magnetic polarity, location, and area of the CHs as well as their association with geomagnetic storms ($Dst \leq -50$ nT). For all pairs, the magnetic polarity of the CHs is found to be consistent with the sunward (or earthward) direction of the interplanetary magnetic fields (IMFs), which confirms the linkage between the CHs and the CIRs in the sample. Our statistical analysis shows that (1) the mean longitude of the center of CHs is about 8°E, (2) 74% of the CHs are located between 30°S and 30°N (*i.e.*, mostly in the equatorial regions), (3) 46% of the CIRs are associated with geomagnetic storms, (4) the area of geoeffective coronal holes is found to be larger than 0.12% of the solar hemisphere area, and (5) the maximum convective electric field E_y in the solar wind is much more highly correlated with the Dst index than any other solar or interplanetary parameter. In addition, we found that there is also a semiannual variation of CIR-associated geomagnetic storms and discovered new tendencies as follows: For negative-polarity coronal holes, the percentage (59%; 16 out of 27 events) of CIRs associated with geomagnetic storms in the first half of the year is much larger than that (25%; 6 out of 24 events) in the second half of the year and the occurrence percentage (63%; 15 out of 24 events) of CIR-associated storms in the southern

hemisphere is significantly larger than that (26%; 7 out of 27 events) in the northern hemisphere. Positive-polarity coronal holes exhibit an opposite tendency.

Constraining the Charge-, Time- and Rigidity-Dependence of Cosmic-Ray Solar Modulation with AMS-02 Observations during Solar Cycle 24

Ilias **Cholis**, [Ian McKinnon](#)

2022

<https://arxiv.org/pdf/2207.12447.pdf>

Our basic theoretical understanding of the sources of cosmic rays and their propagation through the interstellar medium is hindered by the Sun, that through the solar wind affects the observed cosmic-ray spectra. This effect is known as solar modulation. Recently released cosmic-ray observations from the Alpha Magnetic Spectrometer (AMS-02) and publicly available measurements of the solar wind properties from the Advanced Composition Explorer and the Wilcox observatory allow us to test the analytical modeling of the time-, charge- and rigidity-dependence of solar modulation. We rely on associating measurements on the local heliospheric magnetic field and the heliospheric current sheet's tilt angle, to model the time-dependence and amplitude of cosmic-ray solar modulation. We find evidence for the solar modulation's charge- and rigidity-dependence during the era of solar cycle 24. Our analytic prescription to model solar modulation can explain well the large-scale time-evolution of positively charged cosmic-ray fluxes in the range of rigidities from 1 to 10 GV. We also find that cosmic-ray electron fluxes measured during the first years of cycle 24 are less trivial to explain, due to the complex and rapidly evolving structure of the Heliosphere's magnetic field that they experienced as they propagated inwards.

Constraining the Charge-Sign and Rigidity-Dependence of Solar Modulation

Ilias **Cholis**, [Dan Hooper](#), [Tim Linden](#)

2020

<https://arxiv.org/pdf/2007.00669.pdf>

Our ability to identify the sources of cosmic rays and understand how these particles propagate through the interstellar medium is hindered by the combined effects of the solar wind and its embedded magnetic field, collectively known as solar modulation. In this paper, we build upon our previous work to model and constrain the effects of solar modulation on the cosmic-ray spectrum, using data from AMS-02 and BESS Polar II collected between 2007 and 2012, during which the heliospheric magnetic field was in a state of negative polarity. Our model uses measurements of the heliospheric magnetic field and the tilt angle of the heliospheric current sheet to accurately predict the effects of solar modulation as a function of time, charge, and rigidity. By incorporating data from a period of negative polarity, we have been able to robustly observe and constrain the charge-dependent effects of solar modulation.

Prediction of Amplitude and Timing of Solar Cycle 25

[Partha Chowdhury](#), [Rajmal Jain](#), [P. C. Ray](#), [Dipali Burud](#) & [Amlan Chakrabarti](#)

[Solar Physics](#) volume 296, Article number: 69 (2021)

<https://link.springer.com/content/pdf/10.1007/s11207-021-01791-8.pdf>

<https://doi.org/10.1007/s11207-021-01791-8>

We study the geomagnetic activity Ap-index in relation to sunspot number and area for the interval covering Solar Cycles 17 to 24 (1932 – 2019), in view of the availability of data for the Ap-index from 1932 on, in order to predict the amplitude of Sunspot Cycle 25. We examine the statistical relationship between sunspot-maximum amplitude and Ap-index, and similarly that between sunspot area and Ap-index. We apply the χ^2 -test for the best fit between two parameters and obtain the correlation coefficient. We also derive the standard deviation for the error limits in the predicted results. Our study reveals that the amplitude of the Sunspot Cycle 25 is likely to be $\approx 100.21 \pm 15.06$ and it may peak in April 2025 ± 6.5 months. On the other hand, the sunspot area will have maximum amplitude $\approx 1110.62 \pm 186.87 \mu$ Hem and may peak in February 2025 ± 5.8 months, which implies that Solar Cycle 25 will be weaker than or comparable to Solar Cycle 24. In view of our results as well as those of other investigators, we propose that the Sun is perhaps approaching a global minimum.

Short-term periodicities in interplanetary, geomagnetic and solar phenomena during solar cycle 24

Partha **Chowdhury**, D. P. Choudhary, S. Gosain, Y.-J. Moon

[Astrophysics and Space Science](#) March 2015, Volume 356, [Issue 1](#), pp 7-18

In this paper we study the quasi-periodic variations of sunspot area/number, 10.7 cm solar radio flux, Average Photospheric Magnetic Flux, interplanetary magnetic field (B_z) and the geomagnetic activity index A_p during the ascending phase of the current solar cycle 24. We use both Lomb-Scargle periodogram and wavelet analysis technique and find evidence for a multitude of quasi-periodic oscillations in all the data sets. In high frequency range (10 days to 100 days), both methods yield similar significance periodicities around 20–35 days and 45–60 days in all data sets. In the case of intermediate range, the significant periods were around 100–130 days, 140–170 days and 180–240 days. The Morlet wavelet power spectrum shows that all of the above-mentioned periods are intermittent in nature. We find that the well-known “Rieger period” of (150–160 days) and near Rieger periods (130–190 days) were significant in both solar, interplanetary magnetic field and geomagnetic activity data sets during cycle 24. The geomagnetic activity is the result of the solar wind-magnetosphere interaction. Thus the variations in the detected periodicity in variety of solar, interplanetary and geomagnetic indices could be helpful to improve our knowledge of the inter-relationship between various processes in the Sun-Earth-Heliosphere system.

Relativistic electron model in the outer radiation belt using a neural network approach

Space Weather e2021SW002808 2021

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2021SW002808>

<https://doi.org/10.1029/2021SW002808>

We present a machine-learning-based model of relativistic electron fluxes >1.8 MeV using a neural network approach in the Earth’s outer radiation belt. The Outer Radiation belt Electron Neural net model for Relativistic electrons (ORIENT-R) uses only solar wind conditions and geomagnetic indices as input. For the first time, we show that the state of the outer radiation belt can be determined using only solar wind conditions and geomagnetic indices, without any initial and boundary conditions. The most important features for determining outer radiation belt dynamics are found to be AL, solar wind flow speed and density, and SYM-H indices. ORIENT-R reproduces out-of-sample relativistic electron fluxes with a correlation coefficient of 0.95 and an uncertainty factor of ~ 2 . ORIENT-R reproduces radiation belt dynamics during an out-of-sample geomagnetic storm with good agreement to the observations. In addition, ORIENT-R was run for a completely out-of-sample period between March 2018 and October 2019 when the AL index ended and was replaced with the predicted AL index (lasp.colorado.edu/home/personnel/xinlin.li). It reproduces electron fluxes with a correlation coefficient of 0.92 and an out-of-sample uncertainty factor of ~ 3 . Furthermore, ORIENT-R captured the trend in the electron fluxes from low-earth-orbit (LEO) SAMPEX, which is a completely out-of-sample dataset both temporally and spatially. In sum, the ORIENT-R model can reproduce transport, acceleration, decay, and dropouts of the outer radiation belt anywhere from short timescales (i.e., geomagnetic storms) and very long timescales (i.e., solar cycle) variations. **Feb 20-Mar 20, 2017**

REDEFINING THE BOUNDARIES OF INTERPLANETARY CORONAL MASS EJECTIONS FROM OBSERVATIONS AT THE ECLIPTIC PLANE

C. Cid, J. Palacios, E. Saiz, and A. Guerrero

2016 ApJ 828 11

<http://arxiv.org/pdf/1609.01199v1.pdf>

On **2015 January 6–7**, an interplanetary coronal mass ejection (ICME) was observed at L1. This event, which can be associated with a weak and slow coronal mass ejection, allows us to discuss the differences between the boundaries of the magnetic cloud and the compositional boundaries. A fast stream from a solar coronal hole surrounding this ICME offers a unique opportunity to check the boundaries’ process definition and to explain differences between them. Using Wind and ACE data, we perform a complementary analysis involving compositional, magnetic, and kinematic observations providing relevant information regarding the evolution of the ICME as travelling away from the Sun. We propose erosion, at least at the front boundary of the ICME, as the main reason for the difference between the boundaries, and compositional signatures as the most precise diagnostic tool for the boundaries of ICMEs.

A Carrington-like geomagnetic storm observed in the 21st century

Consuelo Cid*, Elena Saiz, Antonio Guerrero, Judith Palacios and Yolanda Cerrato

J. Space Weather Space Clim., 5, A16 (2015)

<http://www.swsc-journal.org/articles/swsc/pdf/2015/01/swsc140015.pdf>

In **September 1859** the Colaba observatory measured the most extreme geomagnetic disturbance ever recorded at low latitudes related to solar activity: the Carrington storm. This paper describes a geomagnetic disturbance case with a

profile extraordinarily similar to the disturbance of the Carrington event at Colaba: the event on **29 October 2003** at Tihany magnetic observatory in Hungary. The analysis of the H-field at different locations during the “Carrington-like” event leads to a re-interpretation of the 1859 event. The major conclusions of the paper are the following: (a) the global Dst or SYM-H, as indices based on averaging, missed the largest geomagnetic disturbance in the 29 October 2003 event and might have missed the 1859 disturbance, since the large spike in the horizontal component (H) of terrestrial magnetic field depends strongly on magnetic local time (MLT); (b) the main cause of the large drop in H recorded at Colaba during the Carrington storm was not the ring current but field-aligned currents (FACs); and (c) the very local signatures of the H-spike imply that a Carrington-like event can occur more often than expected.

On extreme geomagnetic storms

Consuelo **Cid**, Judith Palacios, Elena Saiz, Antonio Guerrero and Yolanda Cerrato

J. Space Weather Space Clim. 4 (2014) A28; **File**

<http://www.swsc-journal.org/articles/swsc/pdf/2014/01/swsc140014.pdf>

Extreme geomagnetic storms are considered as one of the major natural hazards for technology-dependent society. Geomagnetic field disturbances can disrupt the operation of critical infrastructures relying on space-based assets, and can also result in terrestrial effects, such as the **Quebec electrical disruption in 1989**. Forecasting potential hazards is a matter of high priority, but considering large flares as the only criterion for early-warning systems has demonstrated to release a large amount of false alarms and misses. Moreover, the quantification of the severity of the geomagnetic disturbance at the terrestrial surface using indices as Dst cannot be considered as the best approach to give account of the damage in utilities. High temporal resolution local indices come out as a possible solution to this issue, as disturbances recorded at the terrestrial surface differ largely both in latitude and longitude. The recovery phase of extreme storms presents also some peculiar features which make it different from other less intense storms. This paper goes through all these issues related to extreme storms by analysing a few events, highlighting the **March 1989 storm**, related to the Quebec blackout, and the **October 2003 event**, when several transformers burnt out in South Africa.

Clarifying some issues on the geoeffectiveness of limb halo CMEs

Cid, Consuelo; Cremades, Hebe; Aran, Angels; Mandrini, Cristina; Sanahuja, Blai; Schmieder, Brigitte; Menvielle, Michel; Rodriguez, Luciano; Saiz, Elena; Cerrato, Yolanda; Dasso, Sergio; Jacobs, Carla; Lathuillere, Chantal; Zhukov, Andrei

Nature of Prominences and their role in Space Weather, Proceedings of the International Astronomical Union, IAU Symposium, Volume 300, pp. 285-288, **2014**

A recent study by Cid et al. (2012) showed that full halo coronal mass ejections (CMEs) coming from the limb can disturb the terrestrial environment. Although this result seems to rise some controversies with the well established theories, the fact is that the study encourages the scientific community to perform careful multidisciplinary analysis along the Sun-to-Earth chain to fully understand which are the solar triggers of terrestrial disturbances. This paper aims to clarify some of the polemical issues arisen by that paper.

Modeling the recovery phase of extreme geomagnetic storms

C. **Cid**, J. Palacios, E. Saiz, Y. Cerrato, J. Aguado, A. Guerrero

J. Geophys. Res. Space Physics, **2013**, 118, 1-8

<http://arxiv.org/pdf/1405.4804v1.pdf>

The recovery phase of the largest storms ever recorded has been studied. These events provide an extraordinary opportunity for two goals: (1) to validate the hyperbolic model by Aguado et al. [2010] for the recovery phase after disturbances as severe as the Carrington event, or that related to the Hydro-Quebec blackout in March 1989, and (2) to check whether the linear relationship between the recovery time and the intensity of the storm still complies. Our results reveal the high accuracy of the hyperbolic decay function to reproduce the recovery phase of the magnetosphere after an extreme storm. Moreover, the characteristic time that takes the magnetosphere to recover depends in an exponential way on the intensity of the storm, as indicated by the relationship between the two parameters involved in the hyperbolic decay. This exponential function can be approached by a linear function when the severity of the storm diminishes.

Table 1. Chronological list of large geomagnetic storms analyzed in this paper

Event #	Year	Month	Day	Observatory	H range (nT)	Geomagnetic latitude ^a
1	1859	September	1-2	Bombay	1720	9.74
2	1921	May	13-16	Alibag	>700	9.46
3	1928	July	7	Alibag	780	9.45
4	1938	April	16	Alibag	530	9.37
5	1957	September	13	Alibag	580	9.29
6	1958	February	11	Alibag	660	9.29
7	1989	March	13	Kakioka	640	26.6

Can a halo CME from the limb be geoeffective?

Cid, C., H. Cremades, A. Aran, C. Mandrini, B. Sanahuja, B. Schmieder, M. Menvielle, L. Rodriguez, E. Saiz, Y. Cerrato, S. Dasso, C. Jacobs, C. Lathuillere, and A. Zhukov
J. Geophys. Res., 117, A11102, doi:10.1029/2012JA017536, **2012**

The probability for a halo coronal mass ejection (CME) to be geoeffective is assumed to be higher the closer the CME launch site is located to the solar central meridian. However, events far from the central meridian may produce severe geomagnetic storms, like the case in April 2000. In this work, we study the possible geoeffectiveness of full halo CMEs with the source region situated at solar limb. For this task, we select all limb full halo (LFH) CMEs that occurred during solar cycle 23, and we search for signatures of geoeffectiveness between 1 and 5 days after the first appearance of each CME in the LASCO C2 field of view. When signatures of geomagnetic activity are observed in the selected time window, interplanetary data are carefully analyzed in order to look for the cause of the geomagnetic disturbance. Finally, a possible association between geoeffective interplanetary signatures and every LFH CME in solar cycle 23 is checked in order to decide on the CME's geoeffectiveness. After a detailed analysis of solar, interplanetary, and geomagnetic data, we conclude that of the 25 investigated events, there are only four geoeffective LFH CMEs, all coming from the west limb. The geoeffectiveness of these events seems to be moderate, turning to intense in two of them as a result of cumulative effects from previous mass ejections. We conclude that ejections from solar locations close to the west limb should be considered in space weather, at least as sources of moderate disturbances.

Comment on “Interplanetary conditions leading to superintense geomagnetic storms (Dst _ 250 nT) during solar cycle 23”,

Cid, C., E. Saiz, and Y. Cerrato,
Geophys. Res. Lett., 35, L21107, DOI: [10.1029/2008GL034731](https://doi.org/10.1029/2008GL034731), **2008**.
sci-hub.se/10.1029/2008gl034731

Sources of intense geomagnetic storms over the rise of solar cycle 23.

Cid, C., Hidalgo, M.A., Saiz, E., Cerrato, Y., Sequeiros, J.,
2004. Sol. Phys. 223, 231–243.

In this work we present a study of the triggers of intense geomagnetic storms since the launch of the WIND spacecraft, November 1995 until December 2001. Reviewing the signatures of solar wind flow, we looked for two different kinds of interplanetary events associated with intense geomagnetic storms: ejecta and corotating solar wind streams. We also looked for the solar origin related to both events. We provide a list of the solar terrestrial events during the rising phase of this solar cycle. The paper includes statistical conclusions that shed light onto the paradigm of geomagnetic storms.

Large Sunspot Groups and Great Magnetic Storms: Magnetic Suppression of CMEs

Edward W. **Cliver**¹, Werner Pötzi², and Astrid M. Veronig^{2,3}
2022 ApJ 938 136

<https://iopscience.iop.org/article/10.3847/1538-4357/ac847d/pdf>

A solar spot group with a large area is not a requirement for a great magnetic storm. Nearly half (14/30) of all storms with a minimum Dst value ≤ -300 nT from 1932–2014 originated in spot groups with corrected areas ≤ 1000 millionths of a solar hemisphere (μ sh) on the day of the associated eruption. Over the same interval, spot groups with area 3000–4000 μ sh were ~ 250 times more likely to give rise to a great storm than those with areas from 100–1000 μ sh, with the high percentage of great storms originating in small spot groups attributed primarily to the much higher occurrence

frequency of such groups. Above $\sim 3500 \mu\text{sh}$, the ability of a spot group to produce a great storm appears to drop abruptly. For the 1932–2014 interval, we find that for the 71 days when a spot group had a measured daily area of 3000–3500 μsh , five great storms were observed versus none for the 67 times when a group spot with an area from 3500 to $\sim 6000 \mu\text{sh}$ was observed on the Sun. This is consistent with recent studies indicating that large spot groups on the Sun and stars can suppress coronal mass ejections. **May 1951, Sep 1957, Oct 2014**

Extreme solar events

Review

[Edward W. Cliver](#), [Carolus J. Schrijver](#), [Kazunari Shibata](#) & [Ilya G. Usoskin](#)

[Living Reviews in Solar Physics](#) volume 19, Article number: 2 (2022)

<https://link.springer.com/content/pdf/10.1007/s41116-022-00033-8.pdf>

We trace the evolution of research on extreme solar and solar-terrestrial events from the 1859 Carrington event to the rapid development of the last twenty years. Our focus is on the largest observed/inferred/theoretical cases of sunspot groups, flares on the Sun and Sun-like stars, coronal mass ejections, solar proton events, and geomagnetic storms. The reviewed studies are based on modern observations, historical or long-term data including the auroral and cosmogenic radionuclide record, and Kepler observations of Sun-like stars. We compile a table of 100- and 1000-year events based on occurrence frequency distributions for the space weather phenomena listed above. Questions considered include the Sun-like nature of superflare stars and the existence of impactful but unpredictable solar "black swans" and extreme "dragon king" solar phenomena that can involve different physics from that operating in events which are merely large. **774 AD, 17 Sep 1770, 1 September 1859, 4 Feb 1872, 14-15 May 1921, 28 Feb 1942, 5 April 1947, 23 May 1967, 2–11 August 1972, 29 Apr 1973, 21 Apr 2002, 28 October 2003; 6, 13, 14 Dec 2006, 9 Nov 2011, 28 Oct 2013, 4 Nov 2015**

Minimal Magnetic States of the Sun and the Solar Wind: Implications for the Origin of the Slow Solar Wind

Review

E. W. [Cliver](#), R. von Steiger

[Space Science Reviews](#) September 2017, Volume 210, [Issue 1–4](#), pp 227–247

sci-hub.tw/10.1007/s11214-015-0224-1

During the last decade it has been proposed that both the Sun and the solar wind have minimum magnetic states, lowest order levels of magnetism that underlie the 11-yr cycle as well as longer-term variability. Here we review the literature on basal magnetic states at the Sun and in the heliosphere and draw a connection between the two based on the recent deep 2008–2009 minimum between cycles 23 and 24. In particular, we consider the implications of the low solar activity during the recent minimum for the origin of the slow solar wind.

The 1859 Space Weather Event Revisited

Ed [Cliver](#)

RHESSI Science Nugget, No. 213, Nov. 2013

http://sprg.ssl.berkeley.edu/~tohban/wiki/index.php/The_1859_Space_Weather_Event_Revisited

The 1859 space weather event revisited: limits of extreme activity

Edward W. [Cliver](#)^{1*} and William F. Dietrich²

J. Space Weather Space Clim., Volume 3, 2013, A31; **File**

sci-hub.se/10.1051/swsc/2013053

The solar flare on **1 September 1859** and its associated geomagnetic storm remain the standard for an extreme solar-terrestrial event. The most recent estimates of the flare soft X-ray (SXR) peak intensity and Dst magnetic storm index for this event are: SXR class = X45 (± 5) (vs. X35 (± 5) for the 4 November 2003 flare) and minimum Dst = -900 ($+50$, -150) nT (vs. -825 to -900 nT for the great storm of May 1921). We have no direct evidence of an associated solar energetic proton (SEP) event but a correlation between >30 MeV SEP fluence (F30) and flare size based on modern data yields a best guess F30 value of $\sim 1.1 \times 10^{10}$ pr cm^{-2} (with the $\pm 1\sigma$ uncertainty spanning a range from $\sim 10^9$ – 10^{11} pr cm^{-2}) for a composite (multi-flare plus shock) 1859 event. This value is approximately twice that of estimates/measurements – ranging from ~ 5 – 7×10^9 pr cm^{-2} – for the largest SEP episodes (July 1959, November 1960, August 1972) in the modern era.

Great geomagnetic storm of 9 November 1991: Association with a disappearing solar filament

E. W. Cliver, K. S. Balasubramaniam, N. V. Nitta, X. Li

J. Geophys. Res., 114, A00A20, 2009, doi:10.1029/2008JA013232. **File**

<http://dx.doi.org/10.1029/2008JA013232>

sci-hub.se/10.1029/2008JA013232

We attribute the great geomagnetic storm on 8–10 November 1991 to a large-scale eruption that encompassed the disappearance of a $\sim 25^\circ$ solar filament in the southern solar hemisphere. The resultant soft X-ray arcade spanned $\sim 90^\circ$ of solar longitude. The rapid growth of an active region lying at one end of the X-ray arcade appears to have triggered the eruption. This is the largest geomagnetic storm yet associated with the eruption of a quiescent filament. The minimum hourly *Dst* value of **−354 nT on 9 November 1991** compares with a minimum *Dst* value of -161 nT for the largest 27-day recurrent (coronal hole) storm observed from 1972 to 2005 and the minimum -559 nT value observed during the flare-associated storm of 14 March 1989, the greatest magnetic storm recorded during the space age. Overall, the November 1991 storm ranks 15th on a list of *Dst* storms from 1905 to 2004, surpassing in intensity such well-known storms as 14 July 1982 (-310 nT) and 15 July 2000 (-317 nT). We used the Cliver et al. and Gopalswamy et al. empirical models of coronal mass ejection propagation in the solar wind to provide consistency checks on the eruption/storm association.

The 1859 Solar-Terrestrial Disturbance And the Current Limits of Extreme Space Weather Activity

Cliver, E. W., and Svalgaard, L.:

2004, *Solar Phys.* 224, 407, **File**.

<https://link.springer.com/content/pdf/10.1007%2Fs11207-005-4980-z.pdf>

sci-hub.se/10.1007/s11207-005-4980-z

It is generally appreciated that the **September 1859** solar-terrestrial disturbance, the first recognized space weather event, was exceptionally large. How large and how exceptional? To answer these questions, we compiled rank order lists of the various measures of solar-induced disturbance for events from 1859 to the present. The parameters considered included: magnetic crochet amplitude, solar energetic proton fluence (McCracken et al., 2001a), **Sun-Earth disturbance transit time, geomagnetic storm intensity**, and low-latitude auroral extent. While the 1859 event has close rivals or superiors in each of the above categories of space weather activity, it is the only documented event of the last ~ 150 years that appears at or near the top of all of the lists. Taken together, the top-ranking events in each of the disturbance categories comprise a set of benchmarks for extreme space weather activity.

How big was the Carrington 1859 Flare?

Cliver, E. W., Svalgaard, L., and Neidig D.F.

American Geophysical Union, Spring Meeting 2004, abstract #SH43A-03

The 1859 space weather event was distinguished by its great geomagnetic storm, widespread low-latitude aurora, and intense solar energetic particle event (inferred from the NO₃ concentration in polar ice cores). Arguably each of these three effects was the largest ever observed. What can we say about the size of the associated solar flare? We have two observations with which to make such an assessment: (1) Carrington's and Hodgson's report of the white-light flare and (2) the solar flare effect or magnetic crochet observed in the Kew and Greenwich magnetograms. Estimates of the area, duration, spectrum, and intensity of the white-light emission indicate a large ($\sim 2 \times 10^{30}$ erg) but not unequalled event (the white-light emission of the 24 April 1984 >X13 flare contained $\sim 6 \times 10^{30}$ erg). The magnetic crochet of 130 nT in the horizontal force, however, exceeds that for all >X10 soft X-ray flares observed from 1984–2002 (we are presently compiling magnetic data for the recent October–November 2003 activity for comparison with the 1859 event). Thus at this point, we can conservatively say that Carrington's flare likely had a soft X-ray classification >X10 and was at least comparable to the largest flares recorded during the spacecraft era.

Mountains versus valleys: Semiannual variation of geomagnetic activity,

Cliver, E. W., Y. Kamide, and A. G. Ling (2000),

J. Geophys. Res., 105, 2413–2424.

The semiannual variation in geomagnetic activity is generally attributed to the Russell-McPherron effect. In that picture, enhancements of southward field *B_s* near the equinoxes account for the observed higher geomagnetic activity in March and September. In a contrary point of view, we argue that the bulk of the semiannual variation results from an equinoctial effect (based on the ψ angle between the solar wind flow direction and Earth's dipole axis) that makes *B_s*

coupling less effective (by ~25% on average) at the solstices. Thus the semiannual variation is not simply due to "mountain building" (creation of Bs) at the equinoxes but results primarily from "valley digging" (loss of coupling efficiency) at the solstices. We estimate that this latter effect, which clearly reveals itself in the diurnal variation of the am index, is responsible for ~65% of the semiannual modulation. The characteristic imprint of the equinoctial hypothesis is also apparent in hourly/monthly averages of the time-differential Dst index and the AE index.

Energetic Particle Increases Associated with Stream Interaction Regions

C. M. S. [Cohen](#), [E. R. Christian](#), [A. C. Cummings](#), [A. J. Davis](#), [M. I. Desai](#),

ApJS Volume 246, Issue 2, id.20 2020

<https://arxiv.org/ftp/arxiv/papers/1912/1912.08244.pdf>

<https://sci-hub.tw/10.3847/1538-4365/ab4c38>

The **Parker Solar Probe** was launched on 2018 August 12 and completed its second orbit on 2019 June 19 with perihelion of 35.7 solar radii. During this time, the Energetic particle Instrument-Hi (EPI-Hi, one of the two energetic particle instruments comprising the Integrated Science Investigation of the Sun, ISOIS) measured seven proton intensity increases associated with stream interaction regions (SIRs), two of which appear to be occurring in the same region corotating with the Sun. The events are relatively weak, with observed proton spectra extending to only a few MeV and lasting for a few days. The proton spectra are best characterized by power laws with indices ranging from -4.3 to -6.5, generally softer than events associated with SIRs observed at 1 au and beyond. Helium spectra were also obtained with similar indices, allowing He/H abundance ratios to be calculated for each event. We find values of 0.016-0.031, which are consistent with ratios obtained previously for corotating interaction region events with fast solar wind < 600 km s⁻¹. Using the observed solar wind data combined with solar wind simulations, we study the solar wind structures associated with these events and identify additional spacecraft near 1 au appropriately positioned to observe the same structures after some corotation. Examination of the energetic particle observations from these spacecraft yields two events that may correspond to the energetic particle increases seen by EPI-Hi earlier.

Quantitative Comparison of Methods for Predicting the Arrival of Coronal Mass Ejections at Earth based on multi-view imaging†

R. C. [Colaninno](#)*, [A. Vourlidas](#), [C. C. Wu](#)

Journal of Geophysical Research: Space Physics, Nov 2013; File

<http://arxiv.org/pdf/1310.6680v2.pdf>

[1] We investigate the performance of six methods for predicting the coronal mass ejection (CME) time of arrival (ToA) and velocity at Earth using a sample of nine Earth-impacting CMEs between March 2010 and June 2011. The CMEs were tracked continuously from the Sun to near Earth in multi-viewpoint imaging data from STEREO SECCHI and SOHO LASCO. We use the Graduate Cylindrical Shell (GCS) model to estimate the three-dimensional direction and height of the CMEs in every image out to ~200 R_⊙. We fit the derived three-dimensional (deprojected) height and time (HT) data with six different methods to extrapolate the CME ToA and velocity at Earth. We compare the fitting results with the in situ data from the Wind spacecraft. We find that a simple linear fit above a height of 50R_⊙ gives the ToA with an error ±6 hours for seven (78%) of the CMEs. For the full sample, we are able to predict the ToA to within ±13 hours. These results are a half day improvement over past CME arrival time methods that only used SOHO LASCO data. We conclude that heliographic height-time measurements of the CME front made away from the Sun-Earth line and beyond the coronagraphic field of view are sufficient for reasonably accurate predictions of their ToA.

A Framework for Evaluating Geomagnetic Indices Forecasting Models

Armando [Collado-Villaverde](#), [Pablo Muñoz](#), [Consuelo Cid](#)

Space Weather e2024SW003868 [Volume22, Issue3](#) 2024

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2024SW003868>

The use of Deep Learning models to forecast geomagnetic storms is achieving great results. However, the evaluation of these models is mainly supported on generic regression metrics (such as the Root Mean Squared Error or the Coefficient of Determination), which are not able to properly capture the specific particularities of geomagnetic storms forecasting. Particularly, they do not provide insights during the high activity periods. To overcome this issue, we introduce the Binned Forecasting Error to provide a more accurate assessment of models' performance across the different intensity levels of a geomagnetic storm. This metric facilitates a robust comparison of different forecasting models, presenting a true representation of a model's predictive capabilities while being resilient to different storms duration. In this direction, for enabling fair comparison among models, it is important to standardize the sets of geomagnetic storms for model training, validation and testing. To do this, we have started from the current sets used in the literature for forecasting the

SYM-H, enriching them with newer storms not considered previously, focusing not only on disturbances caused by Coronal Mass Ejections but also addressing High-Speed Streams. To operationalize the evaluation framework, a comparative study is conducted between a baseline neural network model and a persistence model, showcasing the effectiveness of the new metric in evaluating forecasting performance during intense geomagnetic storms. Finally, we propose the use of preliminary measurements from ACE to evaluate the model performance in settings closer to an operational real-time scenario, where the forecasting models are expected to operate.

Table 5 Details of the SYM-H Index Storms Used to Train, Validate and Test the Model 1998-2022

Deep Neural Networks With Convolutional and LSTM Layers for SYM-H and ASY-H Forecasting

Armando [Collado-Villaverde](#), [Pablo Muñoz](#), [Consuelo Cid](#)

Space Weather 2021

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2021SW002748>

<https://doi.org/10.1029/2021SW002748>

Geomagnetic indices quantify the disturbance caused by the solar activity on a planetary scale or in particular regions of the Earth. Among them, the SYM-H and ASY-H indices represent the (longitudinally) symmetric and asymmetric geomagnetic disturbance of the horizontal component of the magnetic field at midlatitude with a 1-min resolution. Their resolution, along with their relation to the solar wind parameters, makes the forecasting of the geomagnetic indices a problem that can be addressed through the use of Deep Learning, particularly using Deep Neural Networks (DNNs). In this work, we present two DNNs developed to forecast respectively the SYM-H and ASY-H indices. Both networks have been trained using the Interplanetary Magnetic Field (IMF) and the related index for the solar storms occurred in the last two solar cycles. As a result, the networks are able to accurately forecast the indices 2 h in advance, considering the IMF and indices values for the previous 200 min. The evaluation of both networks reveals a great forecasting precision, including good predictions for large storms that occurred during the solar cycle 23 and comparing with the persistence model for the period 2013–2020.

Corotating Interaction Regions as Seen by the STEREO Heliospheric Imagers 2007–2010

T. M. [Conlon](#), S. E. Milan, J. A. Davies

Solar Phys., Volume 290, Issue 8, pp 2291-2309 2015

NASA's Solar Terrestrial Relations Observatory (STEREO) mission has coincided with a pronounced solar minimum. This allowed for easier detection of corotating interaction regions (CIRs). CIRs are formed by the interaction between fast and slow solar-wind streams ejected from source regions on the solar surface that rotate with the Sun. High-density plasma blobs that have become entrained at the stream interface can be tracked out to large elongations in data from the Heliospheric Imager (HI) instruments onboard STEREO. These blobs act as tracers of the CIR itself such that their HI signatures can be used to estimate CIR source location and radial speed. We estimate the kinematic properties of solar-wind transients associated with 40 CIRs detected by the HI instrument onboard the STEREO-A spacecraft between 2007 and 2010. We identify in-situ signatures of these transients at L1 using the Advanced Composition Explorer (ACE) and compare the in-situ parameters with the HI results. We note that solar-wind transients associated with CIRs appear to travel at or close to the slow solar-wind speed preceding the event as measured in situ. We also highlight limitations in the commonly used analysis techniques of solar-wind transients by considering variability in the solar wind.

Table 2 Timing and propagation speed of the 40 events used in this study. The start time is the start time of the time–elongation profile that starts at $\varphi = 180^\circ$ to the nearest hour in the format dd mmm yyyy hh.

Assessing the Effect of Spacecraft Motion on Single-Spacecraft Solar Wind Tracking Techniques

T. M. [Conlon](#), S. E. Milan, J. A. Davies

Solar Phys., 289, Issue 10, pp.3935-3947 2014

Recent advances in wide-angle imaging by the Solar Mass Ejection Imager (SMEI) on board the Coriolis spacecraft and more recently by the Heliospheric Imagers (HI) aboard NASA's Solar Terrestrial Relations Observatory (STEREO), have enabled solar wind transients to be imaged and tracked from the Sun to 1 AU and beyond. In this paper we consider two of the techniques that have been used to determine the propagation characteristics of solar wind transients based on single-spacecraft observations, in particular propagation direction and radial speed. These techniques usually assume that the observing spacecraft remains stationary for the duration of observation of the solar wind transient. We determine the inaccuracy introduced by this assumption for the two STEREO spacecraft and find that it can be

significant, and it can lead to an overestimation of the transient velocity as seen from STEREO-A and an underestimation as seen by STEREO-B. This has implications for the prediction of solar wind transients at 1 AU and hence is important for the study of space weather.

Forecasting Geomagnetic Storm Disturbances and Their Uncertainties Using Deep Learning

D. Conde, [F. L. Castillo](#), [C. Escobar](#), [C. García](#), [J. E. García](#), [V. Sanz](#), [B. Zaldívar](#), [J. J. Curto](#), [S. Marsal](#), [J. M. Torta](#)

Space Weather [Volume 21, Issue 11](#) e2023SW003474 **2023**

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2023SW003474>

Severe space weather produced by disturbed conditions on the Sun results in harmful effects both for humans in space and in high-latitude flights, and for technological systems such as spacecraft or communications. Also, geomagnetically induced currents (GICs) flowing on long ground-based conductors, such as power networks, potentially threaten critical infrastructures on Earth. The first step in developing an alarm system against GICs is to forecast them. This is a challenging task given the highly non-linear dependencies of the response of the magnetosphere to these perturbations. In the last few years, modern machine-learning models have shown to be very good at predicting magnetic activity indices. However, such complex models are on the one hand difficult to tune, and on the other hand they are known to bring along potentially large prediction uncertainties which are generally difficult to estimate. In this work we aim at predicting the SYM-H index characterizing geomagnetic storms multiple-hour ahead, using public interplanetary magnetic field (IMF) data from the Sun-Earth L1 Lagrange point and SYM-H data. We implement a type of machine-learning model called long short-term memory (LSTM) network. Our scope is to estimate the prediction uncertainties coming from a deep-learning model in the context of forecasting the SYM-H index. These uncertainties will be essential to set reliable alarm thresholds. The resulting uncertainties turn out to be sizable at the critical stages of the geomagnetic storms. Our methodology includes as well an efficient optimization of important hyper-parameters of the LSTM network and robustness tests.

Calculating travel times and arrival speeds of CMEs to Earth: An analytic tool for space weather forecasting

P. [Corona-Romero](#), J. A. Gonzalez-Esparza, C. A. Perez-Alanis, E. Aguilar-Rodriguez, V. de-la-Luz, J. C. Mejia-Ambriz

Space Weather Vol: 15, Pages: 464–483 **2017**

<http://sci-hub.cc/10.1002/2016SW001489>

Coronal mass ejections (CME) are one of the most important phenomena derived from solar activity that potentially perturb space weather of Earth. In this work we present a semiempirical arrival forecasting tool for Earth-directed halo CMEs. This tool combines the piston shock model and an empirical relationship to estimate in situ arrivals of halo CMEs. The empirical relationship uses the initial conditions of CMEs to calculate the value of free parameter of the piston shock model, a parameter which is closely related to the initial inertia of CMEs. Such a value will let the model to simultaneously approximate the travel time and arrival speed of CMEs (i.e., CME arrivals). We test the forecasting capabilities of our model and its empirical relationship by calculating the arrivals of 40 halo CMEs detected during the period of 1995–2015. Our results indicate that, together, the piston shock model and its empirical relationship approximate CME arrivals with average errors of 7 h for travel times, and 100 km s⁻¹ for arrival speeds. Our results show that our model is suitable for arrival forecasting of isolated events propagating through quiet interplanetary medium.

Table 1. Data and results from the analysis of 21 events (Section 2.2).

Kinematics of ICMEs/shocks: blast wave reconstruction using type II emissions

P. [Corona-Romero](#), J.A. Gonzalez-Esparza, E. Aguilar-Rodriguez, V. de-la-Luz, J.C. Mejia-Ambriz

Solar Phys. Volume 290, Issue 9, pp 2439-2454 **2015**

<http://arxiv.org/pdf/1501.05551v1.pdf>

We present a physical methodology to reconstruct the trajectory of interplanetary shocks using type II radio emission data. This technique calculates the shock trajectory assuming that the disturbance propagates as a blast wave in the interplanetary medium. We applied this Blast Wave Reconstruction (BWR) technique to analyze eight fast Earth-directed ICMEs/shocks associated with type II emissions. The technique deduces a shock trajectory that reproduces the type II frequency drifts, and calculates shock onset speed, shock transit time and shock speed at 1~AU. There were good agreements comparing the BWR results with the type II spectra, with data from coronagraph images, { \it in situ }

measurements, and interplanetary scintillation (IPS) observations. Perturbations on the type II data affect the accuracy of the BWR technique. This methodology could be applied to track interplanetary shocks causing TII emissions in real-time, to predict the shock arrival time and shock speed at 1~AU. **6 Jun 2000, 14 July 2000, 26 Apr 2001, 24 Sept 2001, 20011104, 20011122, 20040725, 20050513**

Propagation of Fast Coronal Mass Ejections and Shock Waves Associated with Type II Radio-Burst Emission: An Analytic Study

P. **Corona-Romero**, J. A. Gonzalez-Esparza and E. Aguilar-Rodriguez

Solar Physics, July **2013**, Volume 285, Issue 1-2, pp 391-410

Coronal mass ejections (CMEs) are large-scale eruptive events in the solar corona. Once they are expelled into the interplanetary (IP) medium, they propagate outwards and “evolve” interacting with the solar wind. Fast CMEs associated with IP shocks are a critical subject for space weather investigations. We present an analytic model to study the heliocentric evolution of fast CME/shock events and their association with type II radio-burst emissions. The propagation model assumes an early stage where the CME acts as a piston driving a shock wave; beyond this point the CME decelerates, tending to match the ambient solar wind speed and its shock decays. We use the shock speed evolution to reproduce type II radio-burst emissions. We analyse four fast CME halo events that were associated with kilometric type II radio bursts, and in-situ measurements of IP shock and CME signatures. The results show good agreement with the dynamic spectra of the type II frequency drifts and the in-situ measurements. This suggests that, in general, IP shocks associated with fast CMEs evolve as blast waves approaching 1 AU, implying that the CMEs do not drive their shocks any further at this heliocentric range.

Numeric and analytic study of interplanetary coronal mass ejection and shock evolution: Driving, decoupling, and decaying

Corona-Romero, P.; Gonzalez-Esparza, J. A.

J. Geophys. Res., Vol. 116, No. A5, A05104, **2011**

<http://dx.doi.org/10.1029/2010JA016008>

We analyze the heliocentric evolution of fast interplanetary counterparts of coronal mass ejections (ICMEs) and their transient shocks to investigate how and where they decelerate in the interplanetary medium. We employ two one-dimensional hydrodynamic models, analytic and numeric, to study three fast CME events. We focus on the transferring of momentum from the ICME to the shock. The two models show that initially the fast ICME propagates at about a constant speed and drives the shock (driving stage) until it reaches a certain distance from which it decelerates and decouples from the shock (decoupling process). Then the ICME and its shock decelerate (decaying stage). This deceleration depends on the speed difference with respect to the ambient wind and tends to a negligible value when the ICME-shock approaches to the ambient wind speed. The location and duration of these propagation stages depend on the initial CME conditions and the ambient wind characteristics. We present a parametric study to compare the results by the analytic and numeric models, showing the variations of their results as a function of the initial conditions. We perform three study cases to compare the model's predictions with a set of speed measurements of ICME-shock events.

Constraining the global heliospheric transport of galactic cosmic rays in solar cycles 23 and 24

Claudio **Corti** (1 and 2), [Peter Sadowski](#) (1), [Nikolay Nikonov](#) (1), [Marius Potgieter](#) (3), [Veronica Bindi](#) (1)

Proceedings of the 38th International Cosmic Ray Conference (ICRC23) **2023**

<https://arxiv.org/pdf/2307.15848.pdf>

Galactic cosmic rays (GCRs) are affected by solar modulation while they propagate through the heliosphere. The study of the time variation of GCR spectra observed at Earth can shed light on the underlying physical processes, specifically diffusion and particle drifts. We combine a state-of-the-art 3D numerical model of GCR transport in the heliosphere with a neural-network-accelerated Markov chain Monte Carlo to constrain the rigidity and time dependence of the global transport coefficients, using precise GCR data from the PAMELA and AMS-02 experiments between 2006 and 2019.

Test of validity of the force-field approximation with AMS-02 and PAMELA monthly fluxes

Claudio **Corti** (1), [Veronica Bindi](#) (1), [Cristina Consolandi](#) (1), [Christopher Freeman](#) (1), [Andrew Kuhlman](#) (1), [Christopher Light](#) (1), [Matteo Palermo](#) (1), [Siqi Wang](#) (1) ((1) University of Hawaii at Manoa)

Proceeding of the 36th International Cosmic Ray Conference (ICRC19) **2019**

<https://arxiv.org/pdf/1910.00027.pdf>

Galactic cosmic rays (GCRs) entering the heliosphere are disturbed by the magnetic field of the Sun, which varies the shape and intensity of their local interstellar spectrum. The force-field approximation is a popular way of dealing with

solar modulation, especially for studies focused on galactic transport of cosmic rays. The validity of this approach to reproduce the modulated GCR fluxes at Earth is tested using monthly proton fluxes measured by PAMELA between July 2006 and January 2014 and monthly proton and helium fluxes measured by AMS-02 between May 2011 and May 2017. We show that the precision of the new AMS-02 data requires a rigidity-dependent modification of the force-field approximation.

Effects of different geomagnetic storm drivers on the ring current: CRCM results

W.D. **Cramer**^{1,*}, N.E. Turner, I. M.-C. Fok², N.Y. Buzulukova

JGR, Volume 118, Issue 3, pages 1062–1073, March 2013

The storm-time magnetic disturbance at the Earth's equator, as commonly measured by the Dst index, is induced by currents in the near-Earth magnetosphere. The ring current is generally considered the most important contributor, but other magnetospheric currents have also been found to have significant effects. Of the two main types of solar geomagnetic storm drivers, Coronal Mass Ejections (CMEs) tend to have a much greater impact on Dst than Corotating Interaction Regions (CIRs). Ring current models have been found to underestimate Dst, particularly during storms driven by CIRs. One possible explanation is that the models neglect to handle some aspect of ring current physics that is particularly important for CIRs. This study uses the Comprehensive Ring Current Model (CRCM) to estimate the ring current contribution to Dst for a selection of storms of various strengths and different drivers (CMEs and CIRs) that have solar wind parameters that fit a typical profile. The model boundary is set to 10 RE at the equator, encompassing the entire ring current region. The magnetic field is held fixed, based on average storm parameters, which limits our model results to the effects of convection and plasma sheet density at the model boundary. Our model results generally show good agreement with the size and timing of fluctuations in Dst, which indicates that convection and boundary conditions play an important role in shaping Dst. We also find excellent agreement with the magnitude of Dst for CME-driven storms. For CIR-driven storms, however, the magnitude at the peak of the storm frequently deviates from actual Dst. In general, we agree with the results of previous research that CIR-driven storms are more underpredicted. However, this study includes some weaker CIR-driven storms for which Dst is actually overpredicted. Overall, when examining the dependence of modeled Dst* on actual Dst* at storm peak, we find that there is a statistically significant difference between CME- and CIR-driven storms. We also find that approximately half of the total ring current energy lies beyond an L-value of 6.6. However, this figure could be overestimated due to the use of a static magnetic field, which limits radial transport.

The Sun's Alfvén Surface: Recent Insights and Prospects for the Polarimeter to Unify the Corona and Heliosphere (PUNCH) Review

Steven R. **Cranmer** (CU Boulder), [Rohit Chhiber](#) (U. Del., GSFC), [Chris R. Gilly](#) (SwRI, CU Boulder), [Iver H. Cairns](#) (U. Sydney), [Robin C. Colaninno](#) (NRL), [David J. McComas](#) (Princeton), [Nour E. Raouafi](#) (JH/APL), [Arcadi V. Usmanov](#) (U. Del., GSFC), [Sarah E. Gibson](#) (HAO/NCAR), [Craig E. DeForest](#) (SwRI)

Solar Physics 298, Article number: 127 2023

<https://arxiv.org/pdf/2310.05887.pdf>

<https://doi.org/10.1007/s11207-023-02220-8>

The solar wind is the extension of the Sun's hot and ionized corona, and it exists in a state of continuous expansion into interplanetary space. The radial distance at which the wind's outflow speed exceeds the phase speed of Alfvénic and fast-mode magnetohydrodynamic (MHD) waves is called the Alfvén radius. In one-dimensional models, this is a singular point beyond which most fluctuations in the plasma and magnetic field cannot propagate back down to the Sun. In the multi-dimensional solar wind, this point can occur at different distances along an irregularly shaped "Alfvén surface." In this article, we review the properties of this surface and discuss its importance in models of solar-wind acceleration, angular-momentum transport, MHD waves and turbulence, and the geometry of magnetically closed coronal loops. We also review the results of simulations and data analysis techniques that aim to determine the location of the Alfvén surface. Combined with recent perihelia of Parker Solar Probe, these studies seem to indicate that the Alfvén surface spends most of its time at heliocentric distances between about 10 and 20 solar radii. It is becoming apparent that this region of the heliosphere is sufficiently turbulent that there often exist multiple (stochastic and time-dependent) crossings of the Alfvén surface along any radial ray. Thus, in many contexts, it is more useful to make use of the concept of a topologically complex "Alfvén zone" rather than one closed surface. This article also reviews how the Polarimeter to Unify the Corona and Heliosphere (PUNCH) mission will measure the properties of the Alfvén surface and provide key constraints on theories of solar-wind acceleration.

Inward-propagating Plasma Parcels in the Solar Corona: Models with Aerodynamic Drag, Ablation, and Snowplow Accretion

Steven R. **Cranmer**¹, Craig E. DeForest², and Sarah E. Gibson³

2021 ApJ 913 4

<https://doi.org/10.3847/1538-4357/abf146>

Although the solar wind flows primarily outward from the Sun to interplanetary space, there are times when small-scale plasma inflows are observed. Inward-propagating density fluctuations in polar coronal holes were detected by the COR2 coronagraph on board the STEREO-A spacecraft at heliocentric distances of 7–12 solar radii, and these fluctuations appear to undergo substantial deceleration as they move closer to the Sun. Models of linear magnetohydrodynamic waves have not been able to explain these deceleration patterns, so they have been interpreted more recently as jets from coronal sites of magnetic reconnection. In this paper, we develop a range of dynamical models of discrete plasma parcels with the goal of better understanding the observed deceleration trend. We found that parcels with a constant mass do not behave like the observed flows, and neither do parcels undergoing ablative mass loss. However, parcels that accrete mass in a snowplow-like fashion can become decelerated as observed. We also extrapolated OMNI in situ data down to the so-called Alfvén surface and found that the initial launch point for the observed parcels may often be above this critical radius. In other words, in order for the parcels to flow back down to the Sun, their initial speeds are probably somewhat nonlinear (i.e., supra-Alfvénic), and thus the parcels may be associated with structures such as shocks, jets, or shear instabilities.

Origins of the Ambient Solar Wind: Implications for Space Weather **Review**

Steven R. **Cranmer** (CU Boulder), [Sarah E. Gibson](#) (HAO), [Pete Riley](#) (PSI)

Space Science Reviews. Special issue connected with a 2016 ISSI workshop on "The Scientific Foundations of Space Weather." 2017

<https://arxiv.org/pdf/1708.07169.pdf>

The Sun's outer atmosphere is heated to temperatures of millions of degrees, and solar plasma flows out into interplanetary space at supersonic speeds. This paper reviews our current understanding of these interrelated problems: coronal heating and the acceleration of the ambient solar wind. We also discuss where the community stands in its ability to forecast how variations in the solar wind (i.e., fast and slow wind streams) impact the Earth. Although the last few decades have seen significant progress in observations and modeling, we still do not have a complete understanding of the relevant physical processes, nor do we have a quantitatively precise census of which coronal structures contribute to specific types of solar wind. Fast streams are known to be connected to the central regions of large coronal holes. Slow streams, however, appear to come from a wide range of sources, including streamers, pseudostreamers, coronal loops, active regions, and coronal hole boundaries. Complicating our understanding even more is the fact that processes such as turbulence, stream-stream interactions, and Coulomb collisions can make it difficult to unambiguously map a parcel measured at 1 AU back down to its coronal source. We also review recent progress -- in theoretical modeling, observational data analysis, and forecasting techniques that sit at the interface between data and theory -- that gives us hope that the above problems are indeed solvable.

Pursuing forecasts of the behavior and arrival of coronal mass ejections through modeling and observations. **Review**

Sophisticated instrumentation dedicated to studying and monitoring our Sun's activity has proliferated in the past few decades, together with the increasing demand of specialized space weather forecasts that address the needs of commercial and government systems. As a result, theoretical and empirical models and techniques of increasing complexity have been developed, aimed at forecasting the occurrence of solar disturbances, their evolution, and time of arrival to Earth. Here we will review groundbreaking and recent methods to predict the propagation and evolution of coronal mass ejections and their driven shocks. The methods rely on a wealth of data sets provided by ground- and space-based observatories, involving remote-sensing observations of the corona and the heliosphere, as well as detections of radio waves.

Describe and Forecast the Propagation of 71 CMEs/Shocks

H. Cremades, F. A. Iglesias, O. C. St. Cyr, H. Xie, M. L. Kaiser, N. Gopalswamy
Solar Phys. Volume 290, Issue 9, pp 2455-2478 2015

Motivated by improving predictions of arrival times at Earth of shocks driven by coronal mass ejections (CMEs), we have analyzed 71 Earth-directed events in different stages of their propagation. The study is primarily based on approximated locations of interplanetary (IP) shocks derived from Type-II radio emissions detected by the Wind/WAVES experiment during 1997–2007. Distance–time diagrams resulting from the combination of white-light corona, IP Type-II radio, and in-situ data lead to the formulation of descriptive profiles of each CME’s journey toward Earth. Furthermore, two different methods for tracking and predicting the location of CME-driven IP shocks are presented. The linear method, solely based on Wind/WAVES data, arises after key modifications to a pre-existing technique that linearly projects the drifting low-frequency Type-II emissions to 1 AU. This upgraded method improves forecasts of shock-arrival times by almost 50 %. The second predictive method is proposed on the basis of information derived from the descriptive profiles and relies on a single CME height–time point and on low-frequency Type-II radio emissions to obtain an approximate value of the shock arrival time at Earth. In addition, we discuss results on CME–radio emission associations, characteristics of IP propagation, and the relative success of the forecasting methods.

Low-frequency type II radio detections and coronagraph data to describe and forecast the propagation of 71 CMEs/shocks

H. Cremades, F. A. Iglesias, O. C. St. Cyr, H. Xie, M. L. Kaiser, N. Gopalswamy
Solar Phys. 2015

<http://arxiv.org/pdf/1505.01730v1.pdf>

The vulnerability of technology on which present society relies demands that a solar event, its time of arrival at Earth, and its degree of geoeffectiveness be promptly forecasted. Motivated by improving predictions of arrival times at Earth of shocks driven by coronal mass ejections (CMEs), we have analyzed 71 Earth-directed events in different stages of their propagation. The study is primarily based on approximated locations of interplanetary (IP) shocks derived from type II radio emissions detected by the Wind/WAVES experiment during 1997-2007. Distance-time diagrams resulting from the combination of white-light corona, IP type II radio, and in situ data lead to the formulation of descriptive profiles of each CME's journey toward Earth. Furthermore, two different methods to track and predict the location of CME-driven IP shocks are presented. The linear method, solely based on Wind/WAVES data, arises after key modifications to a pre-existing technique that linearly projects the drifting low-frequency type II emissions to 1 AU. This upgraded method improves forecasts of shock arrival time by almost 50%. The second predictive method is proposed on the basis of information derived from the descriptive profiles, and relies on a single CME height-time point and on low-frequency type II radio emissions to obtain an approximate value of the shock arrival time at Earth. In addition, we discuss results on CME-radio emission associations, characteristics of IP propagation, and the relative success of the forecasting methods.

Coronal Transient Events During Two Solar Minima: Their Solar Source Regions and Interplanetary Counterparts

H. Cremades, C. H. Mandrini und S. Dasso

Solar Physics, Volume 274, Numbers 1-2, 233-249, 2011, File

In the frame of two coordinated observational and research efforts, two full solar rotations were investigated in the times of two distinct solar minima. These two campaigns were dubbed Whole Sun Month (WSM; **10 August – 8 September 1996**) and Whole Heliosphere Interval (WHI; **20 March – 16 April 2008**). The nearly uninterrupted gathering of solar coronal data since the beginning of the Solar and Heliospheric Observatory (SOHO) era offers the exceptional possibility of comparing two solar minima for the first time, with regard to the coronal transient aspect. This study characterizes the variety of outward-traveling transients observed in the solar corona during both time intervals, from very narrow jet-like events to coronal mass ejections (CMEs). Their solar source regions and ensuing interplanetary structures were identified and characterized as well, toward a global-scale description of their role in determining the heliosphere’s conditions. Multi-wavelength images provided by the space missions SOHO, Yohkoh (only WSM), and Solar-Terrestrial Relations Observatory (STEREO; only WHI) and ground-based observatories were analyzed for coronal ejecta and their solar sources, while data registered by the Advanced Composition Explorer (ACE) spacecraft were inspected for interplanetary CMEs and magnetic clouds. Notable differences arise from the analysis of the detailed survey of events: more (fewer) ejecta during WHI (WSM), 12% (40%) were produced by active regions during WHI (WSM), and nearly no (high) deflection from the radial direction was observed during WHI (WSM). Instrumental

aspects such as dissimilar resolution, cadence, and fields of view are considered in order to discern instrumentally driven disparities from inherent differences between solar minima.

A tool to improve space weather forecasts: Kilometric radio emissions from Wind/WAVES

To improve predictions of the arrival time of magnetohydrodynamic shock, which can occur as coronal mass ejections propagate through interplanetary space, scientists study low frequency radio emissions detected by the WIND/WAVES satellite.

Cremades, H.; St. Cyr, O. C.; Kaiser, M. L.
Space Weather, Vol. 5, No. 8, S08001, 2007, File
<http://dx.doi.org/10.1029/2007SW000314>

For decades, space environment forecasters have used the appearance of metric Type II radio emission as a proxy for eruptions in the solar corona. The drift rate of these near-Sun emissions is often turned into a speed, commonly assumed to be that of an MHD shock. However, their utility to forecast shock arrival times has not proved to be conclusive. Metric emissions can be detected by ground-based antennae, while lower-frequency components of these slowly drifting emissions can also be tracked by spacecraft in interplanetary space, as far down in frequency as that of the local plasma frequency. For a spacecraft at L1, this corresponds to about 25 kHz, or an electron density of about 7 cm^{-3} in the ambient solar wind. Here we report a recent study that aims to improve the predictions of shock arrival time at L1 by means of the low-frequency emissions detected by WIND/WAVES. This technique, implemented on an extensive sample of hectometric and kilometric type II radio bursts, has yielded promising results.

Table

Comparison of interplanetary signatures of streamers and pseudostreamers

N. U. **Crooker**^{1,*}, R. L. McPherron² and M. J. Owens
JGR, Volume 119, Issue 6, pages 4157–4163, June 2014

If the source of the slow solar wind is a web comprising pseudostreamer belts connected to the streamer belt, then one expects the properties of interplanetary pseudostreamer flows to be similar to those of streamer flows. That expectation is tested with data from the slow wind preceding stream interfaces in stream interaction regions at 1 AU, where the interfaces separate what was originally slow and fast wind. Pseudostreamer cases were separated from streamer cases with the aid of the streamer identification tool developed by Owens et al. (2013), and superposed epoch analysis was performed to compare the patterns of a number of plasma and composition parameters. The results reveal that pseudostreamer flows have all of the slow-wind characteristics of streamer flows except that they are slightly less pronounced than streamer characteristics when compared to fast wind. The results are consistent with the concept that the solar wind displays a continuum of dynamic states rather than only slow and fast states.

Suprathermal electron flux peaks at stream interfaces: Signature of solar wind dynamics or tracer for open magnetic flux transport on the Sun?

Crooker, N. U.; Appleton, E. M.; Schwadron, N. A.; Owens, M. J.
J. Geophys. Res., Vol. 115, No. A11, A11101, 2010

The high variability of the intensity of suprathermal electron flux in the solar wind is usually ascribed to the high variability of sources on the Sun. Here we demonstrate that a substantial amount of the variability arises from peaks in stream interaction regions, where fast wind runs into slow wind and creates a pressure ridge at the interface. Superposed epoch analysis centered on stream interfaces in 26 interaction regions previously identified in Wind data reveal a twofold increase in 250 eV flux (integrated over pitch angle). Whether the peaks result from the compression there or are solar signatures of the coronal hole boundary, to which interfaces may map, is an open question. Suggestive of the latter, some cases show a displacement between the electron and magnetic field peaks at the interface. Since solar information is transmitted to 1 AU much more quickly by suprathermal electrons compared to convected plasma signatures, the displacement may imply a shift in the coronal hole boundary through transport of open magnetic flux via interchange reconnection. If so, however, the fact that displacements occur in both directions and that the electron and field peaks in the superposed epoch analysis are nearly coincident indicate that any systematic transport expected from differential solar rotation is overwhelmed by a random pattern, possibly owing to transport across a ragged coronal hole boundary.

SOLAR IMPRINT ON ICMES, THEIR MAGNETIC CONNECTIVITY, AND HELIOSPHERIC EVOLUTION

N. U. **CROOKER**^{1,*} and T. S. HORBURY

Space Science Reviews (2006) 123: 93–109; **File**

Interplanetary outflows from coronal mass ejections (ICMEs) are structures shaped by their magnetic fields. Sometimes these fields are highly ordered and reflect properties of the solar magnetic field. Field lines emerging in CMEs are presumably connected to the Sun at both ends, but about half lose their connection at one end by the time they are observed in ICMEs. All must eventually lose one connection in order to prevent a build-up of flux in the heliosphere; but since little change is observed between 1 AU and 5 AU, this process may take months to years to complete. As ICMEs propagate out into the heliosphere, they kinematically elongate in angular extent, expand from higher pressure within, distort owing to inhomogeneous solar wind structure, and can compress the ambient solar wind, depending upon their relative speed. Their magnetic fields may reconnect with solar wind fields or those of other ICMEs with which they interact, creating complicated signatures in spacecraft data.

Evidence in magnetic clouds for systematic open flux transport on the Sun,

Crooker, N. U., S. W. Kahler, J. T. Gosling, and R. P. Lepping (2008)

J. Geophys. Res., 113, A12107, (2008)

<http://dx.doi.org/10.1029/2008JA013628>

Most magnetic clouds encountered by spacecraft at 1 AU display a mix of unidirectional suprathermal electrons signaling open field lines and counterstreaming electrons signaling loops connected to the Sun at both ends. Assuming the open fields were originally loops that underwent interchange reconnection with open fields at the Sun, we determine the sense of connectedness of the open fields found in 72 of 97 magnetic clouds identified by the Wind spacecraft in order to obtain information on the location and sense of the reconnection and resulting flux transport at the Sun. The true polarity of the open fields in each magnetic cloud was determined from the direction of the suprathermal electron flow relative to the magnetic field direction. Results indicate that the polarity of all open fields within a given magnetic cloud is the same 89% of the time, implying that interchange reconnection at the Sun most often occurs in only one leg of a flux rope loop, thus transporting open flux in a single direction, from a coronal hole near that leg to the foot point of the opposite leg. This pattern is consistent with the view that interchange reconnection in coronal mass ejections systematically transports an amount of open flux sufficient to reverse the polarity of the heliospheric field through the course of the solar cycle. Using the same electron data, we also find that the fields encountered in magnetic clouds are only a third as likely to be locally inverted as not. While one might expect inversions to be equally as common as not in flux rope coils, consideration of the geometry of spacecraft trajectories relative to the modeled magnetic cloud axes leads us to conclude that the result is reasonable.

Space weather: science and effects

Norma B. **Crosby**

Universal Heliophysical Processes Proceedings IAU Symposium No. 257, 2008 N. Gopalswamy & D.F. Webb, eds. Volume 4 / Symposium S257, pp 47 – 56, 2009, File

From the point-of-view of somebody standing outside on a cold winter night looking up at a clear cloudless sky, the space environment seems to be of a peaceful and stable nature. Instead, the opposite is found to be true. In fact the space environment is very dynamic on all spatial and temporal scales, and in some circumstances may have unexpected and hazardous effects on technology and humans both in space and on Earth. In fact the space environment seems to have a weather all of its own – its own “space weather”. Our Sun is definitely the driver of our local space weather. Space weather is an interdisciplinary subject covering a vast number of technological, scientific, economic and environmental issues. It is an application-oriented discipline which addresses the needs of “space weather product” users. It can be truly said that space weather affects everybody, either directly or indirectly. The aim of this paper is to give an overview of what space weather encompasses, emphasizing how solar-terrestrial physics is applied to space weather. Examples of “space weather product” users will be given highlighting those products that we as a civilization are most dependent on.

Compressible Turbulence in the Near-Sun Solar Wind: Parker Solar Probe's First Eight Perihelia

Manuel Enrique **Cuesta**¹, Rohit Chhiber^{1,2}, Xiangrong Fu^{3,4}, Senbei Du⁴, Yan Yang¹, Francesco Pecora¹, William H. Matthaeus¹, Hui Li⁴, John Steinberg⁴, Fan Guo⁴Show full author list

<https://iopscience.iop.org/article/10.3847/2041-8213/acd4c2/pdf>

Many questions remain about the compressibility of solar wind turbulence with respect to its origins and properties. Low plasma beta (ratio of thermal to magnetic pressure) environments allow for the easier generation of compressible turbulence, enabling study of the relationship between density fluctuations and turbulent Mach number. Utilizing Parker Solar Probe plasma data, we examine the normalized proton density fluctuations $\langle \delta n_p^2 \rangle^{1/2} / \langle n_p \rangle = \delta n_{p,rms} / \langle n_p \rangle$ as a function of turbulent Mach number M_t conditioned on plasma beta and cross helicity. With consideration of statistical error in the parameters computed from in situ data, we find a general result that $\delta n_{p,rms} / \langle n_p \rangle \sim M_t^{1.18 \pm 0.04}$, consistent with both linear-wave theory and nearly incompressible turbulence in an inhomogeneous background field. We compare observational results conditioned on plasma beta and cross helicity with 3D magnetohydrodynamic simulations and observe rather significant similarities with respect to how those parameters affect the proportionality between density fluctuations and turbulent Mach number. This study further investigates the complexity of compressible turbulence as viewed by the density scaling relationship and may help better understand the compressible environment of the near-Sun solar wind.

Tracking Solar Active Region Outflow Plasma from its Source to the near-Earth Environment

J.L. **Culhane**, D.H. Brooks, L. van Driel-Gesztelyi, P. Demoulin, D. Baker, M.L. DeRosa, C.H. Mandrini, L. Zhao, T.H. Zurbuchen

Solar Phys., Volume 289, Issue 10, pp 3799-3816, **2014**

<http://arxiv.org/pdf/1405.2949v1.pdf>

Seeking to establish whether active region upflow material contributes to the slow solar wind, we examine in detail the plasma upflows from Active Region (AR)10978, which crossed the Sun's disc in the interval **8 to 16 December, 2007** during Carrington rotation (CR)2064. In previous work, using data from the Hinode/EUV Imaging Spectrometer, upflow velocity evolution was extensively studied as the region crossed the disc while a linear force-free magnetic extrapolation was used to confirm aspects of the velocity evolution and to establish the presence of quasi-separatrix layers at the upflow source areas. The plasma properties, temperature, density and first ionisation potential bias (FIP-bias) were measured with the spectrometer during the disc passage of the active region. Global potential field source surface (PFSS) models showed that AR 10978 was completely covered by the closed field of a helmet streamer that is part of the streamer belt. Thus it is not clear how any of the upflowing AR-associated plasma could reach the source surface at 2.5 R(Sun) and contribute to the slow solar wind. However a detailed examination of solar-wind in-situ data obtained by the Advanced Composition Explorer (ACE) spacecraft at the L1 point shows that the increase in O⁷⁺/O⁶⁺, C⁶⁺/C⁵⁺ and Fe/O - a FIP-bias proxy - are present before the heliospheric current sheet crossing. These increases, along with an accompanying reduction in proton velocity and an increase in density are characteristic of both AR and slow-wind plasma. Finally we describe a two-step reconnection process by which some of the upflowing plasma from the AR could reach the heliosphere.

Study of CME transit speeds for the event of 07-NOV-2004

J.L. **Culhane**, S. Pohjolainen, L. van Driel-Gesztelyi, P.K. Manoharan and H.A. Elliott

[Advances in Space Research](#)

[Volume 40, Issue 12, 2007](#), Pages 1807-1814

Several methods for CME speed estimation are discussed. These include velocity derivation based on the frequency drifts observed in metric and decametric radio wave data using a range of coronal density models. Coronagraph height–time plots allow measurement of plane-of-sky and expansion speeds. These in turn can enable propagation speeds to be derived from a range of empirical relations. Simple geometric e.g., cone, models can provide propagation velocity estimates for suitable halo or partial halo events. Interplanetary scintillation observations allow speed estimates at large distances from the Sun detecting in particular the deceleration of the faster CMEs. Related interplanetary shocks and the arrival times and speeds of the associated magnetic clouds at Earth can also be considered. We discuss the application of some of these methods to the transit to Earth of a complex CME that originated earlier than 16:54 U.T. on 07-NOV-2004. The difficulties in making velocity estimates from radio observations, particularly under disturbed coronal conditions, are highlighted.

On the Acceleration Site of Anomalous Cosmic Rays: Voyager 2 Observations of Their Anisotropy in the Heliosheath

A. C. **Cummings**¹, J. Kóta², J. D. Richardson³, J. S. Rankin⁴, and B. C. Heikkilä⁵

2024 ApJ 977 76

<https://iopscience.iop.org/article/10.3847/1538-4357/ad8e66/pdf>

We present the diffusive flow anisotropy vector components for ~0.5–35 MeV anomalous cosmic-ray (ACR) protons observed during Voyager 2 roll maneuvers for the magnetometer instrument in the inner heliosheath. The diffusive flow results are derived from the differences between the observed anisotropy components presented in A. C. Cummings et al. (2021) and the Compton–Getting anisotropies based on measurements of the solar wind speeds from the Plasma Science instrument. We find that the tangential component of the derived diffusive anisotropy vector is in reasonable agreement, both in direction and magnitude, with a numerical model of the acceleration and transport of ACRs by diffusive shock acceleration along a nonspherical solar wind termination shock (TS). The results suggest that there exists a diffusive flow of these particles from the flank or tail of the heliosphere toward the nose, and support models in which higher-energy ACRs are accelerated in the flank or tail of the TS.

Geomagnetic solar flare effects: a review

Juan José **Curto***

J. Space Weather Space Clim. 2020, 10, 27

<https://www.swsc-journal.org/articles/swsc/pdf/2020/01/swsc190079.pdf>

<https://doi.org/10.1051/swsc/2020027>

Solar flare effects (Sfe) are rapid variations in the Earth's magnetic field and are related to the enhancement of the amount of radiation produced during Solar flare events. They mainly appear in the Earth's sunlit hemisphere at the same time as the flare observation and have a crochet-like shape. Much progress has been made since Carrington's first observations in 1859 which are considered to represent the first direct evidence of the connection between the Sun and the Earth's environment but there is still much to discover. In this paper, we review state-of-the-art developments and the advances made in the knowledge concerning Sfe phenomena while also looking at the challenges that lie ahead. First, we offer a historical approach with a comprehensive description that allows for a better understanding of the main characteristics of Sfe. This frames specific topics like the puzzling reversed-Sfe or the nighttime Sfe. The role played by the Service of Rapid Magnetic variations (SRMV) is also assessed, followed by a discussion of the main current limiting factors in the process of detection and proposed ways to overcome challenges such as by creating an automatic detection method. The paper clarifies some aspects related to the geo-effectiveness of the solar flares producing magnetic disturbances. The importance of the global modelling studies covering critical aspects needed to understand this Sun–Earth system is assessed. Also, we provide an overview of the temporal evolution of the electric currents producing Sfe. The importance of key subjects such as the dynamic aspects of Sfe is developed in another section. Finally, estimations of the size of large flares using ionospheric and magnetic data are reviewed as well as the prospects of these large flare events putting technological systems in danger.

Effect of the Heliospheric State on CME Evolution

Fithanegest Kassa **Dagnew**^{1,2,3}, Nat Gopalswamy², Solomon Belay Tessema¹, Sachiko Akiyama^{2,3}, and Seiji Yashiro^{2,3}

2022 ApJ 936 122

<https://arxiv.org/ftp/arxiv/papers/2208/2208.03536.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac8744/pdf>

The culmination of solar cycle 24 by the end of 2019 has created the opportunity to compare the differing properties of coronal mass ejections (CMEs) between two whole solar cycles: solar cycle 23 (SC 23) and solar cycle 24 (SC 24). We report on the width evolution of limb CMEs in SCs 23 and 24 in order to test the suggestion by Gopalswamy et al. that CME flux ropes attain pressure balance at larger heliocentric distances in SC 24. We measure CME width as a function of heliocentric distance for a significantly large number of limb CMEs (~1000) and determine the distances where the CMEs reach constant width in each cycle. We introduced a new parameter, the transition height (h_c) of a CME, defined as the critical heliocentric distance beyond which the CME width stabilizes to a quasi-constant value. Cycle and phase-to-phase comparisons are based on this new parameter. We find that the average value of h_c in SC 24 is 62% higher than that in SC 23. SC 24 CMEs attain their peak width at larger distances from the Sun than SC 23 CMEs do. The enhanced transition height in SC 24 is new observational ratification of the anomalous expansion. The anomalous expansion of SC 24 CMEs, which is caused by the weak state of the heliosphere, accounts for the larger heliocentric distance where the pressure balance between CME flux rope and the ambient medium is attained. **2014 May 6**

Magnetic clouds in the solar wind: a numerical assessment of analytical models

G. Dalakishvili^{1,2,3}, J. Kleimann¹, H. Fichtner¹ and S. Poedts

A&A 536, A100 (2011)

Context. Magnetic clouds (MCs) are “magnetized plasma clouds” moving in the solar wind. MCs transport magnetic flux and helicity away from the Sun. These structures are not stationary but feature temporal evolution as they propagate in the solar wind. Simplified analytical models are frequently used to describe MCs, and they fit certain observational data well.

Aims. The goal of the present study is to numerically investigate the validity of an analytical model that is widely used to describe MCs, and to determine under which conditions this model’s implied assumptions cease to be valid.

Methods. A numerical approach is applied. Analytical solutions derived in previous studies are implemented in a 3D magnetohydrodynamic simulation code as initial conditions. Besides the standard case in which MCs only expand and propagate in the solar wind, the case of an MC rotating around its axis of symmetry is also considered, and the resulting influence on the MC’s dynamics is studied.

Results. Initially, the analytical model represents the main observational features of the MCs. However, these characteristics prevail only if the structure moves with a velocity close to the velocity of the background flow. In this case an MC’s evolution can quite accurately be described using an analytic, self-similar approach. The dynamics of the magnetic structures that move with a velocity significantly above or below that of the velocity of the solar wind is investigated in detail.

Conclusions. Comparison of the numerical results with observational data indicates reasonable agreement especially for the intermediate case, in which the MC’s bulk velocity and the velocity of the background flow are equal. In this particular case, analytical solutions obtained on the basis of a self-similar approach indeed describe the MC’s evolution quite accurately. In general, however, numerical simulations are necessary to investigate the evolution as a function of a wide range of the parameters, which define the initial conditions.

Investigation of dynamics of self-similarly evolving magnetic clouds

G. Dalakishvili^{1,4}, A. Rogava^{2,3}, G. Lapenta⁴, and S. Poedts⁴

A&A 526, A22 (2011)

Context. Magnetic clouds (MCs) are “magnetized plasma clouds” moving in the solar wind. MCs transport magnetic flux and helicity away from the Sun. These structures are not stationary but experience temporal evolution. Simplified MC models are usually considered.

Aims. We investigate the dynamics of more general, *radially expanding* MCs. They are considered as cylindrically symmetric magnetic structures with low plasma β .

Methods. We adopt both a self-similar approach method and a numerical approach.

Results. We demonstrate that the forces are balanced in the considered self-similarly evolving, cylindrically symmetric magnetic structures. Explicit analytical expressions for magnetic field, plasma velocity, density, and pressure within MCs are derived. These solutions are characterized by conserved values of magnetic flux and helicity. We also investigate the dynamics of self-similarly evolving MCs by means of the numerical code “Graale”. In addition, their expansion in a medium of higher density and higher plasma β is studied. It is shown that the physical parameters of the MCs maintain their self-similar character throughout their evolution.

Conclusions. After comparing different self-similar and numerical solutions, we are able to conclude that the evolving MCs are quite adequately described by our self-similar solutions – they retain their self-similar, coherent nature for quite a long time and over large distances from the Sun.

Suprathermal Population Associated with Stream Interaction Regions Observed by STEREO-A: New Insights

Bijoy Dalal^{1,2}, Dibyendu Chakrabarty¹, Nandita Srivastava³, and Aveek Sarkar¹

2024 ApJ 960 16

<https://iopscience.iop.org/article/10.3847/1538-4357/ad08c6/pdf>

Stream interaction regions (SIRs) are often thought to be responsible for the generation of suprathermal population in the interplanetary medium. Even though the source is the same, wide variations in the spectral indices of suprathermal populations are observed at 1 au during SIRs. This poses a significant uncertainty in understanding the generation of suprathermal ion populations by SIRs and indicates an interplay of multiple source mechanisms. By analyzing variations in suprathermal 4He, O, and Fe for 20 SIR events recorded by STEREO-A during 2007–2014, we find that the spectral indices of these elements vary in the range of 2.06–4.08, 1.85–4.56, and 2.11–4.04 for 19 events. However, in one special case, all three suprathermal elements show nearly identical (~1.5) spectral indices. We describe possible mechanisms that might cause significant variations in the spectral indices of suprathermal particles. More importantly, we show the possible role of merging and/or contraction of small-scale magnetic islands near 1 au in producing nearly identical spectral indices for three different elements with different first ionization potentials and mass-to-charge ratios. The occurrence of these magnetic islands near 1 au also supports the minimal modulation in the spectral indices of these particles. We also suggest that a possible solar flare may have played a role in generating these magnetic islands near the heliospheric current sheet. **2012 June 12**

EVOLUTION OF PILED-UP COMPRESSIONS IN MODELED CORONAL MASS EJECTION SHEATHS AND THE RESULTING SHEATH STRUCTURES

Indrajit Das¹, Merav Opher^{1,2}, Rebekah Evans¹, Cristiane Loesch³, and Tamas I. Gombosi⁴

Astrophysical Journal, 729:112 (7pp), **2011** March, **File**

We study coronal mass ejection (CME)-driven shocks and the resulting post-shock structures in the lower corona (2–7R_⊙). Two CMEs are erupted by modified Titov–D’emoulin (TD) and Gibson–Low (GL) type flux ropes (FRs) with the Space Weather Modeling Framework. We observe a substantial pile-up of density compression and a narrow region of plasma depletion layer (PDL) in the simulations. As the CME/FR moves and expands in the solar wind medium, it pushes the magnetized material lying ahead of it. Hence, the magnetic field lines draping around the CME front are compressed in the sheath just ahead of the CME. These compressed field lines squeeze out the plasma sideways, forming PDL in the region. Solar plasma being pushed and displaced from behind forms a strong piled-up compression (PUC) of density downstream of the PDL. Both CMEs have comparable propagation speeds, while GL has larger expansion speed than TD due to its higher initial magnetic pressure. We argue that high CME expansion speed along with high solar wind density in the region is responsible for the large PUC found in the lower corona. In case of GL, the PUC is much wider, although the density compression ratio for both the cases is comparable. Although these simulations artificially initiate out-of-equilibrium CMEs and drive them in an artificial solar wind solution, we predict that PUCs, in general, will be large in the lower corona. This should affect the ion profiles of the accelerated solar energetic particles.

Magnetic clouds along the solar cycle: expansion and magnetic helicity.

Magnetic helicity (H) is an ideal magnetohydrodynamical (MHD) invariant that quantifies the twist and linkage of magnetic field lines. In magnetofluids with low resistivity, H decays much less than the energy, and it is almost conserved during times shorter than the global diffusion timescale. The extended solar corona (i.e., the heliosphere) is one of the physical scenarios where H is expected to be conserved. The amount of H injected through the photospheric level can be reorganized in the corona, and finally ejected in flux ropes to the interplanetary medium. Thus, coronal mass ejections can appear as magnetic clouds (MCs), which are huge twisted flux tubes that transport large amounts of H through the solar wind. The content of H depends on the global configuration of the structure, then, one of the main difficulties to estimate it from single spacecraft in situ observations (one point - multiple times) is that a single spacecraft can only observe a linear (one dimensional) cut of the MC global structure. Another serious difficulty is the intrinsic mixing between its spatial shape and its time evolution that occurs during the observation period. However, using some simple assumptions supported by observations, the global shape of some MCs can be unveiled, and the associated H and magnetic fluxes (F) can be estimated. Different methods to quantify H and F from the analysis of in situ observations in MCs are presented in this review. Some of these methods consider a MC in expansion and going through possible magnetic reconnections with its environment. We conclude that H seems to be a 'robust' MHD quantity in MCs, in the sense that variations of H for a given MC deduced using different methods, are typically lower than changes of H when a different cloud is considered. Quantification of H and F lets us constrain models of coronal formation and ejection of flux ropes to the interplanetary medium, as well as of the dynamical evolution of MCs in the solar wind.

Linking two consecutive nonmerging magnetic clouds with their solar sources,

On 15 May 2005, a huge interplanetary coronal mass ejection (ICME) was observed near Earth. It triggered one of the most intense geomagnetic storms of solar cycle 23 ($Dst_{peak} = -263$ nT). This structure has been associated with the two-ribbon flare, filament eruption, and coronal mass ejection originating in active region 10759 (NOAA number). We analyze here the sequence of events, from solar wind measurements (at 1 AU) and back to the Sun, to understand the origin and evolution of this geoeffective ICME. From a detailed observational study of in situ magnetic field observations and plasma parameters in the interplanetary (IP) medium and the use of appropriate models we propose an alternative interpretation of the IP observations, different to those discussed in previous studies. In our view, the IP structure is formed by two extremely close consecutive magnetic clouds (MCs) that preserve their identity during their propagation through the interplanetary medium. Consequently, we identify two solar events in H α and EUV which occurred in the source region of the MCs. The timing between solar and IP events, as well as the orientation of the MC axes and their associated solar arcades are in good agreement. Additionally, interplanetary radio type II observations allow the tracking of the multiple structures through inner heliosphere and pin down the interaction region to be located midway between the Sun and the Earth. The chain of observations from the photosphere to interplanetary space is in agreement with this scenario. Our analysis allows the detection of the solar sources of the transients and explains the extremely fast changes of the solar wind due to the transport of two attached (though nonmerging) MCs which affect the magnetosphere.

Progressive Transformation of a Flux Rope to an ICME Comparative Analysis Using the Direct and Fitted Expansion Methods

S. **Dasso** · M.S. Nakwacki · P. Démoulin · C.H. Mandrini

Solar Phys (2007) 244: 115–137

The solar wind conditions at one astronomical unit (AU) can be strongly disturbed by interplanetary coronal mass ejections (ICMEs). A subset, called magnetic clouds (MCs), is formed by twisted flux ropes that transport an important amount of magnetic flux and helicity, which is released in CMEs. At 1 AU from the Sun, the magnetic structure of MCs is generally modeled by neglecting their expansion during the spacecraft crossing. However, in some cases, MCs present a significant expansion. We present here an analysis of the huge and significantly expanding MC observed by the Wind spacecraft during 9 - 10 November 2004. This MC was embedded in an ICME. After determining an approximate orientation for the flux rope using the minimum variance method, we obtain a precise orientation of the cloud axis by

relating its front and rear magnetic discontinuities using a direct method. This method takes into account the conservation of the azimuthal magnetic flux between the inbound and outbound branches and is valid for a finite impact parameter (i.e., not necessarily a small distance between the spacecraft trajectory and the cloud axis). The MC is also studied using dynamic models with isotropic expansion. We have found $(6.2 \pm 1.5) \times 10^{20}$ Mx for the axial flux and $(78 \pm 18) \times 10^{20}$ Mx for the azimuthal flux. Moreover, using the direct method, we find that the ICME is formed by a flux rope (MC) followed by an extended coherent magnetic region. These observations are interpreted by considering the existence of a previously larger flux rope, which partially reconnected with its environment in the front. We estimate that the reconnection process started close to the Sun. These findings imply that the ejected flux rope is progressively peeled by reconnection and transformed to the observed ICME (with a remnant flux rope in the front part).

Large scale MHD properties of interplanetary magnetic clouds

Dasso, S., Mandrini, C.H., D'emoulin, P., Luoni, M.L., et al.

Advances in Space Research, Volume 35, Issue 5, p. 711-724, **2005**.

Magnetic Clouds (MCs) are the interplanetary manifestation of Coronal Mass Ejections. These huge astrophysical objects travel from the Sun toward the external heliosphere and can reach the Earth environment. Depending on their magnetic field orientation, they can trigger intense geomagnetic storms. The details of the magnetic configuration of clouds and the typical values of their magnetohydrodynamic magnitudes are not yet well known. One of the most important magnetohydrodynamic quantities in MCs is the magnetic helicity. The helicity quantifies several aspects of a given magnetic structure, such as the twist, kink, number of knots between magnetic field lines, linking between magnetic flux tubes, etc. The helicity is approximately conserved in the solar atmosphere and the heliosphere, and it is very useful to link solar phenomena with their interplanetary counterpart. Since a magnetic cloud carries an important amount of helicity when it is ejected from the solar corona, estimations of the helicity content in clouds can help us to understand its evolution and its coronal origin. In situ observations of magnetic clouds at one astronomical unit are in agreement with a local helical magnetic structure. However, since spacecrafts only register data along a unique direction, several aspects of the global configuration of clouds cannot be observed. In this paper, we review the general properties of magnetic clouds and different models for their magnetic structure at one astronomical unit. We describe the corresponding techniques to analyze in situ measurements. We also quantify their magnetic helicity and compare it with the release of helicity in their solar source for some of the analyzed cases.

Forecast of solar ejecta arrival at 1 AU from radial speed

S. **Dasso**, N. Gopalswamy, and A. Lara

Geofisica Internacional, Vol. 43, Num. 1, pp. 47-52, **2004**, **File**

Solar ejecta produce changes in the interplanetary magnetic field of the terrestrial environment. When the magnetic polarity of the ejecta is suitable, it may trigger intense geomagnetic storms. Therefore, prediction of the arrival of solar ejecta in the geospace is of crucial importance for space weather applications. We implement a simple model, developed by Gopalswamy et al., (2000) to estimate the time of arrival for solar ejecta at 1AU. This model requires just one input parameter: the radial speed of the associated coronal mass ejection (CME) at the moment of its expulsion from the Sun. When the speed of the CME is measured from a location on the Sun-Earth line, only the plane of the sky speed can be obtained. Since the prediction model depends on the initial speed of the CMEs observed remotely, it is important to obtain this speed as accurately as possible. One of the major uncertainties in the measured initial speed is the extent of projection effects. We attempt to correct for projection effects using the solar surface location of the eruption and assuming a width to the CME. We found that the correction is in agreement with a model obtained from stereoscopic observations from the past.

Study of Interplanetary and Geomagnetic Response of Filament Associated CMEs

Kunjal **Dave**, [Wageesh Mishra](#), [Nandita Srivastava](#), [R. M. Jadhav](#)

Proceedings IAU Symposium No. 340, **2018**

<https://arxiv.org/pdf/1807.00809.pdf>

It has been established that Coronal Mass Ejections (CMEs) may have significant impact on terrestrial magnetic field and lead to space weather events. In the present study, we selected several CMEs which are associated with filament eruptions on the Sun. We attempt to identify the presence of filament material within ICME at 1AU. We discuss how different ICMEs associated with filaments lead to moderate or major geomagnetic activity on their arrival at the Earth. Our study also highlights the difficulties in identifying the filament material at 1AU within isolated and in interacting CMEs. **23 May 2010, 6 Oct 2010, 23 Sep 2012**

Flux rope modeling of the 2022 Sep 5 CME observed by Parker Solar Probe and Solar Orbiter from 0.07 to 0.69 au

As both Parker Solar Probe (PSP) and Solar Orbiter (SolO) reach heliocentric distances closer to the Sun, they present an exciting opportunity to study the structure of CMEs in the inner heliosphere. We present an analysis of the global flux rope structure of the **2022 September 5** CME event that impacted PSP at a heliocentric distance of only 0.07 au and SolO at 0.69 au. We compare in situ measurements at PSP and SolO to determine global and local expansion measures, finding a good agreement between magnetic field relationships with heliocentric distance, but significant differences with respect to flux rope size. We use PSP/WISPR images as input to the ELEvoHI model, providing a direct link between remote and in situ observations; we find a large discrepancy between the resulting modeled arrival times, suggesting that the underlying model assumptions may not be suitable when using data obtained close to the Sun, where the drag regime is markedly different in comparison to larger heliocentric distances. Finally, we fit the SolO/MAG and PSP/FIELDS data independently with the 3DCORE model and find that many parameters are consistent between spacecraft, however, challenges are apparent when reconstructing a global 3D structure that aligns with arrival times at PSP and Solar Orbiter, likely due to the large radial and longitudinal separations between spacecraft. From our model results, it is clear the solar wind background speed and drag regime strongly affects the modeled expansion and propagation of CMEs and needs to be taken into consideration.

The effect of magnetic field line topology on ICME-related GCR modulation

Emma E. [Davies](#) (1 and 2), [Camilla Scolini](#) (1), [Réka M. Winslow](#) (1), [Andrew P. Jordan](#) (1), [Christian Möstl](#) (2)

ApJ **959** 133 **2023**

<https://arxiv.org/pdf/2310.11310.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ad046a/pdf>

The large-scale magnetic structure of interplanetary coronal mass ejections (ICMEs) has been shown to affect the galactic cosmic ray (GCR) flux measured in situ by spacecraft, causing temporary decreases known as Forbush decreases (Fds). In some ICMEs, the magnetic ejecta exhibits a magnetic flux rope (FR) structure; the strong magnetic field strength and closed field line geometry of such ICME FRs has been proposed to act as a shield to GCR transport. In this study, we identify four ICMEs near Earth that drove Fds with similar mean magnetic field strengths (20 - 25 nT); two ICMEs with more typical mean speeds (~400 km/s), and two fast (~750 km/s) ICMEs. Within each speed pairing, we identify an ICME that exhibited an open magnetic field line topology and compare its effect on the GCR flux to that which exhibited a mostly closed topology. We investigate the different mechanisms that contribute to the resulting ICME-related Fds and their recovery, and determine which properties, if any, play a more important role than others in driving Fds. We find that much of the GCR response to the ICME events in this study is independent of the open or closed magnetic field line topology of the flux rope, and that features such as the fluctuations in speed, magnetic field structure, and expansion within the FR may play more of a role in determining the smaller-scale structure of the Fd profile. **2002-09-30_Oct 1, 2004-11-09-10, 2005-05-15-16, 2022 March 31_Apr 1**

Characterizing ICME-related Forbush Decreases at Mercury using MESSENGER

Observations: Identification of a One or Two-Step Structure

Emma E. [Davies](#) (1), [Réka M. Winslow](#) (1), [David J. Lawrence](#) (2)

ApJ **2022**

<https://arxiv.org/pdf/2212.02707.pdf>

The large-scale magnetic structure of interplanetary coronal mass ejections (ICMEs) has been shown to cause decreases in the galactic cosmic ray (GCR) flux measured in situ by spacecraft, known as Forbush decreases (Fds). We use measurements of the GCR count rate obtained by MESSENGER during its orbital phase around Mercury to identify such Fds related to the passage of ICMEs and characterize their structure. Of the 42 ICMEs with corresponding high-quality GCR data, 79% are associated with a Fd. Thus a total of 33 ICME-related Fds were identified, 24 of which

(73%) have a two-step structure. We use a superposed epoch analysis to build an average Fd profile at MESSENGER and find that despite the variability of individual events, a two-step structure is produced and is directly linked with the magnetic boundaries of the ICME. By using results from previous studies at Earth and Mars, we also address whether two-step Fds are more commonly observed closer to the Sun; we found that although likely, this is not conclusive when comparing to the wide range of results of previous studies conducted at Earth. Finally, we find that the percentage decrease in GCR flux of the Fd is greater at MESSENGER on average than at Earth and Mars, decreasing with increasing heliocentric distance. The relationship between the percentage decrease and maximum hourly decrease is also in agreement with previous studies, and follows trends relating to the expansion of ICMEs as they propagate through the heliosphere. **19-22 May 2011, 21 Jun 2011, 23 Nov 2011**

Multi-spacecraft Observations of the Evolution of Interplanetary Coronal Mass Ejections between 0.3 and 2.2 au: Conjunctions with the Juno Spacecraft

Emma E. **Davies**^{1,2}, Réka M. Winslow¹, Camilla Scolini^{1,3}, Robert J. Forsyth², Christian Möstl⁴, Noé Lugaz¹, and Antoinette B. Galvin¹

2022 *ApJ* 933 127

<https://iopscience.iop.org/article/10.3847/1538-4357/ac731a/pdf>

We present a catalog of 35 interplanetary coronal mass ejections (ICMEs) observed by the Juno spacecraft and at least one other spacecraft during its cruise phase to Jupiter. We identify events observed by MESSENGER, Venus Express, Wind, and STEREO with magnetic features that can be matched unambiguously with those observed by Juno. A multi-spacecraft study of ICME properties between 0.3 and 2.2 au is conducted: we first investigate the global expansion by tracking the variation in magnetic field strength with increasing heliocentric distance of individual ICME events, finding significant variability in magnetic field relationships for individual events in comparison with statistical trends. With the availability of plasma data at 1 au, the local expansion at 1 au can be compared with global expansion rates between 1 au and Juno. Despite following expected trends, the local and global expansion rates are only weakly correlated. Finally, for those events with clearly identifiable magnetic flux ropes, we investigate the orientation of the flux rope axis as they propagate; we find that 64% of events displayed a decrease in inclination with increasing heliocentric distance, and 40% of events undergo a significant change in orientation as they propagate toward Juno. The multi-spacecraft catalog produced in this study provides a valuable link between ICME observations in the inner heliosphere and beyond 1 au, thereby improving our understanding of ICME evolution. **14-23 Nov 2012**

<https://doi.org/10.3847/1538-4357/ac2ccb>

We use magnetic field measurements by the Juno spacecraft to catalog and investigate interplanetary coronal mass ejections (ICMEs) beyond 1 AU. During its cruise phase, Juno spent about 5 years in the solar wind between 2011 September and 2016 June, providing measurements of the interplanetary magnetic field (IMF) between 1 and 5.4 AU. Juno therefore presents the most recent opportunity for a statistical analysis of ICME properties beyond 1 AU since the Ulysses mission (1990-2009). Our catalog includes 80 such ICME events, 32 of which contain associated flux-rope-like structures. We find that the dependency of the mean magnetic field strength of the magnetic flux ropes decreases with heliocentric distance as $r^{-1.24 \pm 0.43}$ between 1 and 5.4 AU, in good agreement with previous relationships calculated using ICME catalogs at Ulysses. *We combine the Juno catalog with the HELCATS catalog to create a dataset of ICMEs covering 0.3-5.4 AU.* Using a linear regression model to fit the combined dataset on a double-logarithmic plot, we find that there is a clear difference between global expansion rates for ICMEs observed at lesser heliocentric distances and those observed farther out beyond 1 AU. The cataloged ICMEs at Juno present a good basis for future multispacecraft studies of ICME evolution between the inner heliosphere, 1 AU, and beyond. **29 Jan-3 Feb 2013, 20 Feb 2013**

On the Radial and Longitudinal Variation of a Magnetic Cloud: ACE, Wind, ARTEMIS and Juno Observations

Emma E. **Davies**, [Robert J. Forsyth](#), [Simon W. Good](#) & [Emilia K. J. Kilpua](#)
Solar Physics volume 295, Article number: 157 (2020)

<https://link.springer.com/content/pdf/10.1007/s11207-020-01714-z.pdf>

We present observations of the same magnetic cloud made near Earth by the Advance Composition Explorer (ACE), Wind, and the Acceleration, Reconnection, Turbulence and Electrodynamics of the Moon's Interaction with the Sun (ARTEMIS) mission comprising the Time History of Events and Macroscale Interactions during Substorms (THEMIS) B and THEMIS C spacecraft, and later by Juno at a distance of 1.2 AU. The spacecraft were close to radial alignment throughout the event, with a longitudinal separation of 3.6° between Juno and the spacecraft near Earth. The magnetic cloud likely originated from a filament eruption on **22 October 2011** at 00:05 UT, and caused a strong geomagnetic storm at Earth commencing on **24 October**. Observations of the magnetic cloud at each spacecraft have been analysed using minimum variance analysis and two flux rope fitting models, Lundquist and Gold–Hoyle, to give the orientation of the flux rope axis. We explore the effect different trailing edge boundaries have on the results of each analysis method, and find a clear difference between the orientations of the flux rope axis at the near-Earth spacecraft and Juno, independent of the analysis method. The axial magnetic field strength and the radial width of the flux rope are calculated using both observations and fitting parameters and their relationship with heliocentric distance is investigated. Differences in results between the near-Earth spacecraft and Juno are attributed not only to the radial separation, but to the small longitudinal separation which resulted in a surprisingly large difference in the in situ observations between the spacecraft. This case study demonstrates the utility of Juno cruise data as a new opportunity to study magnetic clouds beyond 1 AU, and the need for caution in future radial alignment studies. **22-24 Oct 2011**

Establishing a Stereoscopic Technique for Determining the Kinematic Properties of Solar Wind Transients based on a Generalized Self-similarly Expanding Circular Geometry

J. A. **Davies**¹, C. H. Perry¹, R. M. G. M. Trines^{2,3}, R. A. Harrison¹, N. Lugaz⁴, C. Möstl^{5,6,7}, Y. D. Liu⁸, and K. Steed

2013 ApJ 777 167

http://sprg.ssl.berkeley.edu/~liuxying/pubs/2013_apj_davies.pdf

The twin-spacecraft STEREO mission has enabled simultaneous white-light imaging of the solar corona and inner heliosphere from multiple vantage points. This has led to the development of numerous stereoscopic techniques to investigate the three-dimensional structure and kinematics of solar wind transients such as coronal mass ejections (CMEs). Two such methods—triangulation and the tangent to a sphere—can be used to determine time profiles of the propagation direction and radial distance (and thereby radial speed) of a solar wind transient as it travels through the inner heliosphere, based on its time-elongation profile viewed by two observers. These techniques are founded on the assumption that the transient can be characterized as a point source (fixed, FP, approximation) or a circle attached to Sun-center (harmonic mean, HM, approximation), respectively. These geometries constitute extreme descriptions of solar wind transients, in terms of their cross-sectional extent. Here, we present the stereoscopic expressions necessary to derive propagation direction and radial distance/speed profiles of such transients based on the more generalized self-similar expansion (SSE) geometry, for which the FP and HM geometries form the limiting cases; our implementation of these equations is termed the stereoscopic SSE method. We apply the technique to two Earth-directed CMEs from different phases of the STEREO mission, the well-studied event of **2008 December** and a more recent event from **2012 March**. The latter CME was fast, with an initial speed exceeding 2000 km s⁻¹, and highly geoeffective, in stark contrast to the slow and ineffectual 2008 December CME.

Predicting the arrival of high-speed solar wind streams at Earth using the STEREO Heliospheric Imagers

Davis, C. J.; Davies, J. A.; Owens, M. J.; Lockwood, M.

Space Weather, Vol. 10, No. 2, S02003, **2012**

<http://dx.doi.org/10.1029/2011SW000737>

High-speed solar wind streams modify the Earth's geomagnetic environment, perturbing the ionosphere, modulating the flux of cosmic rays into the Earth atmosphere, and triggering substorms. Such activity can affect modern technological systems. To investigate the potential for predicting the arrival of such streams at Earth, images taken by the Heliospheric Imager (HI) on the STEREO-A spacecraft have been used to identify the onsets of high-speed solar wind streams from observations of regions of increased plasma concentrations associated with corotating interaction regions, or CIRs. In order to confirm that these transients were indeed associated with CIRs and to study their average properties, arrival times predicted from the HI images were used in a superposed epoch analysis to confirm their identity in near-Earth solar wind data obtained by the Advanced Composition Explorer (ACE) spacecraft and to observe their influence on a number of salient geophysical parameters. The results are almost identical to those of a parallel superposed epoch

analysis that used the onset times of the high-speed streams derived from east/west deflections in the ACE measurements of solar wind speed to predict the arrival of such streams at Earth, assuming they corotated with the Sun with a period of 27 days. Repeating the superposed epoch analysis using restricted data sets demonstrates that this technique can provide a timely prediction of the arrival of CIRs at least 1 day ahead of their arrival at Earth and that such advanced warning can be provided from a spacecraft placed 40° ahead of Earth in its orbit.

A comparison of space weather analysis techniques used to predict the arrival of the Earth-directed CME and its shockwave launched on 8 April 2010

Davis, C. J.; de Koning, C. A.; Davies, J. A.; Biesecker, D.; Millward, G.; Dryer, M.; Deehr, C.; Webb, D. F.; Schenk, K.; Freeland, S. L.; MJKstl, C.; Farrugia, C. J.; Odstrcil, D.

Space Weather, Vol. 9, No. 1, S01005, 2011, **File**

The Earth-directed coronal mass ejection (CME) of **8 April 2010** provided an opportunity for space weather predictions from both established and developmental techniques to be made from near-real time data received from the SOHO and STEREO spacecraft; the STEREO spacecraft provide a unique view of Earth-directed events from outside the Sun-Earth line. Although the near-real time data transmitted by the STEREO Space Weather Beacon are significantly poorer in quality than the subsequently downlinked science data, the use of these data has the advantage that near-real time analysis is possible, allowing actual forecasts to be made. The fact that such forecasts cannot be biased by any prior knowledge of the actual arrival time at Earth provides an opportunity for an unbiased comparison between several established and developmental forecasting techniques. We conclude that for forecasts based on the STEREO coronagraph data, it is important to take account of the subsequent acceleration/deceleration of each CME through interaction with the solar wind, while predictions based on measurements of CMEs made by the STEREO Heliospheric Imagers would benefit from higher temporal and spatial resolution. Space weather forecasting tools must work with near-real time data; such data, when provided by science missions, is usually highly compressed and/or reduced in temporal/spatial resolution and may also have significant gaps in coverage, making such forecasts more challenging.

Assessing the Accuracy of CME Speed and Trajectory Estimates from STEREO Observations Through a Comparison of Independent Methods

C.J. **Davis** · J. Kennedy · J.A. Davies

Solar Phys (2010) 263: 209–222, DOI 10.1007/s11207-010-9535-2; **File**

We have estimated the speed and direction of propagation of a number of Coronal Mass Ejections (CMEs) using single-spacecraft data from the STEREO Heliospheric Imager (HI) wide-field cameras. In general, these values are in good agreement with those predicted by Thernisien, Vourlidis, and Howard in *Solar Phys.* **256**, 111 – 130 (2009) using a forward modelling method to fit CMEs imaged by the STEREO COR2 coronagraphs. The directions of the CMEs predicted by both techniques are in good agreement despite the fact that many of the CMEs under study travel in directions that cause them to fade rapidly in the HI images. The velocities estimated from both techniques are in general agreement although there are some interesting differences that may provide evidence for the influence of the ambient solar wind on the speed of CMEs. The majority of CMEs with a velocity estimated to be below 400 km s⁻¹ in the COR2 field of view have higher estimated velocities in the HI field of view, while, conversely, those with COR2 velocities estimated to be above 400 km s⁻¹ have lower estimated HI velocities. We interpret this as evidence for the deceleration of fast CMEs and the acceleration of slower CMEs by interaction with the ambient solar wind beyond the COR2 field of view. We also show that the uncertainties in our derived parameters are influenced by the range of elongations over which each CME can be tracked. In order to reduce the uncertainty in the predicted arrival time of a CME at 1 Astronomical Unit (AU) to within six hours, the CME needs to be tracked out to at least 30 degrees elongation. This is in good agreement with predictions of the accuracy of our technique based on Monte Carlo simulations.

Within the set of studied CMEs, there are two clear events that were predicted from the HI data to travel over another spacecraft; *in-situ* measurements at these other spacecraft confirm the accuracy of these predictions. The ability of the HI cameras to image Corotating Interaction Region (CIR)-entrained transients as well as CMEs can result in some ambiguity when trying to distinguishing individual signatures.

In-Situ Multi-Spacecraft and Remote Imaging Observations of the First CME Detected by Solar Orbiter and BepiColombo

A&A 2020

<https://arxiv.org/pdf/2012.07456.pdf>

On April 19th 2020 a CME was detected in-situ by Solar Orbiter at a heliocentric distance of about 0.8 AU. The CME was later observed in-situ on April 20th by the Wind and BepiColombo spacecraft whilst BepiColombo was located very close to Earth. This CME presents a good opportunity for a triple radial alignment study, as the spacecraft were separated by less than 5° in longitude. The source of the CME, which was launched on April 15th, was an almost entirely isolated streamer blowout. STEREO-A observed the event remotely from -75.1° longitude: an exceptionally well suited viewpoint for heliospheric imaging of an Earth directed CME. The configuration of the four spacecraft has provided an exceptionally clean link between remote imaging and in-situ observations of the CME. We have used the in-situ observations of the CME at Solar Orbiter, Wind and BepiColombo, and the remote observations of the CME at STEREO-A in combination with flux rope models to determine the global shape of the CME and its evolution as it propagated through the inner heliosphere. A clear flattening of the CME cross-section has been observed by STEREO-A, and further confirmed by comparing profiles of the flux rope models to the in-situ data, where the distorted flux rope cross-section qualitatively agrees most with in-situ observations of the magnetic field at Solar Orbiter. Comparing in-situ observations of the magnetic field between spacecraft, we find that the dependence of the maximum (mean) magnetic field strength decreases with heliocentric distance as $r^{-1.22 \pm 0.42}$ ($r^{-1.10 \pm 0.20}$), in disagreement with previous studies. Further assessment of the axial and poloidal magnetic field strength dependencies suggests that the expansion of the CME is likely neither self-similar nor cylindrically symmetric. **15-21 Apr 2020**

A synoptic view of solar transient evolution in the inner heliosphere using the Heliospheric Imagers on STEREO

[Davies](#), J. A.; [Harrison](#), R. A.; [Rouillard](#), A. P.; [Sheeley](#), N. R.; [Perry](#), C. H.; [Bewsher](#), D.; [Davis](#), C. J.; [Eyles](#), C. J.; [Crothers](#), S. R.; [Brown](#), D. S.

Geophysical Research Letters, Volume 36, Issue 2, CiteID L02102, **2009**

By exploiting data from the STEREO/heliospheric imagers (HI) we extend a well-established technique developed for coronal analysis by producing time-elongation plots that reveal the nature of solar transient activity over a far more extensive region of the heliosphere than previously possible from coronagraph images. Despite the simplicity of these plots, their power in demonstrating how the plethora of ascending coronal features observed near the Sun evolve as they move antisunward is obvious. The time-elongation profile of a transient tracked by HI can, moreover, be used to establish its angle out of the plane-of-the-sky an illustration of such analysis reveals coronal mass ejection material that can be clearly observed propagating out to distances beyond 1AU. This work confirms the value of the time-elongation format in identifying/characterising transient activity in the inner heliosphere, whilst also validating the ability of HI to continuously monitor solar ejecta out to and beyond 1AU.

Polytropic behavior in the structures of Interplanetary Coronal Mass Ejections

Maher A [Dayeh](#), [George Livadiotis](#)

2022 *ApJL* **941** L26

<https://arxiv.org/ftp/arxiv/papers/2209/2209.12988.pdf>

<https://iopscience.iop.org/article/10.3847/2041-8213/aca673/pdf>

The polytropic process characterizes the thermodynamics of space plasma particle populations. The polytropic index, γ , is particularly important as it describes the thermodynamic behavior of the system by quantifying the changes in temperature as the system is compressed or expanded. Using Wind spacecraft plasma and magnetic field data during 01/1995–12/2018, we investigate the thermodynamic evolution in 336 Interplanetary Coronal Mass Ejection (ICME) events. For each event, we derive the index γ in the sheath and magnetic ejecta structures, along with the pre- and post- event regions. We then examine the distributions of all γ indices in these four regions and derive the entropic gradient of each, which is indicative of the ambient heating. We find that in the ICME sheath region, where wave turbulence is expected to be highest, the thermodynamics takes longest to recover into the original quasi-adiabatic process, while it recovers faster in the quieter ejecta region. This pattern creates a thermodynamic cycle, featuring a near adiabatic value $\gamma \sim \gamma_a$ ($=5/3$) upstream of the ICMEs, $\gamma_a - \gamma \sim 0.26$ in the sheaths, $\gamma_a - \gamma \sim 0.13$ in the ICME ejecta, and recovers again to $\gamma \sim \gamma_a$ after the passage of the ICME. These results expose the turbulent heating rates in the ICME

plasma: the lower the polytropic index from its adiabatic value and closer to its isothermal value, the larger the entropic gradient, and thus, the rate of turbulent heating that heats the ICME plasma.

The Highly Structured Outer Solar Corona

C. E. [DeForest](#)¹, R. A. Howard², M. Velli³, N. Viall⁴, and A. Vourlidas

2018 ApJ 862 18

<http://iopscience.iop.org/article/10.3847/1538-4357/aac8e3/pdf>

We report on the observation of fine-scale structure in the outer corona at solar maximum, using deep-exposure campaign data from the Solar Terrestrial Relations Observatory-A (STEREO-A)/COR2 coronagraph coupled with postprocessing to further reduce noise and thereby improve effective spatial resolution. The processed images reveal radial structure with high density contrast at all observable scales down to the optical limit of the instrument, giving the corona a "woodgrain" appearance. Inferred density varies by an order of magnitude on spatial scales of 50 Mm and follows an f^{-1} spatial spectrum. The variations belie the notion of a smooth outer corona. They are inconsistent with a well-defined "Alfvén surface," indicating instead a more nuanced "Alfvén zone"—a broad trans-Alfvénic region rather than a simple boundary. Intermittent compact structures are also present at all observable scales, forming a size spectrum with the familiar "Sheeley blobs" at the large-scale end. We use these structures to track overall flow and acceleration, finding that it is highly inhomogeneous and accelerates gradually out to the limit of the COR2 field of view. Lagged autocorrelation of the corona has an enigmatic dip around $10 R_{\odot}$, perhaps pointing to new phenomena near this altitude. These results point toward a highly complex outer corona with far more structure and local dynamics than has been apparent. We discuss the impact of these results on solar and solar-wind physics and what future studies and measurements are necessary to build upon them.

FADING CORONAL STRUCTURE AND THE ONSET OF TURBULENCE IN THE YOUNG SOLAR WIND

C. E. [DeForest](#)¹, W. H. Matthaeus², N. M. Viall³, and S. R. Cranmer⁴

2016 ApJ 828 66

Above the top of the solar corona, the young, slow solar wind transitions from low- β , magnetically structured flow dominated by radial structures to high- β , less structured flow dominated by hydrodynamics. This transition, long inferred via theory, is readily apparent in the sky region close to 10° from the Sun in processed, background-subtracted solar wind images. We present image sequences collected by the inner Heliospheric Imager instrument on board the Solar-Terrestrial Relations Observatory (STEREO/HI1) in 2008 December, covering apparent distances from approximately 4° to 24° from the center of the Sun and spanning this transition in the large-scale morphology of the wind. We describe the observation and novel techniques to extract evolving image structure from the images, and we use those data and techniques to present and quantify the clear textural shift in the apparent structure of the corona and solar wind in this altitude range. We demonstrate that the change in apparent texture is due both to anomalous fading of the radial striae that characterize the corona and to anomalous relative brightening of locally dense puffs of solar wind that we term "flocculae." We show that these phenomena are inconsistent with smooth radial flow, but consistent with the onset of hydrodynamic or magnetohydrodynamic instabilities leading to a turbulent cascade in the young solar wind. See Wendel, J. (2016), Scientists get first glimpse of solar wind as it forms, *Eos*, 97, doi:10.1029/2016EO059053. Published on 09 September 2016.

TRACKING CORONAL FEATURES FROM THE LOW CORONA TO EARTH: A QUANTITATIVE ANALYSIS OF THE 2008 DECEMBER 12 CORONAL MASS EJECTION

C. E. [DeForest](#)¹, T. A. Howard¹, and D. J. McComas

2013 ApJ 769 43, [File](#)

We have tracked a slow magnetic cloud associated coronal mass ejection (CME) continuously from its origin as a flux rope structure in the low solar corona over a four-day passage to impact with spacecraft located near Earth. Combining measurements from the STEREO, ACE, and Wind space missions, we are able to follow major elements with enough specificity to relate pre-CME coronal structure in the low corona to the corresponding elements seen in the near-Earth in situ data. Combining extreme ultraviolet imaging, quantitative Thomson scattering data throughout the flight of the CME, and "ground-truth" in situ measurements, we: (1) identify the plasma observed by ACE and Wind with specific features in the solar corona (a segment of a long flux rope); (2) determine the onset mechanism of the CME (destabilization of a filament channel following flare reconnection, coupled with the mass draining instability) and demonstrate that it is consistent with the in situ measurements; (3) identify the origin of different layers of the sheath material around the central magnetic cloud (closed field lifted from the base of the corona, closed field entrained during passage through the corona, and solar wind entrained by the front of the CME); (4) measure mass accretion of the system via snowplow effects in the solar wind as the CME crossed the solar system; and (5) quantify the kinetic energy

budget of the system in interplanetary space, and determine that it is consistent with no long-term driving force on the CME. **2008 December 12**

DISCONNECTING OPEN SOLAR MAGNETIC FLUX

C. E. DeForest¹, T. A. Howard¹, and D. J. McComas^{1,2}

Astrophysical Journal, 745:36 (9pp), **2012**

http://www.boulder.swri.edu/~howard/Papers/2012_Disconnection.pdf - **File**

Disconnection of open magnetic flux by reconnection is required to balance the injection of open flux by coronal mass ejections and other eruptive events. Making use of recent advances in heliospheric background subtraction, we have imaged many abrupt disconnection events. These events produce dense plasma clouds whose distinctive shape can now be traced from the corona across the inner solar system via heliospheric imaging. The morphology of each initial event is characteristic of magnetic reconnection across a current sheet, and the newly disconnected flux takes the form of a "U"-shaped loop that moves outward, accreting coronal and solar wind material. We analyzed one such event on 2008 December 18 as it formed and accelerated at 20 m s^{-2} to 320 km s^{-1} , thereafter expanding self-similarly until it exited our field of view 1.2 AU from the Sun. From acceleration and photometric mass estimates we derive the coronal magnetic field strength to be $8 \mu\text{T}$, $6R_{\odot}$ above the photosphere, and the entrained flux to be $1.6 \times 10^{11} \text{ Wb}$ ($1.6 \times 10^{19} \text{ Mx}$). We model the feature's propagation by balancing inferred magnetic tension force against accretion drag. This model is consistent with the feature's behavior and accepted solar wind parameters. By counting events over a 36 day window, we estimate a global event rate of 1 day^{-1} and a global solar minimum unsigned flux disconnection rate of $6 \times 10^{13} \text{ Wb yr}^{-1}$ ($6 \times 10^{21} \text{ Mx yr}^{-1}$) by this mechanism. That rate corresponds to $\sim -0.2 \text{ nT yr}^{-1}$ change in the radial heliospheric field at 1 AU, indicating that the mechanism is important to the heliospheric flux balance.

OBSERVATIONS OF DETAILED STRUCTURE IN THE SOLAR WIND AT 1 AU WITH STEREO/HI-2

C. E. DeForest¹, T. A. Howard¹ and S. J. Tappin

2011 ApJ 738 103

We present images of solar wind electron density structures at distances of 1 AU, extracted from the STEREO/HI-2 data. Collecting the images requires separating the Thomson-scattered signal from the other background/foreground sources that are 103 times brighter. Using a combination of techniques, we are able to generate calibrated imaging data of the solar wind with sensitivity of a few $\times 10^{-17} \text{ B}$, compared to the background signal of a few $\times 10^{-13} \text{ B}$, using only the STEREO/HI-2 Level 1 data as input. These images reveal detailed spatial structure in coronal mass ejections (CMEs) and the solar wind at projected solar distances in excess of 1 AU, at the instrumental motion-blur resolution limit of 1° - 3° . CME features visible in the newly reprocessed data from 2008 December include leading-edge pileup, interior voids, filamentary structure, and rear cusps. "Quiet" solar wind features include V-shaped structures centered on the heliospheric current sheet, plasmoids, and "puffs" that correspond to the density fluctuations observed in situ. We compare many of these structures with in situ features detected near 1 AU. The reprocessed data demonstrate that it is possible to perform detailed structural analyses of heliospheric features with visible light imagery, at distances from the Sun of at least 1 AU.

Interplanetary shock wave extent in the inner heliosphere as observed by multiple spacecraft

A. de Lucasa, , R. Schwennb, , A. dal Lagoa, , E. Marschb and A.L. Clúa de Gonzalez

Journal of Atmospheric and Solar-Terrestrial Physics, Volume 73, Issue 10, **2011**, Pages 1281-1292

For over an entire solar cycle, from the end of 1974 until the beginning of 1986, the twin Helios spacecraft explored the inner heliosphere. These in situ, high-resolution plasma and magnetic field measurements covered heliocentric distances between 0.3 and 1 AU from the Sun and are of particular interest to studies of space weather phenomena. During this period the two spacecraft detected 395 ICME-driven shocks and these waves were found to be driven by interplanetary coronal mass ejections (ICMEs). Based on these multi-spacecraft measurements, which include a third vantage point with the observations from ISEE-3/IMP-8, the longitudinal extent of the shock waves were measured in the inner heliosphere. It was found that shock waves have about a 50% chance to be observed by two different locations separated by 90° . In practice, one can expect with about a 50% chance that the shock driven by a limb coronal mass ejections (CMEs) will hit the Earth, considering the expansion in longitude of shock waves driven by their associated ICMEs. For

a larger separation the uncertainty increases, as only a few cases could be observed. With the absence of simultaneous solar disk observations one can then no longer unequivocally identify the shock waves observed at each spacecraft.

Research highlights

► Shock waves can extend to large longitudinal angles. ► A limb CME driven shock has about 50% chance to hit the Earth. ► A significant number of single-spacecraft observations were found for small angular distances between the observations locations.

On the Differences in the Ambient Solar Wind Speed Forecasting Caused by Using Synoptic Maps from Different Observatories

M. L. [Demidov](#), [Y. Hanaoka](#), [X. F. Wang](#) & [P. N. Kirichkov](#)

[Solar Physics](#) volume 298, Article number: 120 (2023)

We consider the problem of forecasting the solar wind speed using not only well-known magnetic field data sets, such as the Wilcox Solar Observatory (WSO) and the Global Oscillations Network Group (GONG) but others, such as the Infrared Magnetograph (IRmag) at the National Astronomical Observatory of Japan and the Solar Telescope for Operative Prediction (STOP) in Russia. We use these observations to study Carrington rotation (CR) 2164 (21 May – 17 June 2015). Our initial calculations are based on the Wang-Sheeley-Argé (WSA) model and include determining the coronal magnetic field using the potential field source surface (PFSS) approximation. The speed of the ambient solar wind near the Sun is calculated using an empirical equation that considers the flux tube expansion factor (FTEF) and the distance of the flux tube footpoint from the coronal hole boundary (DCHB) at the photospheric level. The solar wind bulk speed at the Earth's orbit is calculated using the Heliospheric Upwind eXtrapolation (HUX) model. It is shown that the discrepancies in the speed values from four different data sets could reach $\approx 200 \text{ km s}^{-1}$, which is significant. We compare our predictions with in situ data from the Advance Composition Explorer (ACE) and demonstrate that a better coincidence between calculated and empirical results, accounting for the magnetic field strength in coronal holes, can be achieved.

Contribution of the aging effect to the observed asymmetry of interplanetary magnetic clouds

Large magnetic structures are launched away from the Sun during solar eruptions. They are observed as (interplanetary) coronal mass ejections (ICMEs or CMEs) with coronal and heliospheric imagers. A fraction of them are observed in situ as magnetic clouds (MCs). Fitting these structures properly with a model requires a better understanding of their evolution. In situ measurements are done locally when the spacecraft trajectory crosses the magnetic configuration. These observations are taken for different elements of plasma and at different times, and are therefore biased by the expansion of the magnetic configuration. This aging effect leads to stronger magnetic fields measured at the front than at the rear of MCs, an asymmetry often present in MC data. However, can the observed asymmetry be explained quantitatively only from the expansion? Based on self-similar expansion, we derive a method to estimate the expansion rate from observed plasma velocity. We next correct for the aging effect both the observed magnetic field and the spatial coordinate along the spacecraft trajectory. This provides corrected data as if the MC internal structure was observed at the same time. We apply the method to 90 best observed MCs near Earth (1995-2012). The aging effect is the main source of the observed magnetic asymmetry only for 28% of MCs. After correcting the aging effect, the asymmetry is almost symmetrically distributed between MCs with a stronger magnetic field at the front and those at the rear of MCs. The proposed method can efficiently remove the aging bias within in situ data of MCs, and more generally of ICMEs. This allows one to analyse the data with a spatial coordinate, such as in models or remote sensing observations.

Re-analysis of Lepping's Fitting Method for Magnetic Clouds: Lundquist Fit Reloaded

Pascal [Démoulin](#), [Sergio Dasso](#), [Miho Janvier](#) & [Vanina Lanabere](#)

[Solar Physics](#) volume 294, Article number: 172 (2019)

<https://link.springer.com/content/pdf/10.1007/s11207-019-1564-x.pdf>

<https://arxiv.org/pdf/1912.09829.pdf>

http://www.lesia.obspm.fr/perso/pascal-demoulin/19/Demoulin19_Lundquist_reload.pdf

Magnetic clouds (MCs) are a subset of ejecta, launched from the Sun as coronal mass ejections. The coherent rotation of the magnetic field vector observed in MCs leads to envision MCs as formed by flux ropes (FRs). Among all the methods

used to analyze MCs, Lepping's method (Lepping, Burlaga, and Jones in *J. Geophys. Res.* 95, 11957, [1990](#)) is the broadest used. While this fitting method does not require the axial field component to vanish at the MC boundaries, this idea is largely spread in publications. We revisit Lepping's method to emphasize its hypothesis and the meaning of its output parameters. As originally defined, these parameters imply a fitted FR which could be smaller or larger than the studied MC. We rather provide a re-interpretation of Lepping's results with a fitted model limited to the observed MC interval. We find that typically the crossed FRs are asymmetric with a larger side both in size and magnetic flux before or after the FR axis. At the boundary of the largest side we find an axial magnetic field component distributed around zero which we justify by the physics of solar eruptions. In contrast, at the boundary of the smaller side the axial field distribution is shifted to positive values, as expected with erosion acting during the interplanetary travel. This new analysis of Lepping's results has several implications. First, global quantities, such as magnetic fluxes and helicity, need to be revised depending on the aim (estimating global properties of FRs just after the solar launch or at 1 au). Second, the deduced twist profiles in MCs range quasi-continuously from nearly uniform, to increasing away from the FR axis, up to a reversal near the MC boundaries. There is no trace of outsider cases, but a continuum of cases. Finally, the impact parameter of the remaining FR crossed at 1 au is revised. Its distribution is compatible with weakly flattened FR cross-sections.

Magnetic Flux and Helicity of Magnetic Clouds

Demoulin P., Janvier M., Dasso S.

A&A

2018

<http://arxiv.org/pdf/1509.01068v1.pdf>

Context. Magnetic clouds (MCs) are formed by flux ropes (FRs) launched from the Sun as part of coronal mass ejections (CMEs). They carry away an important amount of magnetic flux and helicity. Aims. The main aim of this study is to quantify these quantities from in situ measurements of MCs at 1 AU.

Methods. The fit of these data by a local FR model provides the axial magnetic field strength, the radius, the magnetic flux and the helicity per unit length along the FR axis. Results. We show that these quantities are statistically independent of the position along the FR axis. We then derive the generic shape and length of the FR axis from two sets of MCs. These results improve the estimation of magnetic helicity. Next, we evaluate the total magnetic flux and helicity crossing the sphere of radius of 1 AU, centered at the Sun, per year and during a solar cycle. We also include in the study two sets of small FRs which do not have all the typical characteristics of MCs. Conclusions. While small FRs are at least ten times more numerous than MCs, the magnetic flux and helicity are dominated by the contribution from the larger MCs. They carry in one year the magnetic flux of about 25 large active regions and the magnetic helicity of 200 of them. MCs carry away an amount of unsigned magnetic helicity comparable to the one estimated for the solar dynamo and the one measured in emerging active regions. **Note:** This article will be published in *Solar Physics* but is set in the A&A format because of LaTeX compilation problem with SP style.

Exploring the biases of a new method based on minimum variance for interplanetary magnetic clouds

Pascal Démoulin, Sergio Dasso, Miho Janvier

A&A

2018

<https://arxiv.org/pdf/1809.00522.pdf>

http://www.lesia.obspm.fr/perso/pascal-demoulin/18/Demoulin18_mv_flux_balance.pdf

Context. Magnetic clouds (MCs) are twisted magnetic structures ejected from the Sun and probed by in situ instruments. They are typically modeled as flux ropes (FRs).

Aims. Magnetic field measurements are only available along the 1D spacecraft trajectory. The determination of the FR global characteristics requires the estimation of the FR axis orientation. Among the developed methods, the minimum variance (MV) is the most flexible, and features only a few assumptions. However, as other methods, MV has biases. We aim to investigate the limits of the method and extend it to a less biased method.

Methods. We first identified the origin of the biases by testing the MV method on cylindrical and elliptical models with a temporal expansion comparable to the one observed in MCs. Then, we developed an improved MV method to reduce these biases.

Results. In contrast with many previous publications we find that the ratio of the MV eigenvalues is not a reliable indicator of the precision of the derived FR axis direction. Next, we emphasize the importance of the FR boundaries selected since they strongly affect the deduced axis orientation. We have improved the MV method by imposing that the same amount of azimuthal flux should be present before and after the time of closest approach to the FR axis. We emphasize the importance of finding simultaneously the FR axis direction and the location of the boundaries corresponding to a balanced magnetic flux, so as to minimize the bias on the deduced FR axis orientation. This method

can also define an inner flux-balanced sub-FR. We show that the MV results are much less biased when a compromise in size of this sub-FR is achieved.

Conclusions. For weakly asymmetric field temporal profiles, the improved MV provides a very good determination of the FR axis orientation. The main remaining bias is moderate (lower than 6°) and is present mostly on the angle between the flux rope axis and the plane perpendicular to the Sun-Earth direction.

Quantitative model for the generic 3D shape of ICMEs at 1 AU

P. **Demoulin**, M. Janvier, J.J. Masias-Meza and S. Dasso

A&A 595, A19 2016

<http://arxiv.org/abs/1608.08550>

Interplanetary imagers provide 2D projected views of the densest plasma parts of interplanetary coronal mass ejections (ICMEs), while in situ measurements provide magnetic field and plasma parameter measurements along the spacecraft trajectory, that is, along a 1D cut. The data therefore only give a partial view of the 3D structures of ICMEs. By studying a large number of ICMEs, crossed at different distances from their apex, we develop statistical methods to obtain a quantitative generic 3D shape of ICMEs. In a first approach we theoretically obtained the expected statistical distribution of the shock-normal orientation from assuming simple models of 3D shock shapes, including distorted profiles, and compared their compatibility with observed distributions. In a second approach we used the shock normal and the flux rope axis orientations together with the impact parameter to provide statistical information across the spacecraft trajectory. The study of different 3D shock models shows that the observations are compatible with a shock that is symmetric around the Sun-apex line as well as with an asymmetry up to an aspect ratio of around 3. Moreover, flat or dipped shock surfaces near their apex can only be rare cases. Next, the sheath thickness and the ICME velocity have no global trend along the ICME front. Finally, regrouping all these new results and those of our previous articles, we provide a quantitative ICME generic 3D shape, including the global shape of the shock, the sheath, and the flux rope. The obtained quantitative generic ICME shape will have implications for several aims. For example, it constrains the output of typical ICME numerical simulations. It is also a base for studying the transport of high-energy solar and cosmic particles during an ICME propagation as well as for modeling and forecasting space weather conditions near Earth.

Magnetic Flux and Helicity of Magnetic Clouds

Demoulin P., Janvier M., Dasso S.

Solar Phys. Vol. 291, Issue 2 2015

http://www.lesia.obspm.fr/perso/pascal-demoulin/15/demoulin15_helicity_MCs.pdf

<http://arxiv.org/pdf/1509.01068v1.pdf>

Note: This article will be published in Solar Physics but is set in the A&A format because of LaTeX compilation problem with SP style.

Magnetic clouds (MCs) are formed by flux ropes (FRs) launched from the Sun as part of coronal mass ejections (CMEs). They carry away an important amount of magnetic flux and helicity. The main aim of this study is to quantify these quantities from in situ measurements of MCs at 1 AU. The fit of these data by a local FR model provides the axial magnetic field strength, the radius, the magnetic flux and the helicity per unit length along the FR axis. We show that these quantities are statistically independent of the position along the FR axis. We then derive the generic shape and length of the FR axis from two sets of MCs. Evolution of interplanetary coronal mass ejections and magnetic clouds in the heliosphere

Review

Demoulin, P.

E-print, Sept 2013, **File**; IAU S300 proceedings; IAUS, 300, 245-254 (2014)

Interplanetary Coronal Mass Ejections (ICMEs), and more specifically Magnetic clouds (MCs), are detected with in situ plasma and magnetic measurements. They are the continuation of the CMEs observed with imagers closer to the Sun. A

review of their properties is presented with a focus on their magnetic configuration and its evolution. Many recent observations, both in situ and with imagers, point to a key role of flux ropes, a conclusion which is also supported by present coronal eruptive models. Then, is a flux rope generically present in an ICME? How to quantify its 3D physical properties when it is detected locally as a MC? Is it a simple flux rope? How does it evolve in the solar wind? This paper reviews our present answers and limited understanding to these questions.

Does the spacecraft trajectory strongly affect the detection of magnetic clouds?

Demoulin, P., Dasso, S., Janvier, M.

E-print, Dec **2012**, A&A, 550, A3 (**2013**)

Magnetic clouds (MCs) are a subset of interplanetary coronal mass ejections (ICMEs) where a magnetic flux rope is detected. Is the difference between MCs and ICMEs without detected flux rope intrinsic or rather due to an observational bias? As the spacecraft has no relationship with the MC trajectory, the frequency distribution of MCs versus the spacecraft distance to the MCs axis is expected to be approximately flat. However, Lepping and Wu (2010) confirmed that it is a strongly decreasing function of the estimated impact parameter. Is a flux rope more frequently undetected for larger impact parameter? In order to answer the questions above, we explore the parameter space of flux rope models, especially the aspect ratio, boundary shape, and current distribution. The proposed models are analyzed as MCs by fitting a circular linear force-free field to the magnetic field computed along simulated crossings. We find that the distribution of the twist within the flux rope, the non-detection due to too low field rotation angle or magnitude are only weakly affecting the expected frequency distribution of MCs versus impact parameter. However, the estimated impact parameter is increasingly biased to lower values as the flux-rope cross section is more elongated orthogonally to the crossing trajectory. The observed distribution of MCs is a natural consequence of a flux-rope cross section flattened in average by a factor 2 to 3 depending on the magnetic twist profile. However, the faster MCs at 1 AU, with $V > 550$ km/s, present an almost uniform distribution of MCs vs. impact parameter, which is consistent with round shaped flux ropes, in contrast with the slower ones. We conclude that either most of the non-MC ICMEs are encountered outside their flux rope or near the leg region, or they do not contain any.

Interaction of ICMEs with the Solar Wind (Review)

Demoulin P.

E-print, Sept **2009**, SW12 proceedings; **File**

Interplanetary Coronal Mass Ejections (ICMEs) are formed of plasma and magnetic field launched from the Sun into the Solar Wind (SW). These coherent magnetic structures, frequently formed by a flux rope, interact strongly with the SW. Such interaction is reviewed by comparing the results obtained from in situ observations and with numerical simulations. Like fast ships in the ocean, fast ICMEs drive an extended shock in front. However, their interaction with the SW is much more complex than that of the ship analogy. For example, as they expand in all directions while traveling away from the Sun, a sheath of SW plasma and magnetic field accumulates in front, which partially reconnects with the ICME magnetic field. Furthermore, not only ICMEs have a profound impact on the heliosphere, but the type of SW encountered by an ICME has an important impact on its evolution (e.g. increase of mass, global deceleration, lost of magnetic flux and helicity, distortion of the configuration).

Magnetic cloud models with bent and oblate cross-section boundary

Demoulin P., Dasso S.

E-print, Sept **2009**; A&A 507, 969-980 (**2009**); **File**

Magnetic clouds (MCs) are formed by magnetic flux ropes that are ejected from the Sun as coronal mass ejections. These structures generally have low plasma beta and travel through the interplanetary medium interacting with the surrounding solar wind (SW). Thus, the dynamical evolution of the internal magnetic structure of a MC is a consequence of both the conditions of its environment and of its own dynamical laws, which are mainly dominated by magnetic forces. With in-situ observations the magnetic field is only measured along the trajectory of the spacecraft across the MC. Therefore, a magnetic model is needed to reconstruct the magnetic configuration of the encountered MC. The main aim of the present work is to extend the widely used cylindrical model to arbitrary cross-section shapes. The flux rope boundary is parametrized to account for a broad range of shapes. Then, the internal structure of the flux rope is computed by expressing the magnetic field as a series of modes of a linear force-free field. We analyze the magnetic field profile along straight cuts through the flux rope, in order to simulate the spacecraft crossing through a MC. We find that the magnetic field orientation is only weakly affected by the shape of the MC boundary. Therefore, the MC axis can

approximately be found by the typical methods previously used (e.g., minimum variance). The boundary shape affects mostly the magnetic field strength. The measure of how much the field strength peaks along the crossing provides an estimation for the aspect ratio of the flux-rope cross-section. The asymmetry of the field strength between the front and the back of the MC, after correcting the time evolution (i.e., its aging during the observation of the MC), provides an estimation of the cross-section global bending. A flat or/and bent cross-section requires a large anisotropy of the total pressure imposed at the MC boundary by the surrounding medium. The new theoretical model developed here relaxes the cylindrical symmetry hypothesis. It is designed to estimate the cross-section shape of the flux rope using the in-situ data of one spacecraft. This allows a more accurate determination of the global quantities, such as magnetic fluxes and helicity. These quantities are especially important for both linking an observed MC to its solar source and for understanding the corresponding evolution.

Why Temperature and Velocity have Different Relationships in the Solar Wind and in Interplanetary Coronal Mass Ejections?

P. **Démoulin**¹

E-print, April **2009**; Solar Phys., 257(1), 169 – 184, DOI: 10.1007/s11207-009-9338-5

In-situ observations of the solar wind (SW) show temperature increasing with the wind speed, while such dependence is not observed in interplanetary coronal mass ejections (ICMEs). The aim of this paper is to understand the main origin of this correlation in the SW and its absence in ICMEs. For that purpose both the internal-energy and momentum equations are solved analytically with various approximations. The internal-energy equation does not provide a strong link between temperature and velocity, but the momentum equation does. Indeed, the observed correlation in the open magnetic-field configuration of the SW is the result of its acceleration and heating close to the Sun. In contrast, the magnetic configuration of ICMEs is closed, and moreover the momentum equation is dominated by magnetic forces. It implies no significant correlation between temperature and velocity, as observed.

Causes and consequences of magnetic cloud expansion

P. **Démoulin**¹ and S. Dasso

E-print, March **2009**; A&A, 498, 551–566 (**2009**), DOI: [10.1051/0004-6361/200810971](https://doi.org/10.1051/0004-6361/200810971)

Context. A magnetic cloud (MC) is a magnetic flux rope in the solar wind (SW), which, at 1 AU, is observed \sim 2-5 days after its expulsion from the Sun. The associated solar eruption is observed as a coronal mass ejection (CME).

Aims. Both the in situ observations of plasma velocity distribution and the increase in their size with solar distance demonstrate that MCs are strongly expanding structures. The aim of this work is to find the main causes of this expansion and to derive a model to explain the plasma velocity profiles typically observed inside MCs.

Methods. We model the flux rope evolution as a series of force-free field states with two extreme limits: (a) ideal magnetohydrodynamics (MHD) and (b) minimization of the magnetic energy with conserved magnetic helicity. We consider cylindrical flux ropes to reduce the problem to the integration of ordinary differential equations. This allows us to explore a wide variety of magnetic fields at a broad range of distances to the Sun.

Results. We demonstrate that the rapid decrease in the total SW pressure with solar distance is the main driver of the flux-rope radial expansion. Other effects, such as the internal over-pressure, the radial distribution, and the amount of twist within the flux rope have a much weaker influence on the expansion. We demonstrate that any force-free flux rope will have a self-similar expansion if its total boundary pressure evolves as the inverse of its length to the fourth power. With the total pressure gradient observed in the SW, the radial expansion of flux ropes is close to self-similar with a nearly linear radial velocity profile across the flux rope, as observed. Moreover, we show that the expansion rate is proportional to the radius and to the global velocity away from the Sun.

Conclusions. The simple and universal law found for the radial expansion of flux ropes in the SW predicts the typical size, magnetic structure, and radial velocity of MCs at various solar distances.

Expected *in Situ* Velocities from a Hierarchical Model for Expanding Interplanetary Coronal Mass Ejections

P. **Démoulin** · M.S. Nakwacki · S. Dasso · C.H. Mandrini

Solar Phys (**2008**) 250: 347–374

<http://springerlink.metapress.com/content/e334866jk04n4047/fulltext.pdf>

In situ data provide only a one-dimensional sample of the plasma velocity along the spacecraft trajectory crossing an interplanetary coronal mass ejection (ICME). Then, to understand the dynamics of ICMEs it is necessary to consider some

models to describe it. We derive a series of equations in a hierarchical order, from more general to more specific cases, to provide a general theoretical basis for the interpretation of in situ observations, extending and generalizing previous studies. The main hypothesis is a self-similar expansion, but with the freedom of possible different expansion rates in three orthogonal directions.

Quantitative links between CMEs and magnetic clouds

P. Démoulin

E-print, Sept. 2007, *Ann. Geophys.*, **2008**, 26, 3113, **File**

Magnetic clouds (MCs), and more generally interplanetary coronal mass ejections (ICMEs), are believed to be the interplanetary counterparts of CMEs. The link has usually been shown by taking into account the CME launch position on the Sun, the expected time delay and by comparing the orientation of the coronal and interplanetary magnetic field. Making such a link more quantitative is challenging since it requires the relation of very different kinds of magnetic field measurements: (i) photospheric magnetic maps, which are observed from a distant vantage point (remote sensing) and (ii) in situ measurements of MCs, which provide precise, directly measured, magnetic field data merely from one-dimensional linear samples. The association between events in these different domains can be made using adequate coronal and MC models. Then, global quantities like magnetic fluxes and helicity can be derived and compared. All the associations criteria are reviewed, with a description of the general trends found. A special focus is given on the cases which do not follow the earlier derived mean laws since interesting physics is usually associated to them.

Recent theoretical and observational developments in magnetic helicity studies

Adv. Space Res. 39(11), *Pages 1674-1693*, **2007**

Review

P. Démoulin

Magnetic helicity quantifies how the magnetic field is sheared and twisted compared to its lowest energy state (potential field). Such stressed magnetic fields are usually observed in association with flares, eruptive filaments, and coronal mass ejections (CMEs). Magnetic helicity plays a key role in magnetohydrodynamics because it is almost preserved on a timescale less than the global diffusion time scale. Its conservation defines a constraint to the magnetic field evolution.

Only relatively recently, scientists have realized that magnetic helicity can be computed from observations, and methods have been derived to bridge the gap between theory and observations. At the photospheric level, the rate (or flux) of magnetic helicity can be computed from the evolution of longitudinal magnetograms. The coronal helicity is estimated from magnetic extrapolation, while the helicity ejected in magnetic clouds (interplanetary counter-part of CMEs) is derived through modelling of in situ magnetic field measurements. Using its conserved property, a quantitative link between phenomena observed in the corona and then in the interplanetary medium has been achieved.

<https://arxiv.org/ftp/arxiv/papers/2111/2111.00954.pdf>

We present observations of >10-100 keV/nucleon suprathermal (ST) H, He, O, and Fe ions associated with crossings of the heliospheric current sheet (HCS) at radial distances <0.1 au from the Sun. Our key findings are: 1) very few heavy ions are detected during the 1st full crossing, the heavy ion intensities are reduced during the 2nd partial crossing and peak just after the 2nd crossing; 2) ion arrival times exhibit no velocity dispersion; 3) He pitch-angle distributions track the magnetic field polarity reversal and show up to ~10:1 anti-sunward, field-aligned flows and beams closer to the HCS

that become nearly isotropic further from the HCS; 4) the He spectrum steepens either side of the HCS and the He, O, and Fe spectra exhibit power-laws of the form $\sim E^{-4-6}$; and 5) maximum energies EX increase with the ion's charge-to-mass (Q/M) ratio as EX/EH proportional to $[(QX/MX)]^\alpha$ where $\alpha \sim 0.65-0.76$, assuming that the average Q-states are similar to those measured in gradual and impulsive solar energetic particle events at 1 au. The absence of velocity dispersion in combination with strong field-aligned anisotropies closer to the HCS appears to rule out solar flares and near-sun coronal mass ejection-driven shocks. These new observations present challenges not only for mechanisms that employ direct parallel electric fields and organize maximum energies according to E/Q, but also for local diffusive and magnetic reconnection-driven acceleration models. Re-evaluation of our current understanding of the production and transport of energetic ions is necessary to understand this near-solar, current-sheet-associated population of ST ions. **2021 Jan 17**

Three Dimensional Simulations of Solar Wind Preconditioning and the 23 July 2012 Interplanetary Coronal Mass Ejection

<https://link.springer.com/content/pdf/10.1007/s11207-020-01700-5.pdf>

Predicting the large-scale eruptions from the solar corona and their propagation through interplanetary space remains an outstanding challenge in solar- and helio-physics research. In this article, we describe three dimensional magnetohydrodynamic simulations of the inner heliosphere leading up to and including the extreme interplanetary coronal mass ejection (ICME) of 23 July 2012, developed using the code PLUTO. The simulations are driven using the output of coronal models for Carrington rotations 2125 and 2126 and, given the uncertainties in the initial conditions, are able to reproduce an event of comparable magnitude to the **23 July** ICME, with similar velocity and density profiles at 1 au. The launch-time of this event is then varied with regards to an initial **19 July** ICME and the effects of solar wind preconditioning are found to be significant for an event of this magnitude and to decrease over a time-window consistent with the ballistic refilling of the depleted heliospheric sector. These results indicate that the 23 July ICME was mostly unaffected by events prior, but would have travelled even faster had it erupted closer in time to the 19 July event where it would have experienced even lower drag forces. We discuss this systematic study of solar wind preconditioning in the context of space weather forecasting.

MULTI-SCALE STRUCTURE AND COMPOSITION OF ICME PROMINENCE MATERIAL FROM THE SOLAR WIND ANALYSER SUITE

ApJS **2020**

<https://arxiv.org/pdf/1912.02856.pdf>

One of the most striking observations made by Parker Solar Probe during its first solar encounter is the omnipresence of rapid polarity reversals in a magnetic field that is otherwise mostly radial. These so-called switchbacks strongly affect the dynamics of the magnetic field. We concentrate here on their macroscopic properties. First, we find that these structures are self-similar, and have neither a characteristic magnitude, nor a characteristic duration. Their waiting time statistics shows evidence for aggregation. The associated long memory resides in their occurrence rate, and is not inherent to the background fluctuations. Interestingly, the spectral properties of inertial range turbulence differ inside and outside of switchback structures; in the latter the $1/f$ range extends to higher frequencies. These results suggest that

outside of these structures we are in the presence of lower amplitude fluctuations with a shorter turbulent inertial range. We conjecture that these correspond to a pristine solar wind.

In Situ Observation of Alfvén Waves in an ICME Shock-Sheath Indicating the Existence of Alfvénic Turbulence.

Dhamane, O., Raghav, A., Shaikh, Z. et al.

Sol Phys 299, 29 (2024).

<https://doi.org/10.1007/s11207-024-02271-5>

<https://link.springer.com/content/pdf/10.1007/s11207-024-02271-5.pdf>

The dynamic evolution of a coronal mass ejection (CME) in the interplanetary space generates a highly turbulent, compressed, and heated shock-sheath. This region provides an exceptional setting for investigating the intricate fluctuations occurring at small scales and offers a valuable opportunity to unravel the underlying physical processes responsible for turbulence dissipation and plasma heating. Understanding the role of turbulence in controlling the energy transport process in a magnetized plasma, within space and astrophysics, remains an enticing challenge of the twenty-first century. In this article, we study sheath regions observed by the Wind spacecraft from 1995 to 2021. We find 80 sheath events out of the studied 384 events that show a significant Alfvénic nature ($\approx 21\%$). These fluctuations are interpreted as Alfvénic wave packets propagating either parallel or antiparallel to the background magnetic field, quantified by the normalized crosshelicity (σ_{\diamond}). We find 47 sheath events with outward-propagating Alfvénic fluctuations and 33 events with inward Alfvénic characteristics. The Alfvénic sheaths had a mean value of $\sigma_{\diamond} = 0.46 \pm 0.03$ and -0.43 ± 0.02 for outward- and inward-directed Alfvénic sheaths, respectively. Furthermore, we compare the average interplanetary parameter values of both the Alfvénic sheaths and the ambient solar wind. The study has strong implications in the domain of interplanetary space plasmas, its interaction with planetary plasmas, and astrophysical plasmas.

Observation of Alfvén Ion Cyclotron Waves in ICME Magnetic Clouds at 1 au

Omkar **Dhamane**¹, Vinit Pawaskar¹, Anil Raghav¹, Zubair Shaikh ⁺⁺⁺

2023 ApJ 957 38

<https://iopscience.iop.org/article/10.3847/1538-4357/acf19f/pdf>

Waves in plasma play an essential role in the energy transfer and plasma-heating processes. This article discusses the in situ observation of Alfvén ion cyclotron (AIC) waves and their characteristics within interplanetary coronal mass ejection (ICME) flux ropes. We analyzed 401 ICME flux ropes, observed by WIND spacecraft from 1995 to 2021 at 1 au. We found only five ICME flux ropes that show an explicit presence of AIC waves; two have normalized magnetic helicity $\sigma_m \leq -0.5$, and the remaining three show $\sigma_m \geq 0.5$ polarization. The angle between velocity and magnetic field (θ_{VB}) for $\sigma_m \leq -0.5$ is $< 40^\circ$, whereas for $\sigma_m \geq 0.5$, $\theta_{VB} > 140^\circ$. This result supports the existence of quasi-parallel and quasi-antiparallel left-handed polarized AIC waves within ICME flux ropes. We suggest that AIC waves are possibly triggered by (i) proton temperature anisotropy $T_{p\perp}/T_{p\parallel} > 1$ driven by cyclotron instability and (ii) low-frequency Alfvén waves through the magnetohydrodynamic turbulent cascade. This study shows evidence of fluid and kinetic scales coupling in the ICME flux rope.

Observation of Alfvén wave in ICME-HSS interaction region

Omkar **Dhamane**, [Anil Raghav](#), [Zubair Shaikh](#), [Utsav Panchal](#), [Kalpesh Ghag](#), [Prathmesh Tari](#), [Komal Chorgha](#), [Ankush Bhaskar](#), [Wageesh Mishra](#)

Solar Physics volume 298, Article number: 34 (2023)

<https://arxiv.org/pdf/2209.04682.pdf>

<https://doi.org/10.1007/s11207-023-02127-4>

The Alfvén wave (AW) is the most common fluctuation present within the emitted solar wind from the Sun. Moreover, the interaction between interplanetary coronal mass ejection (ICME) and high-speed stream (HSS) has been observed on several occasions. However, can such interaction generate an AW? What will be the nature of AW in such a scenario remains an open question. To answer it, we have investigated an ICME-HSS interaction event observed on **21st October 1999** at 1 AU by Wind spacecraft. We have used the Walén test to identify AW and estimated Elsasser variables to find the characteristics of the AWs. We explicitly find that ICME were dominant with Sunward AWs, whereas the trailing HSS has strong anti-Sunward AW. We suggest that the ICME-HSS interaction deforms the MC of the ICME, resulting in the AWs inside the MC. In addition, the existence of reconnection within the ICME early stage can also be the leading cause of the origin of AW within it.

Deep learning reconstruction of sunspot vector magnetic fields for forecasting solar storms

Dattaraj B. [Dhuri](#), [Shamik Bhattacharjee](#), [Shravan M. Hanasoge](#), [Sashi Kiran Mahapatra](#)
ApJ **2022**

<https://arxiv.org/pdf/2209.09944.pdf>

Solar magnetic activity produces extreme solar flares and coronal mass ejections, which pose grave threats to electronic infrastructure and can significantly disrupt economic activity. It is therefore important to appreciate the triggers of explosive solar activity and develop reliable space-weather forecasting. Photospheric vector-magnetic-field data capture sunspot magnetic-field complexity and can therefore improve the quality of space-weather prediction. However, state-of-the-art vector-field observations are consistently only available from Solar Dynamics Observatory/Heliioseismic and Magnetic Imager (SDO/HMI) since 2010, with most other current and past missions and observational facilities such as Global Oscillations Network Group (GONG) only recording line-of-sight (LOS) fields. Here, using an inception-based convolutional neural network, we reconstruct HMI sunspot vector-field features from LOS magnetograms of HMI as well as GONG with high fidelity (~ 90% correlation) and sustained flare-forecasting accuracy. We rebuild vector-field features during the 2003 Halloween storms, for which only LOS-field observations are available, and the CNN-estimated electric-current-helicity accurately captures the observed rotation of the associated sunspot prior to the extreme flares, showing a striking increase. Our study thus paves the way for reconstructing three solar cycles worth of vector-field data from past LOS measurements, which are of great utility in improving space-weather forecasting models and gaining new insights about solar activity. **2003-10-26-31**

Backstreaming ions at a high Mach number interplanetary shock Solar Orbiter measurements during the nominal mission phase

A. P. [Dimmock](#)¹, M. Gedalin², A. Lalti^{1,3}, D. Trotta⁴, Yu. V. Khotyaintsev¹, D. B. Graham¹, A. Johlander^{5,1}, R. Vainio⁶, X. Blanco-Cano⁷, P. Kajdič⁷, C. J. Owen⁸ and R. F. Wimmer-Schweingruber⁹
A&A 679, A106 (**2023**)

<https://www.aanda.org/articles/aa/pdf/2023/11/aa47006-23.pdf>

Context. Solar Orbiter, a mission developed by the European Space Agency, explores in situ plasma across the inner heliosphere while providing remote-sensing observations of the Sun. The mission aims to study the solar wind, but also transient structures such as interplanetary coronal mass ejections and stream interaction regions. These structures often contain a leading shock wave that can differ from other plasma shock waves, such as those around planets. Importantly, the Mach number of these interplanetary shocks is typically low (1–3) compared to planetary bow shocks and most astrophysical shocks. However, our shock survey revealed that on **30 October 2021**, Solar Orbiter measured a shock with an Alfvén Mach number above 6, which can be considered high in this context.

Aims. Our study examines particle observations for the **30 October 2021** shock. The particles provide clear evidence of ion reflection up to several minutes upstream of the shock. Additionally, the magnetic and electric field observations contain complex electromagnetic structures near the shock, and we aim to investigate how they are connected to ion dynamics. The main goal of this study is to advance our understanding of the complex coupling between particles and the shock structure in high Mach number regimes of interplanetary shocks.

Methods. We used observations of magnetic and electric fields, probe-spacecraft potential, and thermal and energetic particles to characterize the structure of the shock front and particle dynamics. Furthermore, ion velocity distribution functions were used to study reflected ions and their coupling to the shock. To determine shock parameters and study waves, we used several methods, including cold plasma theory, singular-value decomposition, minimum variance analysis, and shock Rankine-Hugoniot relations. To support the analysis and interpretation of the experimental data, test-particle analysis, and hybrid particle in-cell simulations were used.

Results. The ion velocity distribution functions show clear evidence of particle reflection in the form of backstreaming ions several minutes upstream. The shock structure has complex features at the ramp and whistler precursors. The backstreaming ions may be modulated by the complex shock structure, and the whistler waves are likely driven by gyrating ions in the foot. Supra-thermal ions up to 20 keV were observed, but shock-accelerated particles with energies above this were not.

Modeling the Geomagnetic Response to the September 2017 Space Weather Event Over Fennoscandia Using the Space Weather Modeling Framework: Studying the Impacts of Spatial Resolution

A. P. [Dimmock](#), [D. T. Welling](#), [L. Rosenqvist](#), [C. Forsyth](#), [M. P. Freeman](#), [I. J. Rae](#), [A. Viljanen](#), [E. Vandegriff](#), [R. J. Boynton](#), [M. A. Balikhin](#), [E. Yordanova](#)

Space Weather [Volume19, Issue5](#) May **2021** e2020SW002683

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2020SW002683>

<https://doi.org/10.1029/2020SW002683>

We must be able to predict and mitigate against geomagnetically induced current (GIC) effects to minimize socio-economic impacts. This study employs the space weather modeling framework (SWMF) to model the geomagnetic response over Fennoscandia to the September 7–8, 2017 event. Of key importance to this study is the effects of spatial resolution in terms of regional forecasts and improved GIC modeling results. Therefore, we ran the model at comparatively low, medium, and high spatial resolutions. The virtual magnetometers from each model run are compared with observations from the IMAGE magnetometer network across various latitudes and over regional-scales. The virtual magnetometer data from the SWMF are coupled with a local ground conductivity model which is used to calculate the geoelectric field and estimate GICs in a Finnish natural gas pipeline. This investigation has led to several important results in which higher resolution yielded: (1) more realistic amplitudes and timings of GICs, (2) higher amplitude geomagnetic disturbances across latitudes, and (3) increased regional variations in terms of differences between stations. Despite this, substorms remain a significant challenge to surface magnetic field prediction from global magnetohydrodynamic modeling. For example, in the presence of multiple large substorms, the associated large-amplitude depressions were not captured, which caused the largest model-data deviations. The results from this work are of key importance to both modelers and space weather operators. Particularly when the goal is to obtain improved regional forecasts of geomagnetic disturbances and/or more realistic estimates of the geoelectric field. **7-8 Sep 2017**

Anomalous dynamics of the extremely compressed magnetosphere during 21 January 2005 magnetic storm

A. V. **Dmitriev**, A. V. Suvorova, J.-K. Chao, C. B. Wang, L. Rastaetter, M. I. Panasyuk, L. L. Lazutin, A. S. Kovtyukh, I. S. Veselovsky and I. N. Myagkova

JGR, Volume 119, Issue 2, pages 877–896, February **2014**

The dayside magnetosphere and proton radiation belt were analyzed during unusual magnetic storm on **21 January 2005**. We have found that from 1712 to 2400 UT, the subsolar magnetopause was continuously located inside geosynchronous orbit due to strong compression. The compression was extremely strong from 1846 to 2035 UT when the dense plasma of fast erupting filament produced the solar wind dynamic pressure that peaked up to > 100 nPa, and during the first time, the upstream solar wind was observed at geosynchronous orbit for almost 2 h. Under the extreme compression, the outer magnetosphere at $L > 5$ was pushed inward, and the outer radiation belt particles moved earthward, became adiabatically accelerated, and accumulated in the inner magnetosphere at $L < 4$ that produced the intensified ring current with an exceptionally long lifetime. The observations were compared with predictions of various empirical and first-principles models. All the models failed to predict the magnetospheric dynamics under the extreme compression when the minimal magnetopause distance was estimated to be ~ 3 RE. The inconsistencies might result from distortions of plasma measurements by extreme heliospheric conditions consisting in very fast solar wind streams and intense fluxes of solar energetic particles. We speculated that anomalous dynamics of the magnetosphere could be well described by the models if the He abundance in the solar wind was assumed to be $> 20\%$, which is well appropriate for erupting filaments and which is in agreement with the upper 27% threshold for the He/H ratio obtained from Cluster measurements.

Interplanetary sources of space weather disturbances in 1997 to 2000,

Dmitriev, A. V., N. B. Crosby, and J.-K. Chao; **File**

(**2005**), *Space Weather*, 3, S03001, doi:10.1029/2004SW000104.

Seventy-five disturbed intervals from 1997 through 2000 were analyzed and selected on the basis of space weather effect occurrences such as significant compression of the dayside magnetosphere, strong magnetic storms, ionospheric perturbations, relativistic electron enhancements, and increases in the rate of data failures and radiation doses on board the Mir station. Solar wind disturbances were considered as the main factor influencing the Earth's magnetosphere. We distinguished four geoeffective interplanetary (IP) phenomena: interplanetary coronal mass ejections (ICME), interplanetary forward shocks with compressed region (IS), fast solar wind streams from coronal holes (CH), and corotating interaction regions (CIR) between the CH and relatively slow ambient solar wind. Each selected interval was studied and classified under the IP phenomena that it was a direct consequence of. It was found that IP phenomena “containing” ISs, ICMEs, and CIRs were mostly responsible for geosynchronous magnetopause crossings, strong geomagnetic storms, and intensification of geomagnetically induced currents. The fast solar wind streams from coronal holes controlled mainly geosynchronous relativistic electron enhancements. The rate of data failures and variations of the radiation dose on board the Mir station were related to both IS-ICME and CIR-CH phenomena. Such a relationship was interpreted in terms of (1) decrease of cutoff

threshold for solar energetic particles due to the magnetospheric compression and/or ring current intensification on the main phase of geomagnetic storms and (2) intensive relativistic electron precipitation from the outer radiation belt and its contribution to the radiation conditions at low altitudes during recovery phase of recurrent magnetic storms.

Mapping the solar wind HI outflow velocity in the inner heliosphere by coronagraphic ultraviolet and visible-light observations★

A&A 612, A84 (2018)

<http://sci-hub.tw/https://www.aanda.org/articles/aa/abs/2018/04/aa32118-17/aa32118-17.html>

We investigated the capability of mapping the solar wind outflow velocity of neutral hydrogen atoms by using synergistic visible-light and ultraviolet observations. We used polarised brightness images acquired by the LASCO/SOHO and Mk3/MLSO coronagraphs, and synoptic Ly α line observations of the UVCS/SOHO spectrometer to obtain daily maps of solar wind H I outflow velocity between 1.5 and 4.0 R \odot on the SOHO plane of the sky during a complete solar rotation (from 1997 June 1 to 1997 June 28). The 28-days data sequence allows us to construct coronal off-limb Carrington maps of the resulting velocities at different heliocentric distances to investigate the space and time evolution of the outflowing solar plasma. In addition, we performed a parameter space exploration in order to study the dependence of the derived outflow velocities on the physical quantities characterising the Ly α emitting process in the corona. Our results are important in anticipation of the future science with the Metis instrument, selected to be part of the Solar Orbiter scientific payload. It was conceived to carry out near-sun coronagraphy, performing for the first time simultaneous imaging in polarised visible-light and ultraviolet H I Ly α line, so providing an unprecedented view of the solar wind acceleration region in the inner corona.

A Machine Learning and Computer Vision Approach to Geomagnetic Storm Forecasting

Geomagnetic storms, disturbances of Earth's magnetosphere caused by masses of charged particles being emitted from the Sun, are an uncontrollable threat to modern technology. Notably, they have the potential to damage satellites and cause instability in power grids on Earth, among other disasters. They result from high sun activity, which are induced from cool areas on the Sun known as sunspots. Forecasting the storms to prevent disasters requires an understanding of how and when they will occur. However, current prediction methods at the National Oceanic and Atmospheric Administration (NOAA) are limited in that they depend on expensive solar wind spacecraft and a global-scale magnetometer sensor network. In this paper, we introduce a novel machine learning and computer vision approach to accurately forecast geomagnetic storms without the need of such costly physical measurements. Our approach extracts features from images of the Sun to establish correlations between sunspots and geomagnetic storm classification and is competitive with NOAA's predictions. Indeed, our prediction achieves a 76% storm classification accuracy. This paper serves as an existence proof that machine learning and computer vision techniques provide an effective means for augmenting and improving existing geomagnetic storm forecasting methods.

Space weather and dangerous phenomena on the Earth: principles of great geomagnetic storms forecasting by online cosmic ray data

L. I. [Dorman](#)

[Nuclear Physics B - Proceedings Supplements](#) Volume 39, Issue 1, February 1995, Pages 136-143

It is well known that big geomagnetic storms have an adverse influence on technological devices and radio wave propagation. Major geomagnetic storms, associated with Forbush decreases (FDs) in cosmic ray (CR) intensity, have also been found to increase the incidence of some diseases (in particular, the frequency of myocardial infarction increases by $13 \pm 1.4\%$). We discuss here three phenomena that can be used for forecasting FDs: 1) CR intensity

increase, of non solar-flare origin, occurring before sudden commencement of a major geomagnetic storm connected with FD (preincrease effect), 2) CR intensity decrease before FD (predecrease effect), 3) change in CR fluctuations before FD. First we investigate several such events by the global survey method for the years 1989–1991. We analyse the behaviour of the isotropic CR intensity and of the 3-dimensional vector of CR anisotropy before FDs, as well as results on CR scintillation of 1-hour and 5-minute data. We discuss a possible procedure of data treatment for future FD-forecasting analyses.

On 17 and 22 January 2005 Events in Space Weather

Dorotovič, I., Kudela, K., Lorenc, M., & Rybanský, M.

2008a, *Solar Phys.*, 250, 339-346

<https://doi.org/10.1007/s11207-008-9222-8>

<https://link.springer.com/content/pdf/10.1007/s11207-008-9222-8.pdf>

This contribution is a follow-up to the recent paper of Kuznetsov et al. (Contrib. Astron. Obs. Skalnaté Pleso36, 85, 2006) on the ground level enhancement (GLE) on 20 January 2005. We focused on a study of Forbush decrease (FD) of 17 - 18 and 21 - 22 January 2005, respectively. The data from the neutron monitor at Lomnický Štít (1 min counts) and from the Geomagnetic Observatory in Hurbanovo, both in Slovakia, were used as the basis for our investigation. The data on magnetic field and solar wind from GOES 10 and 12, SOHO-CELIAS, ACE and WIND satellites were used for better understanding of the global evolution of the event. The magnetic field is transformed to the RTN (Radial - Tangential - Normal) system where only the disturbed part of the field is compared, i.e., daily variations and a constant part are subtracted. The field reduction method is described. Our results are temporal vector diagrams of variation of all parameters at all positions from where we used the data. The amplitudes of $|B|$ exceed 100 nT and variations during the arrival of the wavefront of CME take place simultaneously at the ground-based station and at GOES satellites. The character of the variations is as if there would be regions with the dominant electric charge of opposite signs, or electric currents with different orientations in the CME. On the basis of the values v_p and n_p and using certain assumptions we determined the mass of CME on 17 January and 21 January, respectively, of 1012 kg. A decrease of the cosmic ray level runs suddenly (during 10 minutes), starting, however, about two hours after a sudden change of the magnetic field.

Magnetic Lasso: A New Kinematic Solar Wind Propagation Method

M. **Dósa**, A. Opitz, Z. Dály, K. Szegő

Solar Physics September 2018, 293:127

<https://link.springer.com/content/pdf/10.1007%2Fs11207-018-1340-3.pdf>

Solar wind propagation from the point of measurement to an arbitrary target in the heliosphere is an important input for heliospheric, planetary and cometary studies. In this paper a new kinematic propagation method, the magnetic lasso method is presented. Compared to the simple ballistic approach our method is based on reconstructing the ideal Parker spiral connecting the target with the Sun by testing a previously defined range of heliographic longitudes. The model takes into account the eventual evolution of stream-stream interactions and handles these with a simple model based on the dynamic pressure difference between the two streams. Special emphasis is given to input data cleaning by handling interplanetary coronal mass ejection events as data gaps due to their different propagation characteristics. The solar wind bulk velocity is considered radial and constant. Density and radial magnetic field are propagated by correcting with the inverse square of the radial distance. The model has the advantage that it can be coded easily and fitted to the problem; it is flexible in selecting and handling input data and requires little running time.

Long-term Longitudinal Recurrences of the Open Magnetic Flux Density in the Heliosphere

M. **Dósa** and G. Erdős

2017 ApJ 838 104

<http://iopscience.iop.org/article/10.3847/1538-4357/aa657b/pdf>

<http://iopscience.iop.org/sci-hub.cc/0004-637X/838/2/104/>

Open magnetic flux in the heliosphere is determined from the radial component of the magnetic field vector measured onboard interplanetary space probes. Previous Ulysses research has shown remarkable independence of the flux density from heliographic latitude, explained by super-radial expansion of plasma. Here we are investigating whether any longitudinal variation exists in the 50 year long OMNI magnetic data set. The heliographic longitude of origin of the plasma package was determined by applying a correction according to the solar wind travel time. Significant recurrent enhancements of the magnetic flux density were observed throughout solar cycle 23, lasting for several years. Similar, long-lasting recurring features were observed in the solar wind velocity, temperature and the deviation angle of the solar

wind velocity vector from the radial direction. Each of the recurrent features has a recurrence period slightly differing from the Carrington rotation rate, although they show a common trend in time. Examining the coronal temperature data of ACE leads to the possible explanation that these long-term structures are caused by slow-fast solar wind interaction regions. A comparison with MESSENGER data measured at 0.5 au shows that these longitudinal magnetic modulations do not exist closer to the Sun, but are the result of propagation.

Are switchbacks signatures of magnetic flux ropes generated by interchange reconnection in the corona?

A&A **2020**

<https://arxiv.org/pdf/2009.05645.pdf>

The structure of magnetic flux ropes injected into the solar wind during reconnection in the coronal atmosphere is explored with particle-in-cell simulations and compared with *in situ* measurements of magnetic "switchbacks" from the Parker Solar Probe. We suggest that multi-x-line reconnection between open and closed flux in the corona will inject flux ropes into the solar wind and that these flux ropes can convect outward over long distances before disintegrating. Simulations that explore the magnetic structure of flux ropes in the solar wind reproduce key features of the "switchback" observations: a rapid rotation of the radial magnetic field into the transverse direction (a consequence of reconnection with a strong guide field); and the potential to reverse the radial field component. The potential implication of the injection of large numbers of flux ropes in the coronal atmosphere for understanding the generation of the solar wind is discussed. **Nov. 5, 2018**

Efficiency of particle acceleration at interplanetary shocks: Statistical study of STEREO observations

N. [Dresing](#), S. Theesen, A. Klassen and B. Heber

A&A 588, A17 (2016)

<https://www.aanda.org/articles/aa/pdf/2016/04/aa27853-15.pdf>

doi:10.1051/0004-6361/201527853

Context. Among others, shocks are known to be accelerators of energetic charged particles. However, many questions regarding the acceleration efficiency and the required conditions are not fully understood. In particular, the acceleration of electrons by shocks is often questioned.

Aims. In this study we determine the efficiency of interplanetary shocks for <100 keV electrons, and for ions at ~0.1 and ~2 MeV energies, as measured by the Solar Electron and Proton Telescope (SEPT) instruments aboard the twin Solar Terrestrial Relations Observatory (STEREO) spacecraft.

Methods. We employ an online STEREO *in situ* shock catalog that lists all shocks observed between 2007 and mid 2014 (observed by STEREO A) and until end of 2013 (observed by STEREO B). In total 475 shocks are listed. To determine the particle acceleration efficiency of these shocks, we analyze the associated intensity increases (shock spikes) during the shock crossings. For the near-relativistic electrons, we take into account the issue of possible ion contamination in the SEPT instrument.

Results. The highest acceleration efficiency is found for low energy ions (0.1 MeV), which show a shock-associated increase at 27% of all shocks. The 2 MeV ions show an associated increase only during 5% of the shock crossings. In the case of the electrons, the shocks are nearly ineffective. Only five shock-associated electron increases were found, which correspond to only 1% of all shock crossings.

Injection of solar energetic particles into both loop legs of a magnetic cloud

Nina [Dresing](#), Raquel Gómez-Herrero, Bernd Heber, Miguel Angel Hidalgo, Andreas Klassen, Manuela Temmer, Astrid Veronig

A&A **2016**

<http://arxiv.org/pdf/1601.00491v1.pdf>

Context. Each of the two Solar Terrestrial Relations Observatory (STEREO) spacecraft carries a Solar Electron and Proton Telescope (SEPT) which measures electrons and protons. Anisotropy observations are provided in four viewing directions: along the nominal magnetic field Parker spiral in the ecliptic towards the Sun (SUN) and away from the Sun (Anti-Sun / ASUN), and towards the north (NORTH) and south (SOUTH). The solar energetic particle (SEP) event on 7 November 2013 was observed by both STEREO spacecraft, which were longitudinally separated by 68° at that time. While STEREO A observed the expected characteristics of an SEP event at a well-connected position, STEREO B

detected a very anisotropic bi-directional distribution of near-relativistic electrons and was situated inside a magnetic-cloud-like structure during the early phase of the event.

Aims. We examine the source of the bi-directional SEP distribution at STEREO B. On the one hand this distribution could be caused by a double injection into both loop legs of the magnetic cloud (MC). On the other hand, a mirroring scenario where the incident beam is reflected in the opposite loop leg could be the reason. Furthermore, the energetic electron observations are used to probe the magnetic structure inside the magnetic cloud.

Methods. We investigate in situ plasma and magnetic field observations and show that STEREO B was embedded in an MC-like structure ejected three days earlier on **4 November** from the same active region. We apply a Graduated Cylindrical Shell (GCS) model to the coronagraph observations from three viewpoints as well as the Global Magnetic Cloud (GMC) model to the in situ measurements at STEREO B to determine the orientation and topology of the MC close to the Sun and at 1 AU. We also estimate the path lengths of the electrons propagating through the MC to estimate the amount of magnetic field line winding inside the structure.

Results. The relative intensity and timing of the energetic electron increases in the different SEPT telescopes at STEREO B strongly suggest that the bi-directional electron distribution is formed by SEP injections in both loop legs of the MC separately instead of by mirroring farther away beyond the STEREO orbit. Observations by the Nancay Hadioheliograph (NRH) of two distinct radio sources during the SEP injection further support the above scenario. The determined electron path lengths are around 50% longer than the estimated lengths of the loop legs of the MC itself (based on the GCS model) suggesting that the amount of field line winding is moderate.

The correlation between solar and geomagnetic activity – Part 3: An integral response model

Z. L. Du

Ann. Geophys., 29, 1005-1018, 2011

An integral response model is proposed to describe the relationship between geomagnetic activity (aa index) and solar activity (represented by sunspot number R_z): The aa at a given time t is the integral of R_z at past times ($t' \leq t$) multiplied by an exponential decay factor of the time differences ($e^{-(t-t')/\tau}$), where τ is the decay time scale (~40 months). The correlation coefficient of aa with the reconstructed series based on this model ($r_f=0.85$) is much higher than that of aa with R_z ($r_0=0.61$). If this model is applied to each solar cycle, the correlation coefficient will be higher ($r_f=0.95$). This model can naturally explain some phenomena related to aa and R_z , such as (i) the significant increase in the aa index (and its baseline) over the twentieth century; (ii) the longer lag times of aa to R_z at solar cycle maxima than at minima; and (iii) the variations in the correlations related to solar and Hale cycles. These results demonstrate that aa depends not only on the present R_z but also on past values. The profile of aa can be better predicted from R_z by this model than by point-point correspondence.

Interplanetary Coronal Mass Ejections Observed by *Ulysses* Through Its Three Solar Orbits

D. Du · P.B. Zuo · X.X. Zhang

Solar Phys (2010) 262: 171–190

<https://sci-hub.ru/10.1007/s11207-009-9505-8>

An extended *Ulysses* interplanetary coronal mass ejections (ICMEs) list is used to statistically study the occurrence rate of ICMEs, the interaction of ICMEs with solar wind, and the magnetic field properties in ICMEs. About 43% of the ICMEs are identified as magnetic clouds (MCs). It is found that the occurrence rate of ICMEs approximately follows the solar activity level, except for the second solar orbit; the rate is higher in the southern heliolatitude than in the northern heliolatitude; and it roughly decreases with the increase of ICME speeds. Our results show that the speed difference between the ICME and the solar wind in front of it shows a slight decrease with increasing heliocentric distance for ICMEs preceded by a shock, whereas no such dependence is found for the ICMEs without shock association. It is also found that approximately 23% of the ICMEs are associated with radial field events, in which the interplanetary magnetic field with near-radial direction lasts for many hours, in the *Ulysses* detected range, and these associated events are not necessarily confined to fast ICMEs or the trailing portions of ICMEs. Nearly all these associated events occur during the period of declining solar wind speed and most of them occur at low heliolatitudes.

Anomalous geomagnetic storm of 21–22 January 2005: a storm main phase during northward IMFs.

Du, A.M., Tsurutani, B.T., Sun, W.,

2008. J. Geophys. Res. 113, A10214. doi:10.1029/2008JA013284.

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2008JA013284>

The major (minimum Dst = -105 nT) magnetic storm which occurred on **21–22 January 2005** is highly anomalous because the storm main phase (identified by the SYM-H indices) developed during northward interplanetary magnetic fields (IMFs). We believe this to be the first event of its type to be reported in the literature. Interplanetary ACE and Cluster C1 data are used for solar wind diagnostics, and LANL 90 and 97, GOES 10 and 12 and GEOTAIL data are used for magnetospheric diagnostics. An unusually strong (magnetosonic Mach number equal to 5.4) shock detected at ~1647 UT, 21 January 2005 by ACE causes a SI+ (of 57 nT) at ~1712 UT at Earth. Southward magnetic fields in the sheath following the shock caused a decrease of SYM-H with a peak value ~-41 nT. A dynamic pressure jump across a double discontinuity in the solar wind at 1823 UT observed by ACE induced a second SI+ (of 25 nT) at 1847 UT at Earth. Southward magnetic fields following this event led to a second SYM-H decrease with peak intensity -2 nT. However, when the storm main phase developed starting at 1946 UT, the IMF Bz turned northward. The IMF was northward from the portion of the main phase from ~1946 UT to 0124 UT (almost 6 h). By comparing solar wind energy input (represented by integrated interplanetary E_y) with accumulated energy in the ring current (represented by integrated SYM-H), we arrive at a possible explanation that there is first energy storage in the magnetotail and then a delayed energy injection (after storage in the magnetotail) into the magnetosphere. Other interpretations/mechanisms are possible.

CME Deflection and East-West Asymmetry of Energetic Storm Particle Intensity during Solar Cycles 23 and 24

A. Santa Fe **Dueñas**^{1,2}, R. W. Ebert^{1,2}, Gang Li³, Zheyi Ding⁴, M. A. Dayeh^{1,2}, M. I. Desai^{1,2}, and L. K. Jian⁵

ApJ **2024**

<https://arxiv.org/pdf/2404.01993.pdf>

We investigate the East-West asymmetry in energetic storm particle (ESP) heavy ion intensities at interplanetary shocks driven by coronal mass ejections (CMEs) during solar cycles (SCs) 23 and 24. We use observations from NASA's ACE and STEREO missions of helium (He), oxygen (O), and iron (Fe) intensities from ~0.13 to 3 MeV/nucleon. We examine the longitudinal distribution of ESP intensities and the correlation of ESP intensities with the near-Sun CME speed and the average transit CME speed for eastern and western events. We observed an East-West asymmetry reversal of ESP heavy ion intensities from SC 23 to 24. We have determined that this change in asymmetry is caused by a shift in the heliolongitude distribution of the CME speed ratio (the ratio of CME near-Sun speed to CME average transit speed) from west to east. **November 10 and 11, 2012**

Comparing Energetic Storm Particle Heavy-ion Properties in Solar Cycles 23 and 24

A. Santa Fe **Dueñas**^{1,2}, R. W. Ebert^{1,2}, M. A. Dayeh^{1,2}, M. I. Desai^{1,2}, L. K. Jian³, and G. Li⁴
2023 ApJ 953 176

<https://iopscience.iop.org/article/10.3847/1538-4357/acdede/pdf>

We examine variations in energetic storm particle (ESP) heavy-ion average intensities and energy spectra between ~0.1 and 75 MeV nucleon⁻¹ at coronal mass ejection (CME)-driven interplanetary shocks for events observed at the ACE spacecraft. We compare ESP events observed during the weaker solar cycle (SC) 24 and the relatively stronger SC 23 to investigate any effects on the strength of an SC, including the associated transient events, on ESP properties at 1 au. We find that the number of clearly defined heavy-ion ESP events at ACE during SC 23 is about twice that observed during SC 24 (76 versus 41). The average transit speed of the driving interplanetary CMEs (ICMEs) at 1 au is 20% higher during SC 23 than during SC 24 (859.4 km s⁻¹ versus 729.1 km s⁻¹). The correlation of ESP average intensities with ICME speeds shows that lower-speed ICMEs in SC 24 can be as efficient as the higher-speed events in SC 23 at producing ESPs below 2 MeV nucleon⁻¹. The distribution and magnitude of the average intensities for energies below ~1 MeV nucleon⁻¹ are consistent between both SCs. However, events with intensity enhancements at higher energies (>~10 MeV nucleon⁻¹) are more frequent and their intensity distributions are harder for SC 23, resulting in an increase in the rollover energy (E₀) for their spectra profiles. This suggests more efficient ESP acceleration at >10 MeV nucleon⁻¹ during SC 23. **2005 September 15**

Table 1. List of ESP Events Used in This Study, Including the Shock Arrival Time, the Average Intensity at 0.1365 MeV nucleon⁻¹, the Spectral Index (γ), and the e-folding Energy (E₀) for He, O, and Fe 1998-2017

Dependence of Energetic Storm Particle Heavy Ion Peak Intensities and Spectra on Source CME Longitude and Speed

A. Santa Fe **Dueñas**^{1,2}, R. W. Ebert^{1,2}, M. A. Dayeh^{1,2}, M. I. Desai^{1,2}, L. K. Jian³, G. Li⁴, and C. W. Smith⁵

2022 ApJ 935 32

<https://iopscience.iop.org/article/10.3847/1538-4357/ac73f5/pdf>

We examine variations in energetic storm particle (ESP) heavy ion peak intensities and energy spectra at CME-driven interplanetary shocks. We focus on their dependence with heliolongitude relative to the source region of their associated CMEs, and with CME speed, for events observed in Solar Cycle 24 at the STEREO-A, STEREO-B, and/or ACE spacecraft. We find that observations of ESP events at 1 au are organized by longitude relative to their CME solar source. The ESP event longitude distribution also showed organization with CME speed. The near-Sun CME speeds (V_i) for these events ranged from ~ 560 to 2650 km s^{-1} while the average CME transit speeds to 1 au were significantly slower. The angular width of the events had a clear threshold at V_i of $\sim 1300 \text{ km s}^{-1}$, above which events showed significantly larger angular extension compared to events with speeds below. High-speed events also showed larger heavy ion peak intensities near the nose of the shock compared to the flanks while their spectral index was smaller near the nose and larger near the flanks. This organization for events with $V_i < 1300 \text{ km s}^{-1}$ was not as clear. These ESP events were observed over a narrower range of longitudes though the heavy ion peak intensities still appeared largest near the nose of the shock. Their heavy ion spectra showed no clear organization with longitude. These observations highlight the impact of spacecraft position relative to the CME source longitude and V_i on the properties of ESP events at 1 au. **28 Nov 2011**

A new method of measuring Forbush decreases

M. [Dumbovic](#), [L. Kramaric](#), [I. Benko](#), [B. Heber](#), [B. Vrsnak](#)

A&A 683, A168 (2024)

<https://arxiv.org/pdf/2401.09000.pdf>

Forbush decreases (FDs) are short-term depressions in the galactic cosmic ray flux and one of the common signatures of coronal mass ejections (CMEs) in the heliosphere. They often show a two-step profile, the second one associated with the CMEs magnetic structure (flux rope, FR), which can be described by the recently developed model ForbMod. The aim of this study is to utilise ForbMod to develop a best-fit procedure to be applied on FR-related FDs as a convenient measurement tool. We develop a best-fit procedure that can be applied to a data series from an arbitrary detector. Thus, the basic procedure facilitates measurement estimation of the magnitude of the FR-related FD, with the possibility of being adapted for the energy response of a specific detector for a more advanced analysis. The non-linear fitting was performed by calculating all possible ForbMod curves constrained within the FR borders to the designated dataset and minimising the mean square error (MSE). In order to evaluate the performance of the ForbMod best-fit procedure, we used synthetic measurements produced by calculating the theoretical ForbMod curve for a specific example CME and then applying various effects to the data to mimic the imperfection of the real measurements. We also tested the ForbMod best-fit function on the real data, measured by detector F of the SOHO-EPHIN instrument on a sample containing 30 events, all of which have a distinct FD corresponding to the CMEs magnetic structure. Overall, we find that the ForbMod best-fit procedure performs similar to the traditional algorithm-based observational method, but with slightly smaller values for the FD amplitude, as it is taking into account the noise in the data. Furthermore, we find that the best-fit procedure has an advantage compared to the traditional method as it can estimate the FD amplitude even when there is a data gap at the onset of the FD.

Generic profile of a long-lived corotating interaction region and associated recurrent Forbush decrease

M. [Dumbović](#)¹, [B. Vršnak](#)¹, [M. Temmer](#)², [B. Heber](#)³ and [P. Kùhl](#)³

A&A 658, A187 (2022)

<https://www.aanda.org/articles/aa/pdf/2022/02/aa40861-21.pdf>

<https://doi.org/10.1051/0004-6361/202140861>

Context. Corotating interaction regions (CIRs), formed by the interaction of slow solar wind and fast streams that originate from coronal holes (CHs), produce recurrent Forbush decreases, which are short-term depressions in the galactic cosmic ray (GCR) flux.

Aims. Our aim is to prepare a reliable set of CIR measurements to be used as a textbook for modeling efforts. For that purpose, we observe and analyse a long-lived CIR, originating from a single CH, recurring in 27 consecutive Carrington rotations 2057–2083 in the time period from June 2007–May 2009.

Methods. We studied the in situ measurements of this long-lived CIR as well as the corresponding depression in the cosmic ray (CR) count observed by SOHO/EPHIN throughout different rotations. We performed a statistical analysis, as

well as the superposed epoch analysis, using relative values of the key parameters: the total magnetic field strength, B, the magnetic field fluctuations, dBrms, plasma flow speed, v, plasma density, n, plasma temperature, T, and the SOHO/EPHIN F-detector particle count, and CR count.

Results. We find that the mirrored CR count-time profile is correlated with that of the flow speed, ranging from moderate to strong correlation, depending on the rotation. In addition, we find that the CR count dip amplitude is correlated to the peak in the magnetic field and flow speed of the CIR. These results are in agreement with previous statistical studies. Finally, using the superposed epoch analysis, we obtain a generic CIR example, which reflects the in situ properties of a typical CIR well.

Conclusions. Our results are better explained based on the combined convection-diffusion approach of the CIR-related GCR modulation. Furthermore, qualitatively, our results do not differ from those based on different CHs samples. This indicates that the change of the physical properties of the recurring CIR from one rotation to another is not qualitatively different from the change of the physical properties of CIRs originating from different CHs. Finally, the obtained generic CIR example, analyzed on the basis of superposed epoch analysis, can be used as a reference for testing future models.

Drag-based model (DBM) tools for forecast of coronal mass ejection arrival time and speed

Review

Mateja **Dumbovic**, [Jasa Calogovic](#), [Karmen Martinic](#), [Bojan Vrsnak](#), [Davor Sudar](#), [Manuela Temmer](#), [Astrid Veronig](#)

Frontiers March 24th 2021

<https://arxiv.org/pdf/2103.14292.pdf>

Forecasting the arrival time of CMEs and their associated shocks is one of the key aspects of space weather research. One of the commonly used models is, due to its simplicity and calculation speed, the analytical drag-based model (DBM) for heliospheric propagation of CMEs. DBM relies on the observational fact that slow CMEs accelerate whereas fast CMEs decelerate, and is based on the concept of MHD drag, which acts to adjust the CME speed to the ambient solar wind. Although physically DBM is applicable only to the CME magnetic structure, it is often used as a proxy for the shock arrival. In recent years, the DBM equation has been used in many studies to describe the propagation of CMEs and shocks with different geometries and assumptions. Here we give an overview of the five DBM versions currently available and their respective tools, developed at Hvar Observatory and frequently used by researchers and forecasters. These include: 1) basic 1D DBM, a 1D model describing the propagation of a single point (i.e. the apex of the CME) or concentric arc (where all points propagate identically); 2) advanced 2D self-similar cone DBM, a 2D model which combines basic DBM and cone geometry describing the propagation of the CME leading edge which evolves self-similarly; 3) 2D flattening cone DBM, a 2D model which combines basic DBM and cone geometry describing the propagation of the CME leading edge which does not evolve self-similarly; 4) DBEM, an ensemble version of the 2D flattening cone DBM which uses CME ensembles as an input and 5) DBEMv3, an ensemble version of the 2D flattening cone DBM which creates CME ensembles based on the input uncertainties. All five versions have been tested and published in recent years and are available online or upon request. We provide an overview of these five tools, of their similarities and differences, as well as discuss and demonstrate their application. **April 3rd 2010**

Drag-based model (DBM) tools for forecast of coronal mass ejection arrival time and speed

Review

Mateja **Dumbovic**, [Jasa Calogovic](#), [Karmen Martinic](#), [Bojan Vrsnak](#), [Davor Sudar](#), [Manuela Temmer](#), and [Astrid Veronig](#)

Front. Astron. Space Sci., 8:639986 2021 |

<https://www.frontiersin.org/articles/10.3389/fspas.2021.639986/full>

Forecasting the arrival time of coronal mass ejections (CMEs) and their associated shocks is one of the key aspects of space weather research. One of the commonly used models is the analytical drag-based model (DBM) for heliospheric propagation of CMEs due to its simplicity and calculation speed. The DBM relies on the observational fact that slow CMEs accelerate whereas fast CMEs decelerate and is based on the concept of magnetohydrodynamic (MHD) drag, which acts to adjust the CME speed to the ambient solar wind. Although physically DBM is applicable only to the CME magnetic structure, it is often used as a proxy for shock arrival. In recent years, the DBM equation has been used in many studies to describe the propagation of CMEs and shocks with different geometries and assumptions. In this study, we provide an overview of the five DBM versions currently available and their respective tools, developed at Hvar Observatory and frequently used by researchers and forecasters (1) basic 1D DBM, a 1D model describing the

propagation of a single point (i.e., the apex of the CME) or a concentric arc (where all points propagate identically); (2) advanced 2D self-similar cone DBM, a 2D model which combines basic DBM and cone geometry describing the propagation of the CME leading edge which evolves in a self-similar manner; (3) 2D flattening cone DBM, a 2D model which combines basic DBM and cone geometry describing the propagation of the CME leading edge which does not evolve in a self-similar manner; (4) DBEM, an ensemble version of the 2D flattening cone DBM which uses CME ensembles as an input; and (5) DBEMv3, an ensemble version of the 2D flattening cone DBM which creates CME ensembles based on the input uncertainties. All five versions have been tested and published in recent years and are available online or upon request. We provide an overview of these five tools, as well as of their similarities and differences, and discuss and demonstrate their application. **April 3, 2010**

Evolution of coronal mass ejections and the corresponding Forbush decreases: modelling vs multi-spacecraft observations

One of the very common in situ signatures of interplanetary coronal mass ejections (ICMEs), as well as other interplanetary transients, are Forbush decreases (FDs), i.e. short-term reductions in the galactic cosmic ray (GCR) flux. A two-step FD is often regarded as a textbook example, which presumably owes its specific morphology to the fact that the measuring instrument passed through the ICME head-on, encountering first the shock front (if developed), then the sheath and finally the CME magnetic structure. The interaction of GCRs and the shock/sheath region, as well as the CME magnetic structure, occurs all the way from Sun to Earth, therefore, FDs are expected to reflect the evolutionary properties of CMEs and their sheaths. We apply modelling to different ICME regions in order to obtain a generic two-step FD profile, which qualitatively agrees with our current observation-based understanding of FDs. We next adapt the models for energy dependence to enable comparison with different GCR measurement instruments (as they measure in different particle energy ranges). We test these modelling efforts against a set of multi-spacecraft observations of the same event, using the Forbush decrease model for the expanding flux rope (ForbMod). We find a reasonable agreement of the ForbMod model for the GCR depression in the CME magnetic structure with multi-spacecraft measurements, indicating that modelled FDs reflect well the CME evolution. **2014 February 12-15**

Unusual plasma and particle signatures at Mars and STEREO-A related to CME-CME interaction

<https://arxiv.org/pdf/1906.02532.pdf>

On **July 25 2017** a multi-step Forbush decrease (FD) with the remarkable total amplitude of more than 15% was observed by MSL/RAD at Mars. We find that these particle signatures are related to very pronounced plasma and magnetic field signatures detected in situ by STEREO-A on July 24 2017, with a higher than average total magnetic field strength reaching more than 60 nT. In the observed time period STEREO-A was at a relatively small longitudinal separation (46 degrees) to Mars and both were located at the back side of the Sun as viewed from Earth. We analyse a number of multi-spacecraft and multi-instrument (both in situ and remote-sensing) observations, and employ modelling to understand these signatures. We find that the solar sources are two CMEs which erupted on July 23 2017 from the same source region on the back side of the Sun as viewed from Earth. Moreover, we find that the two CMEs interact non-uniformly, inhibiting the expansion of one of the CMEs in STEREO-A direction, whereas allowing it to expand more freely in the Mars direction. The interaction of the two CMEs with the ambient solar wind adds up to the complexity of the event, resulting in a long, sub-structured interplanetary disturbance at Mars, where different sub-structures correspond to different steps of the FD, adding-up to a globally large-amplitude FD. **23-25 July 2017**

Forbush decrease model for expanding CMEs (ForbMod)

An Analytical Diffusion-Expansion Model for Forbush Decreases Caused by Flux Ropes

Mateja **Dumbović**, [Bernd Heber](#), [Bojan Vršnak](#), [Manuela Temmer](#), [Anamarija Kirin](#)

2018 *ApJ* 860 71

<https://arxiv.org/pdf/1805.00916.pdf>

We present an analytical diffusion-expansion Forbush decrease (FD) model ForbMod which is based on the widely used approach of the initially empty, closed magnetic structure (i.e. flux rope) which fills up slowly with particles by perpendicular diffusion. The model is restricted to explain only the depression caused by the magnetic structure of the interplanetary coronal mass ejection (ICME). We use remote CME observations and a 3D reconstruction method (the Graduated Cylindrical Shell method) to constrain initial boundary conditions of the FD model and take into account CME evolutionary properties by incorporating flux rope expansion. Several flux rope expansion modes are considered, which can lead to different FD characteristics. In general, the model is qualitatively in agreement with observations, whereas quantitative agreement depends on the diffusion coefficient and the expansion properties (interplay of the diffusion and the expansion). A case study was performed to explain the FD observed **2014 May 30**. The observed FD was fitted quite well by ForbMod for all expansion modes using only the diffusion coefficient as a free parameter, where the diffusion parameter was found to correspond to expected range of values. Our study shows that in general the model is able to explain the global properties of FD caused by FR and can thus be used to help understand the underlying physics in case studies.

The Drag-based Ensemble Model (DBEM) for Coronal Mass Ejection Propagation

Mateja **Dumbović**, Jaša Čalogović, Bojan Vršnak, Manuela Temmer, M. Leila Mays, Astrid Veronig, and Isabell Piantschitsch

2018 *ApJ* 854 180

<http://sci-hub.tw/http://iopscience.iop.org/0004-637X/854/2/180/>

The drag-based model for heliospheric propagation of coronal mass ejections (CMEs) is a widely used analytical model that can predict CME arrival time and speed at a given heliospheric location. It is based on the assumption that the propagation of CMEs in interplanetary space is solely under the influence of magnetohydrodynamical drag, where CME propagation is determined based on CME initial properties as well as the properties of the ambient solar wind. We present an upgraded version, the drag-based ensemble model (DBEM), that covers ensemble modeling to produce a distribution of possible ICME arrival times and speeds. Multiple runs using uncertainty ranges for the input values can be performed in almost real-time, within a few minutes. This allows us to define the most likely ICME arrival times and speeds, quantify prediction uncertainties, and determine forecast confidence. The performance of the DBEM is evaluated and compared to that of ensemble WSA-ENLIL+Cone model (ENLIL) using the same sample of events. It is found that the mean error is $ME = -9.7$ hr, mean absolute error $MAE = 14.3$ hr, and root mean square error $RMSE = 16.7$ hr, which is somewhat higher than, but comparable to ENLIL errors ($ME = -6.1$ hr, $MAE = 12.8$ hr and $RMSE = 14.4$ hr). Overall, DBEM and ENLIL show a similar performance. Furthermore, we find that in both models fast CMEs are predicted to arrive earlier than observed, most likely owing to the physical limitations of models, but possibly also related to an overestimation of the CME initial speed for fast CMEs.

Validation of the CME Geomagnetic Forecast Alerts Under the COMESEP Alert System

Mateja **Dumbović**, Nandita Srivastava, Yamini K. Rao, Bojan Vršnak, Andy Devos, Luciano Rodriguez
[Solar Physics](#) August 2017, 292:96 **File**

<https://link.springer.com/content/pdf/10.1007%2Fs11207-017-1120-5.pdf>

Under the European Union 7th Framework Programme (EU FP7) project Coronal Mass Ejections and Solar Energetic Particles (COMESEP, <http://comesep.aeronomy.be>), an automated space weather alert system has been developed to forecast solar energetic particles (SEP) and coronal mass ejection (CME) risk levels at Earth. The COMESEP alert system uses the automated detection tool called Computer Aided CME Tracking (CACTus) to detect potentially threatening CMEs, a drag-based model (DBM) to predict their arrival, and a CME geoeffectiveness tool (CGFT) to predict their geomagnetic impact. Whenever CACTus detects a halo or partial halo CME and issues an alert, the DBM calculates its arrival time at Earth and the CGFT calculates its geomagnetic risk level. The geomagnetic risk level is calculated based on an estimation of the CME arrival probability and its likely geoeffectiveness, as well as an estimate of the geomagnetic storm duration. We present the evaluation of the CME risk level forecast with the COMESEP alert system based on a study of geoeffective CMEs observed during 2014. The validation of the forecast tool is made by comparing the forecasts with observations. In addition, we test the success rate of the automatic forecasts (without

human intervention) against the forecasts with human intervention using advanced versions of the DBM and CGFT (independent tools available at the Hvar Observatory website, <http://oh.geof.unizg.hr>). The results indicate that the success rate of the forecast in its current form is unacceptably low for a realistic operation system. Human intervention improves the forecast, but the false-alarm rate remains unacceptably high. We discuss these results and their implications for possible improvement of the COMESEP alert system.

Forbush Decrease Prediction Based on the Remote Solar Observations

Mateja **Dumbovic**, Bojan Vrsnak, Jasa Calogovic

Solar Phys. January 2016, Volume 291, Issue 1, pp 285-302

<http://arxiv.org/pdf/1510.03282v1.pdf>

We employ remote observations of coronal mass ejections (CMEs) and the associated solar flares to forecast the CME-related Forbush decreases, i.e., short-term depressions in the galactic cosmic-ray flux. The relationship between the Forbush effect at the Earth and remote observations of CMEs and associated solar flares is studied via a statistical analysis. Relationships between Forbush decrease magnitude and several CME/flare parameters was found, namely the initial CME speed, apparent width, source position, associated solar-flare class and the effect of successive-CME occurrence. Based on the statistical analysis, remote solar observations are employed for a Forbush-decrease forecast. For that purpose, an empirical probabilistic model is constructed that uses selected remote solar observations of CME and associated solar flare as an input, and gives expected Forbush-decrease magnitude range as an output. The forecast method is evaluated using several verification measures, indicating that as the forecast tends to be more specific it is less reliable, which is its main drawback. However, the advantages of the method are that it provides early prediction, and that the input is not necessarily spacecraft-dependent.

Geoeffectiveness of Coronal Mass Ejections in the SOHO era

sci-hub.se/10.1007/s11207-014-0613-8

<https://link.springer.com/content/pdf/10.1007%2Fs11207-014-0613-8.pdf>

The main objective of the study is to determine the probability distributions of the geomagnetic Dst index as a function of the coronal mass ejection (CME) and solar flare parameters for the purpose of establishing a probabilistic forecast tool for the geomagnetic storm intensity. Several CME and flare parameters as well as the effect of successive-CME occurrence in changing the probability for a certain range of Dst index values, were examined. The results confirm some of already known relationships between remotely-observed properties of solar eruptive events and geomagnetic storms, namely the importance of initial CME speed, apparent width, source position, and the associated solar flare class. In this paper we quantify these relationships in a form to be used for space weather forecasting in future. The results of the statistical study are employed to construct an empirical statistical model for predicting the probability of the geomagnetic storm intensity based on remote solar observations of CMEs and flares. **15 June 2000, 24 June 2000, 13 December 2006**

Cosmic ray modulation by different types of solar wind disturbances

M. **Dumbović**, B. Vršnak, J. Čalogović and R. Župan

A&A 538, A28 (2012), **File**

Context. Solar wind disturbances such as interplanetary coronal mass ejections (ICMEs) and corotating interaction regions (CIRs) cause short-term cosmic ray depressions, generally denoted as Forbush decreases.

Aims. We conduct a systematic statistical study of various aspects of Forbush decreases. The analysis provides empirical background for physical interpretations of short-term cosmic ray modulations.

Methods. Firstly, we analyzed the effects of different types of solar wind disturbances, and secondly, we focused on the phenomenon of over-recovery (the return of the cosmic ray count to a value higher than the pre-decrease level). The analysis is based on ground-based neutron monitor data and the solar wind data recorded by the Advanced Composition Explorer. The correlations between various cosmic ray depressions and solar wind parameters as well as their statistical

significance are analyzed in detail. In addition, we performed a normalized superposed epoch analysis for depressions and magnetic field enhancements.

Results. The analysis revealed differences in the relationship between different solar wind disturbances and cosmic ray depression parameters. The amplitude of the depression for ICMEs was found to correlate well with the amplitudes of magnetic field strength and fluctuations, whereas for CIRs we found only the correlation between the amplitude of the depression and the solar wind disturbance dimension proxy v_tB . Similar behavior was found for shock and no-shock events, respectively. The CIR/ICME composites show a specific behavior that is a mixture of both ICMEs and CIRs. For all analyzed categories we found that the duration of the depression correlates with the duration of the solar wind disturbance. The analysis of the over-recovery showed that there is no straightforward relationship to either "branching-effect" or geomagnetic effects, therefore we propose a scenario where the "branching-effect" is caused by several factors and is only indirectly related to the over-recovery.

Cosmic ray modulation by solar wind disturbances

M. **Dumbović**, B. Vršnak, J. Čalogović and M. Karlica

Astronomy & Astrophysics, Volume 531, id.A91, 17 pp., **2011, File**

Aims: We perform a systematic statistical study of the relationship between characteristics of solar wind disturbances, caused by interplanetary coronal mass ejections and corotating interaction regions, and properties of Forbush decreases (FDs). Since the mechanism of FDs is still being researched, this analysis should provide a firm empirical basis for physical interpretations of the FD phenomenon.

Methods: The analysis is based on the ground-based neutron monitor data and the solar wind data recorded by the Advanced Composition Explorer, where the disturbances were identified as increases in proton speed, magnetic field, and magnetic field fluctuations. We focus on the relative timing of FDs, as well as on the correlations between various FD and solar wind parameters, paying special attention to the statistical significance of the results.

Results: It was found that the onset, the minimum, and the end of FDs are delayed after the onset, the maximum, and the end of the magnetic field enhancement. The t-test shows that at the 95% significance level the average lags have to be longer than 3, 7, and 26 h, respectively. FD magnitude ($|FD|$) is correlated with the magnetic field strength (B), magnetic field fluctuations (δB), and speed (v), as well as with combined parameters, BtB , Bv , v_tB , and $BvtB$, where tB is the duration of the magnetic field disturbance. In the $|FD|(B)$ dependence, a "branching" effect was observed, i.e., two different trends exist. The analysis of the FD duration and recovery period reveals a correlation with the duration of the magnetic field enhancement. The strongest correlations are obtained for the dependence on combined solar wind parameters of the product of the FD duration and magnitude, implying that combined parameters are in fact true variables themselves, rather than just a product of variables.

Conclusions: From the time lags we estimate that "the penetration depth" in the disturbance, at which FD onset becomes recognizable, is on the order of 100 Larmor radii and is comparable to a typical shock-sheath dimension. The results for the FD time profile indicate "shadow effect" of the solar wind disturbance before and after it passes the observer. The importance of reduced parallel diffusion during the passage of the disturbance is discussed, along with the influence of terrestrial effects on the observed "branching effect".

A new method to detect the ICMEs boundaries

Cristiana **Dumitrache**, Nedelia A. Popescu

2014

<http://arxiv.org/pdf/1405.6002v1.pdf>

A new method to infer the boundaries of the interplanetary coronal mass ejections is proposed. The local minima of a proton temperature anisotropy are used as potential boundaries of the interplanetary event. The low-beta plasma values are then invoked to detect at least four boundaries, two for the beginning and two for the end of an interplanetary coronal mass ejection (ICME). Intermediate boundaries can be identified, as indicated by other plasma and magnetic field signatures, and mark substructures of an event. Using the algorithm we propose here, we have compiled a list with ICME events boundaries registered by *Ulysses* spacecraft during 2000-2002. Three magnetic clouds (observed on **23 January 2001**, **10 June 2001** and **24 August 2001**) are analysed with details. This method provides premises for an alternative way of automatic detection of the ICMEs boundaries.

ICMEs list for a period of three important years of the solar cycle 23: 2000, 2001 and 2002.

The interplanetary mass ejections behaviour in the heliosphere

Cristiana **Dumitrache**, Nedelia A. Popescu

Review

Romanian Journal of Physics, 58, 3-4, p.383-394, **2013**

<http://arxiv.org/pdf/1406.3245v1.pdf>

We present here an overview of an important solar phenomenon with major implication for space weather and planetary life. The coronal mass ejections (CMEs) come from the Sun and expand in the heliosphere, becoming interplanetary coronal mass ejections (ICMEs). They represent huge clouds of plasma and magnetic fields that travel with velocities reaching even 2000 km/s and perturbing the planetary and interplanetary field. The magnetic clouds (MC) are a special class of ICMEs. We summarize some aspects as the ICMEs identification, propagation and track back to the Sun, where the solar source could be found. We notice here few known catalogs of the ICMEs and magnetic clouds.

Tracking a *Ulysses* High-latitude ICME Event Back to Its Solar Origins

C. **Dumitrache** · N.A. Popescu · A. Oncica

Solar Phys (2011) 272:137–157, **File**

High-latitude interplanetary mass ejections (ICMEs) observed beyond 1 AU are not studied very often. They are useful for improving our understanding of the 3D heliosphere. As there are only few such events registered by the *Ulysses* spacecraft, the task of detecting their solar counterparts is a challenge, especially during high solar activity periods, because there are dozens coronal mass ejections (CMEs) registered by SOHO that might be chosen as candidates. We analyzed a high-latitude ICME registered by the *Ulysses* spacecraft on 18 January 2002. Our investigation focused on the correlation between various plasma parameters that allow the identification to be made of the ICME and its components such as the forward shock, the magnetic cloud and the reverse shock.

Using a linear approach and a graphical method we have been able to track the ICME event back to the Sun and to compute the day of the occurrence of the solar CME. In order to decide among several CME candidates which one is the right solar counterpart of our event, we have performed a follow-up computation of these CMEs from the Sun to *Ulysses*, by using two different speed formulas. First, the computation was simply based on the initial CME velocity, while the other was based on the ICME velocity estimated from the CME initial speed (Lindsay et al. 1999). Differences of hours have been obtained between the arrival time predicted in these two ways, but the second one gave the best results. Both methods indicated the same two CMEs as the solar counterparts. We have found the solar source of these CMEs as being a huge polar filament that erupted in several steps.

This ICME event displayed a double magnetic cloud configuration. A minimum variance analysis helped us to detect the smooth rotation of the clouds and their helicity. Both magnetic clouds show the same helicity as the filament that erupted and released them. A cylinder-shape model of both clouds gives the same helicity sign.

Filament eruption of 8 January 2002.

A PSP Perihelion

CMEs' speed, travel time and temperature: A Thermodynamic approach

Héctor J. **Durand-Manterola**, Alberto Flandes, Ana Leonor Rivera, Alejandro Lara and Tatiana Niembro

JGR Volume 122, Issue 12 Pages 11,810–11,834 **2017**

<http://onlinelibrary.wiley.com/doi/10.1002/2017JA024369/epdf>

<http://sci-hub.cc/10.1002/2017JA024369>

Due to their important role in Space weather, Coronal Mass Ejections or CMEs have been thoroughly studied in order to forecast their speed and transit time from the Sun to the Earth. We present a Thermodynamic analytical model that describes the dynamics of CMEs. The thermodynamic approach has some advantages with respect to the hydrodynamic approach. First, it deals with the energy involved, which is a scalar quantity. Second, one may calculate the work done by the different forces separately and sum all contributions to determine the changes in speed, which simplifies the problem and allows us to obtain fully rigorous results. Our model considers the drag force, which dominates the dynamics of CMEs and the solar gravitational force, which has a much smaller effect, but it is, still, relevant enough to be considered.

We derive an explicit analytical expression for the speed of CMEs in terms of its most relevant parameters and obtain an analytical expression for the CME temperature. The model is tested with a CME observed at three different heliocentric distances with three different spacecraft (SOHO, ACE and *Ulysses*); also, with a set of 11 CMEs observed with the SOHO, Wind and ACE spacecraft and, finally, with two events observed with the STEREO spacecraft. In all cases, we

have a consistent agreement between the theoretical and the observed speeds and transit times. Additionally, for the set of 11 events, we estimate their temperatures at their departure position from their temperatures measured near the orbit of the Earth.

Table 2. CMEs data parameters for the 11 selected CMEs. 2001-2007

Evolution of the α -proton Differential Motion across Stream Interaction Regions

Tereza [Đurovcová](#), Zdeněk Němeček, and Jana Šafránková

2019 ApJ 873 24

<https://doi.org/10.3847/1538-4357/ab01c8>

A corotating interaction region (CIR) develops between the solar wind streams with different bulk speeds emanating from distinct coronal sources. The arising pressure perturbations redistribute momentum between adjacent streams forming the regions of the compressed solar wind around the stream interface. We focus on properties of α -particles with respect to protons in CIRs using measurements of the Wind and Helios spacecraft. In the slow solar wind in front of CIRs, the relative helium abundance A_{He} is usually low (about 1%) and the α -proton differential drift, $V_{\alpha p}$ is close to zero. In the high-speed stream behind CIRs, both of these characteristics are significantly higher. Inside CIRs, a large enhancement of A_{He} accompanied by a decrease in $V_{\alpha p}$ is often observed in the compressed and slowed down fast solar wind close to the CIR leading edge. On the other hand, a depletion of A_{He} is sometimes present in the compressed and accelerated slow solar winds. We explain these observations in terms of magnetic mirroring of the multicomponent solar wind in a converging magnetic field that develops within CIRs.

The Vigil Magnetometer for Operational Space Weather Services From the Sun-Earth L5 Point

Space Weather [Volume22, Issue6](#) June 2024 e2024SW003867

<https://doi.org/10.1029/2024SW003867>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2024SW003867>

Severe space weather has the potential to cause significant socio-economic impact and it is widely accepted that mitigating this risk requires more comprehensive observations of the Sun and heliosphere, enabling more accurate forecasting of significant events with longer lead-times. In this context, it is now recognized that observations from the L5 Sun-Earth Lagrange point (both remote and in situ) would offer considerable improvements in our ability to monitor and forecast space weather. Remote sensing from L5 allows for the observation of solar features earlier than at L1, providing early monitoring of active region development, as well as tracking of interplanetary coronal mass ejections through the inner heliosphere. In situ measurements at L5 characterize the solar wind's geoeffectiveness (particularly stream interaction regions), and can also be ingested into heliospheric models, improving their performance. The Vigil space weather mission is part of the ESA Space Safety Program and will provide a real-time data stream for space weather services from L5 following its anticipated launch in the early 2030s. The interplanetary magnetic field is a key observational parameter, and here we describe the development of the Vigil magnetometer instrument for operational space weather monitoring at the L5 point. We summarize the baseline instrument capabilities, demonstrating how heritage from science missions has been leveraged to develop a low-risk, high-heritage instrument concept.

The Scientific Foundations of Forecasting Magnetospheric Space Weather

Review

J. P. [Eastwood](#), R. Nakamura, L. Turc, L. Mejnertsen, M. Hesse

[Space Science Reviews](#) 2017

<https://link.springer.com/content/pdf/10.1007%2Fs11214-017-0399-8.pdf>

The magnetosphere is the lens through which solar space weather phenomena are focused and directed towards the Earth. In particular, the non-linear interaction of the solar wind with the Earth's magnetic field leads to the formation of highly inhomogeneous electrical currents in the ionosphere which can ultimately result in damage to and problems with the operation of power distribution networks. Since electric power is the fundamental cornerstone of modern life, the interruption of power is the primary pathway by which space weather has impact on human activity and technology. Consequently, in the context of space weather, it is the ability to predict geomagnetic activity that is of key importance. This is usually stated in terms of geomagnetic storms, but we argue that in fact it is the substorm phenomenon which contains the crucial physics, and therefore prediction of substorm occurrence, severity and duration, either within the context of a longer-lasting geomagnetic storm, but potentially also as an isolated event, is of critical importance. Here

we review the physics of the magnetosphere in the frame of space weather forecasting, focusing on recent results, current understanding, and an assessment of probable future developments. **20-30 Oct 2001**

Possible Cause of Extremely Bright Aurora Witnessed in East Asia on 17 September 1770

Yusuke [Ebihara](#) [Hisashi Hayakawa](#) [Kiyomi Iwahashi](#) [Harufumi Tamazawa](#) [Akito Davis Kawamura](#) [Hiroaki Isobe](#)

[Space Weather](#) [Volume 15, Issue 10](#) **2017**

sci-hub.tw/10.1002/2017SW001693

Extremely bright aurora was witnessed in East Asia on **17 September 1770**, according to historical documents. The aurora was described as “as bright as a night with full moon” at magnetic latitude of 25° . The aurora was dominated by red color extending from near the horizon up beyond the polar star (corresponding to elevation angle of $\sim 35^\circ$). We performed a two-stream electron transport code to calculate the volume emission rates at 557.7 nm (OI) and 630.0 nm (OI). Two types of distribution of precipitating electrons were assumed. The first one is based on the unusually intense electron flux measured by the DMSP satellite in the March 1989 storm. The distribution consists of hot (peaking at 3 keV) and cold (peaking at 71 eV) components. The second one is the same as the first one, but the hot component is removed. We call this high-intensity low-energy electrons (HILEEs). The first spectrum results in an auroral display with a bright, lower green border. The second one results in red-dominated aurora extending up to the elevation angle of 35° when the equatorward boundary of the electron precipitation is located at 32° invariant latitude. The poleward boundary of the precipitation would be 42° invariant latitude or greater to explain the auroral display extending from near the horizon. The origin of the HILEEs is probably the plasma sheet or the plasmasphere that is transported earthward to $L \sim 1.39$ due to enhanced magnetospheric convection. Local heating or acceleration is also plausible.

Solar-Wind High-Speed Stream (HSS) Alfvén Wave Fluctuations at High Heliospheric Latitudes: Ulysses Observations During Two Solar-Cycle Minima

We study Alfvén wave fluctuations in solar-wind high-speed streams (HSSs) at high heliolatitudes during the last two solar-cycle minima (SCM). Solar-wind plasma and interplanetary magnetic field (IMF) measured by Ulysses during four 50-day intervals in 1994, 1995, 2007, and 2008 were analyzed using wavelet and Fourier analyses, cross-correlation and kurtosis techniques. Intervals during 1994 and 1995 (2007 and 2008) correspond to the Ulysses polar passes through the southern and northern solar hemispheres, respectively, during the minimum between Cycles 22 and 23 or SCM22–23 (the minimum between Cycles 23 and 24 or SCM23–24). The solar-wind plasma density [NpNp], IMF magnitude [B0B0], and IMF-component variances are found to be lower during SCM23–24 than during SCM22–23 by $\approx 20 - 30\%$. The cross-correlation between the plasma velocity and IMF vector components, an indicative of Alfvénicity, is smaller during SCM23–24 than during SCM22–23. The Alfvén wave periodicity exhibits a large range, from $\approx 8 \sim 8$ hours to 10 days, with peak occurrences near 1 – 5 days during both minima. The statistical kurtosis analysis shows that the IMF distributions are mostly sub-Gaussian. Further, the Fourier power law analysis reveals a higher spectral power of transverse IMF components BtBt and BnBn than the radial field-aligned component BrBr. The power spectrum shows a spectral break near 10–4 Hz, with its high-frequency portion following a -1.7 power law dependence (Kolmogorov spectrum), while the low-frequency portion shows an $\approx -1.0 \sim -1.0$ power law index dependence. This low-frequency index is slightly higher during SCM22–23 (-0.65 to -0.87) than during SCM23–24 (-0.49 to -0.78). We conclude that while the Alfvénicity of the high-latitude HSSs does not vary substantially between the two minima, the amplitude of the Alfvén wave fluctuations is reduced during SCM23–24 compared to SCM22–23.

Interplanetary origins of moderate ($-100 \text{ nT} < \text{Dst} \leq -50 \text{ nT}$) geomagnetic storms during solar cycle 23 (1996–2008)

JGR, Volume 118, Issue 1, pp. 385-392, **2013**

<http://onlinelibrary.wiley.com/doi/10.1029/2012JA018086/pdf>

sci-hub.se/10.1029/2012JA018086

The interplanetary causes of 213 moderate-intensity ($-100 \text{ nT} < \text{peak Dst} \leq -50 \text{ nT}$) geomagnetic storms that occurred in solar cycle 23 (1996–2008) are identified. Interplanetary drivers such as corotating interaction regions (CIRs), pure high-speed streams (HSSs), interplanetary coronal mass ejections (ICMEs) of two types [those with magnetic clouds (MCs) and those without (nonmagnetic cloud or ICME_nc)], sheaths (compressed and/or draped sheath fields), as well

as their combined occurrence were identified as causes of the storms. The annual rate of occurrence of moderate storms had two peaks, one near solar maximum and the other in the descending phase, around 3 years later. The highest rate of moderate storm occurrence was found in the declining phase (25 storms year⁻¹). The lowest occurrence rate was 5.7 storms year⁻¹ and occurred at solar minimum. All moderate-intensity storms were associated with southward interplanetary magnetic fields, indicating that magnetic reconnection was the main mechanism for solar wind energy transfer to the magnetosphere. Most of these storms were associated with CIRs and pure HSSs (47.9%), followed by MCs and noncloud ICMEs (20.6%), pure sheath fields (10.8%), and sheath and ICME combined occurrence (9.9%). In terms of solar cycle dependence, CIRs and HSSs are the dominant drivers in the declining phase and at solar minimum. CIRs and HSSs combined have about the same level of importance as ICMEs plus their sheaths in the rising and maximum solar cycle phases. Thus, CIRs and HSSs are the main driver of moderate storms throughout a solar cycle but with variable contributions from ICMEs, their shocks (sheaths), and combined occurrence within the solar cycle. This result is significantly different than that for intense ($Dst \leq -100$ nT) and superintense ($Dst \leq -250$ nT) magnetic storms shown in previous studies. For superintense geomagnetic storms, 100% of the events were due to ICME events, while for intense storms, ICMEs, sheaths, and their combination caused almost 80% of the storms. CIRs caused only 13% of the intense storms. The typical interplanetary electric field (E_y) criteria for moderate magnetic storms were identified. It was found that ~80.1% of the storms follow the criterion of $E_y \geq 2$ mV m⁻¹ for intervals longer than 2 h. It is concluded that southward directed interplanetary magnetic fields within CIRs/HSSs may be the main energy source for long-term averaged geomagnetic activity on Earth.

Extremely low geomagnetic activity during the recent deep solar cycle minimum.

Statistical studies of geomagnetic storms with peak $Dst \leq -50$ nT from 1957 to 2008

E. **Echer**, W.D. Gonzalez and B.T. Tsurutani

Journal of Atmospheric and Solar-Terrestrial Physics, Volume 73, Issues 11-12, 2011, Pages 1454-1459, **File**
A catalog of 1377 geomagnetic storms with peak Dst (Dst_p) ≤ -50 nT for the period 1957–2008 has been compiled. The dependence of Dst_p on the solar cycle and annual variation are studied in this paper. It is found that geomagnetic storm peak intensity distribution can be described by an exponential form, where P is the probability of geomagnetic storm occurrence with a given value Dst_p . The updated solar cycle and annual distribution of geomagnetic storms have confirmed the expected behavior. For the solar cycle variation, geomagnetic storms display a two-peak distribution, with one peak close to solar maximum and the other a few years later in the beginning of the declining phase. Geomagnetic storms follow the well-known seasonal variation of geomagnetic activity. More intense storms show a peak in probability occurrence in July, confirming previous observations. These results are of practical importance for space weather applications.

Interplanetary fast forward shocks and their geomagnetic effects: CAWSES events

E. **Echer**, , B.T. Tsurutanib, c, F.L. Guarnierid and J.U. Kozyra

Journal of Atmospheric and Solar-Terrestrial Physics, Volume 73, Issues 11-12, 2011, Pages 1330-1338

The seven CAWSES interplanetary fast forward shocks and their geomagnetic effects during 2004–2005 have been analyzed. It is found that the arrival time of the shocks at Earth can be estimated within an accuracy of 5 min. Furthermore, AL decreases are found to occur within 10 min of shock impingement on the magnetopause. It was also determined that there is a direct correlation between the interplanetary magnetic field southward directed (IMF B_s) prior to shock arrival and substorms triggered by the shocks. If the IMF is northward prior to shock arrival, the geomagnetic activity is present but is low. One interpretation of this result is that the preconditioning energy stored in the magnetotail leaks away rapidly. A correlation between substorm peak AL and shock strength (Mach number) has also been noted, which could imply that shock strength is important for the amount of energy released into the magnetosphere/ionosphere.

High Speed Stream Properties and Related Geomagnetic Activity During the Whole Heliosphere Interval (WHI): 20 March to 16 April 2008.

Solar and interplanetary origins of the November 2004 superstorms

Ezequiel **Echer**, Bruce T. Tsurutani^b and Fernando L. Guarnieric

[Advances in Space Research](#), [Volume 44, Issue 5](#), 1 September 2009, Pages 615-620, 2009

During the first half of November 2004, many solar flares and coronal mass ejections (CMEs) were associated with solar active region (AR) 10696. This paper attempts to identify the solar and interplanetary origins of two superstorms which occurred on 8 and 10 November with peak intensities of $Dst = -373$ nT and -289 nT, respectively. Southward interplanetary magnetic fields within a magnetic cloud (MC), and a sheath + MC were the causes of these two superstorms, respectively. Two different CME propagation models [Gopalswamy, N., Yashiro, S., Kaiser, M.L. et al. Predicting the 1-AU arrival times of coronal mass ejections. *J. Geophys. Res.* 106, 29207–29219, 2001; Gopalswamy, N.S., Lara, A., Manoharan, P.K. et al. An empirical model to predict the 1-AU arrival of interplanetary shocks. *Adv. Space Res.* 36, 2289–2294, 2005] were employed to attempt to identify the solar sources. It is found that the models identify several potential CMEs as possible sources for each of the superstorms. The two Gopalswamy et al. models give the possible sources for the first superstorm as CMEs on 2330 UT 4 November 2004 or on 1454 UT 5 November 2004. For the second superstorm, the possible solar source was a CME that on 0754 UT 5 November 2004 or one that occurred on 1206 UT 5 November 2004. We note that other propagation models sometimes agree and other times disagree with the above results. It is concluded that during high solar/interplanetary activity intervals such as this one, the exact solar source is difficult to identify. More refined propagation models are needed.

Interplanetary conditions causing intense geomagnetic storms ($Dst = -100$ nT) during solar cycle 23 (1996-2006),

Echer, E., W. D. Gonzalez, B. T. Tsurutani, and A. L. C. Gonzalez

J. Geophys. Res., 113, A05221, 2008, **File**

<http://dx.doi.org/10.1029/2007JA012744>

The interplanetary causes of intense geomagnetic storms and their solar dependence occurring during solar cycle 23 (1996–2006) are identified. During this solar cycle, all intense ($Dst \leq -100$ nT) geomagnetic storms are found to occur when the interplanetary magnetic field was southwardly directed (in GSM coordinates) for long durations of time. This implies that the most likely cause of the geomagnetic storms was magnetic reconnection between the southward IMF and magnetopause fields. Out of 90 storm events, none of them occurred during purely northward IMF, purely intense IMF B_y fields or during purely high speed streams. We have found that the most important interplanetary structures leading to intense southward B_z (and intense magnetic storms) are magnetic clouds which drove fast shocks (sMC) causing 24% of the storms, sheath fields (Sh) also causing 24% of the storms, combined sheath and MC fields (Sh+MC) causing 16% of the storms, and corotating interaction regions (CIRs), causing 13% of the storms. These four interplanetary structures are responsible for three quarters of the intense magnetic storms studied. The other interplanetary structures causing geomagnetic storms were: magnetic clouds that did not drive a shock (nsMC), non magnetic clouds ICMEs, complex structures resulting from the interaction of ICMEs, and structures resulting from the interaction of shocks, heliospheric current sheets and high speed stream Alfvén waves. During the rising phase of the solar cycle, sMC and sheaths are the dominant structure driving intense storms. At solar maximum, sheath fields, followed by Sh+MCs and then by sMC were responsible for most of the storms. During the declining phase, sMC, Sh and CIR fields are the main interplanetary structures leading to intense storms. We have also observed that around 70% of the storms follow the interplanetary criteria of $E_y \geq 5$ mV/m for at least 3 h. Around 90% of the storms used in the study followed a less stringent set of criteria: $E_y \geq 3$ mV/m for at least 3 h. Finally, we obtain the approximate rate of intense magnetic storms per solar cycle phases: minimum/rising phase 3 storms.year⁻¹, maximum phase 8.5 storms.year⁻¹, and declining/minimum phases 6.5 storms.year⁻¹.

Table

Interplanetary conditions leading to superintense geomagnetic storms ($Dst \leq -250$ nT) during solar cycle 23

Echer, E., W. D. Gonzalez, B. T. Tsurutani

Geophysical Research Letters, Volume 35, Issue 6, CiteID L06S03, 2008, File

<http://adsabs.harvard.edu/abs/2008GeoRL..3506S03E>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2007GL031755>

The interplanetary causes of superintense geomagnetic storms (superstorms, $Dst \leq -250$ nT) that occurred during solar cycle 23 are studied. Eleven superstorms occurred during the cycle, five close to solar maximum (2000-2001) and six in the post-maximum/declining phase (2003-2004). About 1/3 of the superstorms were caused by magnetic clouds (MCs), 1/3 by a combination of sheath and MC fields, and 1/3 by sheath fields alone. The interplanetary parameter best correlated with peak Dst was the time-integrated E_y during the storm main phase (in contrast with peak B_z and/or peak E_y for less intense geomagnetic storms). The range of peak Dst for these storms was -263 to -422 nT. The storm main phase durations had a range of 3-33 h. We conclude from this study that: (1) only MCs and/or interplanetary sheaths had fields intense enough and with long enough durations to cause superstorms; (2) superstorms occurred only in the maximum and declining phases; (3) the total energy transferred from the solar wind to the magnetosphere is best correlated with the time-integrated solar wind E_y parameter.

Influence of Non-Potential Coronal Magnetic Topology on Solar-Wind Models

S. J. Edwards, A. R. Yeates, F.-X. Bocquet,

Solar Phys. 2015

By comparing a magneto-frictional model of the low-coronal magnetic-field to a potential-field source-surface model, we investigate the possible impact of non-potential magnetic structure on empirical solar-wind models. These empirical models (such as Wang–Sheeley–Arge) estimate the distribution of solar-wind speed solely from the magnetic-field structure in the low corona. Our models are computed in a domain between the solar surface and 2.5 solar radii, and they are extended to 0.1 AU using a Schatten current-sheet model. The non-potential field has a more complex magnetic skeleton and quasi-separatrix structures than the potential field, leading to different sub-structure in the solar-wind speed proxies. It contains twisted magnetic structures that can perturb the separatrix surfaces traced down from the base of the heliospheric current sheet. A significant difference between the models is the greater amount of open magnetic flux in the non-potential model. Using existing empirical formulae this leads to higher predicted wind speeds for two reasons: partly because magnetic-flux tubes expand less rapidly with height, but more importantly because more open-field lines are further from coronal-hole boundaries.

Coronal Radio Occultation Experiments with the Helios Solar Probes: Correlation/Spectral Analysis of Faraday Rotation Fluctuations

A. I. Efimov, L. A. Lukanina, A. I. Rogashkova, L. N. Samoznaev, I. V. Chashei, M. K. Bird, M. Pätzold
Solar Phys. 2015

The coronal Faraday rotation (FR) experiments using the linearly polarized signals of the *Helios-1* and *Helios-2* interplanetary probes remain a unique investigation of the magnetic field of the solar corona and its aperiodic and quasi-periodic variations. The unexpectedly long lifetime of these spacecraft (1974 – 1986) enabled studies from very deep solar-activity minimum (1975 – 1976) into the strong activity maximum (1979). Important experimental data were also obtained for the rising (1977 – 1978) and declining (1980 – 1984) branches of the solar-activity cycle. Previous publications have presented results of the initial experimental data only for coronal-sounding experiments performed during individual solar-conjunction opportunities. This report is a more detailed analysis of the *Helios* FR measurements for the entire period 1975 – 1984. Radial profiles of the FR fluctuation (FRF) intensity recorded during the deepest solar-

activity minimum in 1975 – 1976 are shown to differ distinctly from those during the strong solar-activity maximum in 1979. In particular, the decrease of the FRF intensity with solar-offset distance is substantially steeper in 1979 than in 1975/1976. In all cases, however, the FR data reveal quasi-periodic wave-like fluctuations in addition to the random background with a power-law spectrum. The dominant period of these fluctuations, recorded during 35 % of the total measurement time, is found to be close to five minutes. Large-scale FR variations at considerably longer periods (1.1 – 2.7 hours) were observed during 20 % of the measurement time. Knowing the intrinsic motion of the radio ray path from spacecraft to Earth and making a reasonable assumption about the solar-wind velocity, FRF observations at widely spaced ground stations have been used to estimate the velocity of coronal Alfvén waves. The velocity values range between 290 and 550 km s⁻¹ at heliocentric distances between 3.5 and 4.5 R_⊙ and are marginally lower (150 – 450 km s⁻¹) at distances between 5.5 and 6.5 R_⊙. Occasional FR variations with a period near 160 minutes and harmonics with periods 60, 30, and 20 minutes were also observed.

The Interconnection between the Periodicities of Solar Wind Parameters Based on the Interplanetary Magnetic Field Polarity (1967–2018): A Cross Wavelet Analysis

M. A. [El-Borie](#), [A. M. El-Taher](#), [A. A. Thabet](#) & [A. A. Bishara](#)

[Solar Physics](#) volume 295, Article number: 122 (2020)

<https://link.springer.com/content/pdf/10.1007/s11207-020-01692-2.pdf>

In this article, we have examined the possible interconnection and phase asynchrony between the periodicities of solar wind parameters (solar wind velocity VV, plasma density NN, and dynamic pressure PP), and the interplanetary magnetic field (IMF) magnitude BB, taking into account the polarity state, toward (TT) and away (AA) from the Sun, of the IMF. For this purpose, the daily measurements of VV, NN, PP, and BB during the period 1967–2018, thus covering almost five solar cycles, were sorted into two groups according to the IMF sense. Days of mixed IMF polarity or having no data were eliminated from our analysis during the entire period. The monthly averages of TT and AA polarity groups have been calculated for each parameter. BTBT (BABA), VTVT (VAVA), NTNT (NANA), and PTPT (PAPA), refer to the monthly averages of TT (AA) polarity group for BB, VV, NN, and PP, respectively. In this study, three techniques were applied, including the running correlation analysis, cross-wavelet transform (XWT) and wavelet coherence (WTC) to the monthly means of each polarity group. Our results reveal that the running correlation coefficient for toward and away groups of each parameter reflect a positive correlation value during most of the entire period. The long-term periodicities within the 8–16 yr band are also detected for all toward and away components of the considered parameters with a significant common power during most of the entire period. Moreover, the WTC reflects an almost in-phase relationship behavior between the toward and away groups of each parameter during this range. On the other hand, within the 4–8 yr, 2–4 yr, and 1–2 yr bands, the toward and away groups of each solar wind parameter show mid-term periodicities at different periods, displaying sometimes significant powers.

The impact of asymmetrical distribution of solar activity on geomagnetic indices throughout five solar activity cycles

M.A. [El-Borie](#), [A.M. El-Taher](#), [A.A. Thabet](#), [A.A. Bishara](#)

[Advances in Space Research](#) Volume 64, Issue 1, 1 July 2019, Pages 278-286

[sci-hub.se/10.1016/j.asr.2019.03.040](https://doi.org/10.1016/j.asr.2019.03.040)

The [irregularity](#) of the [solar activities](#) based on [sunspot numbers](#) (SSNs) and areas (SSAs) over the solar disk has been considered. More activities phenomena occurred in one of the solar hemispheres than the other at the same time, which they are referred to as the North-South (N-S) [asymmetry](#) of solar activity. Daily averages of geomagnetic indices aa, Ap, Kp, and Dst over the period 1967–2016 have been examined according to the asymmetrical distribution of both solar hemispheric activities. The possible connection between the geomagnetic activity disturbances and the sign of [non-uniformity](#) of solar activity, i.e. the N-S asymmetry for each geomagnetic index has been confirmed. The dependence of the sign of geomagnetic disturbances on the solar activity cycle, has been examined. We have classified the considered data into two groups according to the activity of northern (N) or southern (S) solar hemisphere. The [solar cycles](#) 20 and 24 have [northern hemisphere](#) dominance. These activities shifted from northern to [southern hemisphere](#) in solar cycles 21, 22, and 23. The geomagnetic disturbances exhibited significant asymmetrical states at different periods. The most significant northern and southern peaks occurred at/near the minimum of the solar cycle or in periods of descending phase of the solar cycle. The geomagnetic activity has southern dominance during solar cycle 22 and it favoured the northern activity during solar cycle 23. The dependence of the geomagnetic activity disturbance of aa, Ap, Kp, and Dst indices over the solar activity cycle is confirmed and the sign of the asymmetry changes from one solar cycle to another.

The Dependence of Solar, Plasma, and Geomagnetic Parameters' Oscillations on the Heliospheric Magnetic Field Polarities: Wavelet Analysis

M. A. [El-Borie](#)¹, A. M. El-Taher^{2,4}, A. A. Thabet³, and A. A. Bishara

2019 ApJ 880 86

[sci-hub.se/10.3847/1538-4357/ab12d8](https://doi.org/10.3847/1538-4357/ab12d8)

We investigate the dependence of solar, plasma, and geomagnetic parameters' periodicities on the heliospheric magnetic field polarities for the past five solar activity cycles (1967–2016). For this purpose, the Morlet wavelet technique has been performed to extract information about significant periods. The monthly averages of toward (T) and away (A) polarity groups have been calculated for each parameter. The solar and plasma parameters used in this work are the interplanetary magnetic field (B), sunspot numbers (R), and solar plasma speed (V), and the geomagnetic indices aa, Kp, and Ap. We found that the wavelet power spectra (WPS) for the monthly averages of BT and BA nearly showed a symmetrical power spectra distribution. The global wavelet spectra (GWS) for BT and BA displayed a coupling at some level between 3.2–3.5, 10.7, and 18.3 yr of variations. The GWS for VA provided two significant peaks, within the 95% confidence level, at 9.8 and 15.2 yr, as well as at 1 and 9.8 yr, for VT. In addition, the existence of a periodicity of 1 yr is obvious for VT spectra and it shifted to a 1.5 yr variation in VA spectra. Both the WPS and GWS for RT and RA reflect symmetric power spectra for both groups in the northern and southern hemispheres. The aa spectra exhibited prominent periodicities at 10.7 yr for aaA and 9.8 yr for aaT. Also, the well-known 9.8 yr periodicity variation is a dominant variation in both the spectra of ApT and ApA. On the other hand, within the cone of influence, the periodicities of 10.7 and 13.9 yr are observed for the KpA spectra and 9.8 yr for KpT spectra. The GWS showed double-peak structure for the spectrum of KpA.

Long-term variation of the semiannual amplitude in the aa index

Ana G. [Elias](#), Virginia M. Silbergleitner, c, , and Alicia L. Clua de Gonzalez

Journal of Atmospheric and Solar-Terrestrial Physics, Volume 73, Issues 11-12, 2011, Pages 1492-1499

The long-term variation of the semiannual amplitude in the geomagnetic activity index aa is analyzed with the purpose of contributing to the understanding of solar variability, directly linked to geomagnetic variability. The time series of the semiannual oscillation amplitude, obtained through a wavelet analysis of the daily aa series, presents a long-term variation similar to that shown by solar and geomagnetic indices, like aa itself or Dst. However, the maximum in the semiannual amplitude series occurs around 1947, almost 10 years before it occurs in solar and geomagnetic indices time series. The phase of the semiannual oscillation fluctuates around the values predicted by the equinoctial and Russell–McPherron models, with a predominance of the equinoctial mechanism during the period of maximum semiannual amplitude. A possible source of changes in the equinoctial mechanism would be the secular variation of the Earth's dipole tilt. But, since it does not follow the semiannual amplitude trend, at first sight, it seems not to be responsible for the equinoctial predominance around 1947. The analysis of quiet and disturbed days separately indicates that only disturbed days present the semiannual annual amplitude maximum around 1947, so the 10 year time shift could be due to the mechanism responsible for the semiannual variation in geomagnetically active periods.

Improving Multiday Solar Wind Speed Forecasts

H. A. [Elliott](#), [C. N. Arge](#), [C. J. Henney](#), [M. A. Dayeh](#), [G. Livadiotis](#), [J.-M. Jahn](#), [C. E DeForest](#)

Space Weather e2021SW002868 **Volume 20, Issue 9** 2022

<https://doi.org/10.1029/2021SW002868>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2021SW002868>

We analyze the residual errors for the Wang-Sheeley-Arge (WSA) solar wind speed forecasts as a function of the photospheric magnetic field expansion factor (f_p) and the minimum separation angle (d) in the photosphere between the footpoints of open field lines and the nearest coronal hole boundary. We find the map of residual speed errors are systematic when examined as a function of f_p and d . We use these residual error maps to apply corrections to the model speeds. We test this correction approach using 3-day lead time speed forecasts for an entire year of observations and model results. Our methods can readily be applied to develop corrections for the remaining WSA forecast lead times which range from 1 to 7 days in 1-day increments. Since the solar wind density, temperature, and the interplanetary magnetic field strength all correlate well with the solar wind speed, the improved accuracy of solar wind speed forecasts enables the production of multiday forecasts of the solar wind density, temperature, pressure, and interplanetary field strength, and geophysical indices. These additional parameters would expand the usefulness of ADAPT-WSA forecasts for space weather clients.

The Multifaceted M1.7 GOES-class Flare Event of 21 April 2023 in AR13283.

[Elmhamdi](#), A., Marassi, A., Romano, P. et al.

Sol Phys 299, 109 (2024).

<https://doi.org/10.1007/s11207-024-02355-2>

On **21 April 2023**, a significant M1.7 solar flare erupted from Active Region 13283, accompanied by a filament eruption and a full-halo Coronal Mass Ejection, which reached Earth on **23 April**, triggering a severe geomagnetic storm, with Kp reaching 8 (G4) and Dst plummeting to -212 nT together with a sharply distinguished long-lasting negative double-dip behavior of the z-component of the interplanetary magnetic field. This event led to remarkable auroral displays, even at mid-latitudes in Europe. The flare-induced filament eruption caused distinct intensity dimming in the solar corona, observed in specific EUV wavelengths. We observed the dimming region growing at its fastest rate before the flare reached its peak of intensity. Notably, the proximity of the flare to a large southern coronal hole influenced the expansion and propagation of the coronal mass ejection toward Earth, probably impacting the solar wind speed and density. Additionally, we observed a sudden expansion of the coronal hole during the flare, leading us to speculating that the adjacent flare may have further stimulated the flow of solar-wind particles along the open magnetic-field lines. In accordance with the severe Dst-index disturbance, we also report changes in the potential of the pipeline of an Italian energy infrastructure company with respect to the surrounding soil as well as double-dip variation in the H-component of the terrestrial magnetic field observed locally (reminiscent to what reported in Dst-index and IMF Bz) temporal profiles, confirming the effects of the geomagnetic storm at Italy mid-latitudes. Several solar radio events have been observed too. Therefore this study provides insights into the dynamic solar phenomena and their potential geomagnetic implications.

Estimating the occurrence of geomagnetic activity using the Hilbert-Huang

S. Elvidge

Space Weather 2020 e2020SW002513

<https://doi.org/10.1029/2020SW002513>

In this paper extreme value theory (EVT) has been used to estimate the return levels for geomagnetic activity based on the aa index. The aa index is the longest, continuously recorded, geomagnetic dataset (from 1868 – Present). This long, 150 year, dataset is an ideal candidate for extreme value analysis. However the data are not independent and identically distributed as required for EVT since they are impacted by the approximately 11 year solar cycle. The Hilbert-Huang Transform has been used to identify the solar cycle component in the data and the data has been split into solar maximum and minimum times. In these two regimes the generalised extreme value distribution has been fit to the datasets. These have also been combined for an estimate of the overall return times. The results suggest that the largest event in the database (March 1989) is a one in 25 year event. However, considering separate solar maximum and minimum times has a large impact on the return times. During solar minimum conditions the return time of the March 1989 event is 130 years. This suggests that the occurrence of extreme space weather events is conditionally dependent on where in the Solar Cycle we are.

Theory of Cosmic Ray Transport in the Heliosphere

Review

Modelling the transport of cosmic rays (CRs) in the heliosphere represents a global challenge in the field of heliophysics, in that such a study, if it were to be performed from first principles, requires the careful modelling of both large scale heliospheric plasma quantities (such as the global structure of the heliosphere, or the heliospheric magnetic field) and small scale plasma quantities (such as various turbulence-related quantities). Here, recent advances in our understanding of the transport of galactic cosmic rays are reviewed, with an emphasis on new developments pertaining to their transport coefficients, with a special emphasis on novel theoretical and numerical simulation results, as well as the CR transport studies that employ them. Furthermore, brief reviews are given of recent progress in CR focused transport modelling, as well as the modelling of non-diffusive CR transport.

Solar Event Simulations using the HAWC Scaler System

the 34th International Cosmic Ray Conference (ICRC2015), The Hague, The Netherlands.

<http://arxiv.org/pdf/1508.07285v1.pdf>

The High Altitude Water Cherenkov (HAWC) Observatory is an air shower array located near the volcano Sierra Negra in Mexico. The observatory has a scaler system sensitive to low energy cosmic rays (the geomagnetic cutoff for the site is 8 GV) suitable for conducting studies of solar or heliospheric transients such as Ground Level Enhancements (GLEs)

and Forbush decreases. In this work we present the simulation of the HAWC response to these phenomena. We computed HAWC effective areas for different array configurations (different selection of photomultiplier tubes per detector) relevant for Forbush decreases and GLEs. 2014 September 14

Effects of strong geomagnetic storms on Northern railways in Russia.

Anomalous Forbush effects from remote by longitude solar sources

E. [Eroshenko](#)¹, Belov A.1, Mavromichalaki, H.2, Oleneva, V.1, Papaioannou, A.2, Yanke V. Proceedings IAU Symposium No. 257, 2008, **File**

The Forbush effects associated with far western and eastern powerful sources on the Sun and occurred on the background of unsettled and moderate interplanetary and geomagnetic disturbance have been studied by the data from neutron monitor network and relevant measurements of the solar wind parameters. These Forbush effects may be referred to a special sub-class of events, with the characteristics closed to the event in July 2005, and incorporated by the common conditions: absence of a significant disturbance in the Earth vicinity; absence of the strong geomagnetic storm; slow decrease of cosmic ray intensity during the main phase of the Forbush effect. General features and separate properties in behavior of density and anisotropy of 10 GV cosmic rays for this subclass are investigated.

Compositional Metrics of Fast and Slow Alfvénic Solar Wind Emerging from Coronal Holes and Their Boundaries

Tamar [Ervin](#)^{1,2}, Stuart D. Bale^{1,2}, Samuel T. Badman³, Yeimy J. Rivera³, Orlando Romeo^{2,4}, Jia Huang², Pete Riley⁵, Trevor A. Bowen², Susan T. Lepri⁶, and Ryan M. Dewey⁶ 2024 ApJ 969 83

<https://iopscience.iop.org/article/10.3847/1538-4357/ad4604/pdf>

We seek to understand the composition and variability of fast solar wind (FSW) and slow Alfvénic solar wind emerging from coronal holes (CHs). We leverage an opportune conjunction between Solar Orbiter and Parker Solar Probe (PSP) during PSP Encounter 11 to include compositional diagnostics from the Solar Orbiter Heavy Ion Sensor as these variations provide crucial insights into the origin and nature of the solar wind. We use potential field source surface and magnetohydrodynamic models to connect the observed plasma at PSP and Solar Orbiter to its origin footprint in the photosphere and compare these results with the in situ measurements. A very clear signature of a heliospheric current sheet crossing as evidenced by enhancements in low first ionization potential (FIP) elements, ion charge state ratios, proton density, low Alfvénicity, and polarity estimates validates the combination of modeling, data, and mapping. We identify two FSW streams emerging from small equatorial CHs with low ion charge state ratios, low FIP bias, high Alfvénicity, and low footprint brightness, yet anomalously low alpha particle abundance for both streams. We identify high-Alfvénicity slow solar wind emerging from the overexpanded boundary of a CH having intermediate alpha abundance, high Alfvénicity, and dips in ion charge state ratios corresponding to CH boundaries. Through this comprehensive analysis, we highlight the power of multi-instrument conjunction studies in assessing the sources of the solar wind. 2022-02-24-28, 2022/02/21-03/04

In situ measurement of slow solar wind emerging from a pseudostreamer: a conjunction study with Parker Solar Probe and Solar Orbiter

ApJ 2023

<https://arxiv.org/pdf/2309.07949.pdf>

We seek to identify the source regions of the slow solar wind (SSW) through combining models with in situ observations. We leverage an opportune conjunction between Solar Orbiter and Parker Solar Probe (PSP) during PSP Encounter 11 to include compositional diagnostics from the Solar Orbiter heavy ion sensor (HIS) as these variations provide crucial insights into the origin and nature of the solar wind. We use Potential Field Source Surface (PFSS) and Magnetohydrodynamic (MHD) models to connect the observed plasma at PSP and Solar Orbiter to its origin footprint in the photosphere, and compare these results with the in situ measurements. A very clear signature of a heliospheric

current sheet (HCS) crossing as evidenced by enhancements in low FIP elements, ion charge state ratios, proton density, low-Alfvénicity, and polarity estimates validates the combination of modeling, data, and mapping. Fast wind from a small equatorial coronal hole (CH) with low ion charge state ratios, low FIP bias, high-Alfvénicity, and low footpoint brightness mostly fits together, yet includes anomalously low alpha particle abundance. We identify slow wind from many different sources, with broad variation in composition and Alfvénicity. We distinguish between classical non-Alfvénic and high-Alfvénicity SSW and make the association of low-Alfvénicity, decreased alpha-to-proton abundance, high charge state ratios, and FIP bias with streamer wind while intermediate alpha abundance, high-Alfvénicity, and dips in ion charge state ratios correspond to CH boundaries. Through this comprehensive analysis, we highlight the power of multi-instrument conjunction studies in assessing the sources of the solar wind. **2022-02-24-27**

Solar Wind Laws Valid for any Phase of a Solar Cycle **A Review**

Geomagnetism and Aeronomy, **2009**, Vol. 49, No. 1, pp. 133–135, File.

Original Russian Text published in Geomagnetizm i Aeronomiya, **2009**, Vol. 49, No. 1, pp. 142–144.

The solar sources of the magnetic storms of November 8 and 10, 2004, are analyzed. The preliminary results of such an analysis [Yermolaev et al., 2005] are critically compared with the results of the paper [Tsurutani et al., 2008], where solar flares were put in correspondence with these magnetic storms. The method for determining solar sources that cause powerful magnetospheric storms is analyzed. It has been indicated that an optimal approach consists in considering coronal mass ejections (CMEs) as storm sources and accompanying flares as additional information about the location of CME origination.

LEARNING FROM THE OUTER HELIOSPHERE: INTERPLANETARY CORONAL MASS EJECTION SHEATH FLOWS AND THE EJECTA ORIENTATION IN THE LOWER CORONA

R. M. **Evans**¹, M. Opher^{1,2}, and T. I. Gombosi³

Astrophysical Journal, 728:41 (7pp), **2011** February

The magnetic field structure of the ejecta of a coronal mass ejection (CME) is not known well near the Sun. Here we demonstrate, with a numerical simulation, a relationship between the subsonic plasma flows in the CME-sheath and the ejecta magnetic field direction. We draw an analogy to the outer heliosphere, where Opher et al. used *Voyager 2* measurements of the solar wind in the heliosheath to constrain the strength and direction of the local interstellarmagnetic field. We simulate three ejections with the same initial free energy, but different ejectamagnetic field orientations in relation to the global coronal field. Each ejection is launched into the same background solar wind using the Space Weather Modeling Framework. The different ejecta magnetic field orientations cause the CME-pause (the location of pressure balance between solar wind and ejecta material) to evolve differently in the lower corona. As a result, the CME-sheath flow deflections around the CME-pauses are different. To characterize this non-radial deflection, we use $\theta_F = \tan^{-1} v_{N/V_T}$, where V_N and V_T are the normal and tangential plasma flow as measured in a spacecraft-centered coordinate system. Near the CME-pause, we found that θ_F is very sensitive to the ejecta magnetic field, varying from 45° to 98° between the cases when the CME-driven shock is located at $4.5R_\odot$. The deflection angle for each case is found to evolve due to rotation of the ejecta magnetic field. We find that this rotation should slow or stop by $10R_\odot$ (also suggested by observational studies). These results indicate that an observational study of CME-sheath flow deflection angles from several events (to account for the interaction with the solar wind), combined with numerical simulations (to estimate the ejecta magnetic field rotation between eruption and $10R_\odot$) can be used to constrain the ejecta magnetic field in the lower corona.

Impulsive Increase of Galactic Cosmic Ray Flux Observed by IceTop

P. **Evenson**, IceCube Collaboration, P.S. Mangedard, P. Muangha, R. Pyle, D. Ruffolo and A. Sáiz
Proc. 35th Int. Cosmic Ray. Conf. Busan, PoS(ICRC2017)133 (**2017**).

<https://pos.sissa.it/301/133/pdf>

On 2017 January 18 scaler rates in the IceTop detectors at the South Pole revealed an impulsive increase in the galactic cosmic ray flux lasting a few hours. In addition to the neutron monitor at Pole the event was detected clearly by the Mawson neutron monitor and faintly at Jang Bogo. No other neutron monitors appear to have seen the increase. The event was in many ways reminiscent of the 2015 June 22 event observed by the GRAPES muon detectors. Both events occurred during the declining phase of a Forbush decrease, at a time of increasing geomagnetic activity, and were observed by a limited number of neutron monitors with similar asymptotic directions. The magnitude of the impulse was in both cases such that the flux returned briefly to approximately the pre-decrease level. Distinctly unlike the 2015 June 22 event, a changing geomagnetic cutoff cannot explain the 2017 January 18 event because the cutoff at South Pole is nearly zero and the detector response is atmosphere limited. We therefore interpret the 2017 January 18 event in terms of the structure of the Forbush decrease and (possibly changing) asymptotic directions. With our interpretation of the January event in mind we also comment on possible alternative interpretations of the GRAPES event. **2015 June 22, 2017 January 18**

The heliospheric imagers onboard the STEREO mission.

Eyles, C. J., Harrison, R. A., Davis, C. J., Waltham, N. R., Shaughnessy, B. M., Mapson-Menard, H. C. A., ... & Howard, R. A.

(2009). *Solar Physics*, 254(2), 387-445

<http://sci-hub.tw/10.1007/s11207-008-9299-0>

Mounted on the sides of two widely separated spacecraft, the two Heliospheric Imager (HI) instruments onboard NASA's STEREO mission view, for the first time, the space between the Sun and Earth. These instruments are wide-angle visible-light imagers that incorporate sufficient baffling to eliminate scattered light to the extent that the passage of solar coronal mass ejections (CMEs) through the heliosphere can be detected. Each HI instrument comprises two cameras, HI-1 and HI-2, which have 20° and 70° fields of view and are off-pointed from the Sun direction by 14.0° and 53.7°, respectively, with their optical axes aligned in the ecliptic plane. This arrangement provides coverage over solar elongation angles from 4.0° to 88.7° at the viewpoints of the two spacecraft, thereby allowing the observation of Earth-directed CMEs along the Sun – Earth line to the vicinity of the Earth and beyond. Given the two separated platforms, this also presents the first opportunity to view the structure and evolution of CMEs in three dimensions. The STEREO spacecraft were launched from Cape Canaveral Air Force Base in late October 2006, and the HI instruments have been performing scientific observations since early 2007. The design, development, manufacture, and calibration of these unique instruments are reviewed in this paper. Mission operations, including the initial commissioning phase and the science operations phase, are described. Data processing and analysis procedures are briefly discussed, and groundtest results and in-orbit observations are used to demonstrate that the performance of the instruments meets the original scientific requirements.

Evaluating predictions of ICME arrival at Earth and Mars

T. V. **Falkenberg**,¹ A. Taktakishvili,² A. Pulkkinen,^{2,3} S. Vennerstrom,¹ D. Odstrcil,² D. Brain,⁴ G. Delory,⁴ and D. Mitchell⁴

SPACE WEATHER, VOL. 9, S00E12, doi:10.1029/2011SW000682, 2011, File

We present a study of interplanetary coronal mass ejection (ICME) propagation to Earth and Mars. Because of the significant space weather hazard posed by ICMEs, understanding and predicting their arrival and impact at Mars is important for current and future robotic and manned missions to the planet. We compare running ENLILv2.6 with coronal mass ejection (CME) input parameters from both a manual and an automated method. We analyze shock events identified at Mars in Mars Global Surveyor data in 2001 and 2003, when Earth and Mars were separated by <80° in heliocentric longitude. The shocks identified at Mars were also identified at Earth, and the majority of the shock sources were identified through the Solar and Heliospheric Observatory–Large Angle and Spectrometric Coronagraph catalogue. We find that arrival times predicted by the two methods at both planets are statistically similar, dynamic pressures predicted when using the automated method are better, and the automated method tends to underestimate both CME width and speed. Using the location of the related flare as the CME direction did not improve results. In addition, changing the CME speed toward the plane- of- sky speed at 20 RS improves the match to observations, mainly because the speed found by the automated method is underestimated. The time lapse between the shock arrival at Earth and Mars, for the events studied here, is shorter than expected from simulations, and the presence of high speed streams can enable an ICME to arrive almost simultaneously at Earth and Mars. This work will be applied to improve the input parameter methods for ENLIL.

Multipoint observations of coronal mass ejection and solar energetic particle events on Mars and Earth during November 2001

Falkenberg, T. V.; Vennerstrom, S.; Brain, D. A.; Delory, G.; Taktakishvili, A.

J. Geophys. Res., Vol. 116, No. A6, A06104, **2011**

Multipoint spacecraft observations provide unique opportunities to constrain the propagation and evolution of interplanetary coronal mass ejections (ICMEs) throughout the heliosphere. Using Mars Global Surveyor (MGS) data to study both ICME and solar energetic particle (SEP) events at Mars and OMNI and Geostationary Operational Environmental Satellite (GOES) data to study ICMEs and SEPs at Earth, we present a detailed study of three CMEs and flares in late November 2001. In this period, Mars trailed Earth by 56° solar longitude so that the two planets occupied interplanetary magnetic field lines separated by only $\sim 25^\circ$. We model the interplanetary propagation of CME events using the ENLIL version 2.6 3-D MHD code coupled with the Wang-Sheeley-Arge version 1.6 potential source surface model, using Solar and Heliospheric Observatory (SOHO) Large Angle and Spectrometric Coronagraph (LASCO) images to determine CME input parameters. We find that multipoint observations are essential to constrain the simulations of ICME propagation, as two very different ICMEs may look very similar in only one observational location. The direction and width of the CME as parameters essential to a correct estimation of arrival time and amplitude of the ICME signal. We find that these are problematic to extract from the analysis of SOHO/LASCO images commonly used for input to ICME propagation models. We further confirm that MGS magnetometer and electron reflectometer data can be used to study not only ICME events but also SEP events at Mars, with good results providing a consistent picture of the events when combined with near-Earth data.

Investigations of the sensitivity of a coronal mass ejection model (ENLIL) to solar input parameters

Falkenberg, T. V.; Vršnak, B.; Taktakishvili, A.; Odstrcil, D.; MacNeice, P.; Hesse, M.

Space Weather, Volume 8, Issue 6, CiteID S06004, **2010**

Understanding space weather is not only important for satellite operations and human exploration of the solar system but also to phenomena here on Earth that may potentially disturb and disrupt electrical signals. Some of the most violent space weather effects are caused by coronal mass ejections (CMEs), but in order to predict the caused effects, we need to be able to model their propagation from their origin in the solar corona to the point of interest, e.g., Earth. Many such models exist, but to understand the models in detail we must understand the primary input parameters. Here we investigate the parameter space of the ENLILv2.5b model using the CME event of 25 July 2004. ENLIL is a time-dependent 3-D MHD model that can simulate the propagation of cone-shaped interplanetary coronal mass ejections (ICMEs) through the solar system. Excepting the cone parameters (radius, position, and initial velocity), all remaining parameters are varied, resulting in more than 20 runs investigated here. The output parameters considered are velocity, density, magnetic field strength, and temperature. We find that the largest effects on the model output are the input parameters of upper limit for ambient solar wind velocity, CME density, and elongation factor, regardless of whether one's main interest is arrival time, signal shape, or signal amplitude of the ICME. We find that though ENLILv2.5b currently does not include the magnetic cloud of the ICME, it replicates the signal at L1 well in the studied event. The arrival time difference between satellite data and the ENLILv2.5b baseline run of this study is less than 30 min.

Application of Novel Interplanetary Scintillation Visualisations using LOFAR: A Case Study of Merged CMEs from September 2017

R.A. **Fallows**, **K. Iwai**, **B.V. Jackson**, **P. Zhang**, **M.M. Bisi**, **P. Zucca**

Advances in Space Research **2022**

<https://arxiv.org/pdf/2210.02135.pdf>

Observations of interplanetary scintillation (IPS - the scintillation of compact radio sources due to density variations in the solar wind) enable the velocity of the solar wind to be determined, and its bulk density to be estimated, throughout the inner heliosphere. A series of observations using the Low Frequency Array (LOFAR - a radio telescope centred on the Netherlands with stations across Europe) were undertaken using this technique to observe the passage of an ultra-fast CME which launched from the Sun following the X-class flare of **10 September 2017**. LOFAR observed the strong radio source 3C147 at an elongation of 82 degrees from the Sun over a period of more than 30 hours and observed a

strong increase in speed to 900km/s followed two hours later by a strong increase in the level of scintillation, interpreted as a strong increase in density. Both speed and density remained enhanced for a period of more than seven hours, to beyond the period of observation. Further analysis of these data demonstrates a view of magnetic-field rotation due to the passage of the CME, using advanced IPS techniques only available to a unique instrument such as LOFAR.

Clustering of magnetic reconnection exhausts in the solar wind: An automated detection study

Naïs **Fargette**^{1,2}, Benoît Lavraud^{3,2}, Alexis P. Rouillard², Pierre S. Houdayer⁴, Tai D. Phan⁵, Marit Øieroset⁵, Jonathan P. Eastwood¹, Georgios Nicolaou⁶, Andrei Fedorov², Philippe Louarn², Christopher J. Owen⁶ and Tim S. Horbury¹

A&A 674, A98 (2023)

<https://www.aanda.org/articles/aa/pdf/2023/06/aa46043-23.pdf>

Context. Magnetic reconnection is a fundamental process in astrophysical plasmas that enables the dissipation of magnetic energy at kinetic scales. Detecting this process in situ is therefore key to furthering our understanding of energy conversion in space plasmas. However, reconnection jets typically scale from seconds to minutes in situ, and as such, finding them in the decades of data provided by solar wind missions since the beginning of the space era is an onerous task.

Aims. In this work, we present a new approach for automatically identifying reconnection exhausts in situ in the solar wind. We apply the algorithm to Solar Orbiter data obtained while the spacecraft was positioned at between 0.6 and 0.8 AU and perform a statistical study on the jets we detect.

Methods. The method for automatic detection is inspired by the visual identification process and strongly relies on the Walén relation. It is enhanced through the use of Bayesian inference and physical considerations to detect reconnection jets with a consistent approach.

Results. Applying the detection algorithm to one month of Solar Orbiter data near 0.7 AU, we find an occurrence rate of seven jets per day, which is significantly higher than in previous studies performed at 1 AU. We show that they tend to cluster in the solar wind and are less likely to occur in the tenuous solar wind ($< 10 \text{ cm}^{-3}$ near 0.7 AU). We discuss why the source and the degree of Alfvénicity of the solar wind might have an impact on magnetic reconnection occurrence.

Conclusions. By providing a tool to quickly identify potential magnetic reconnection exhausts in situ, we pave the way for broader statistical studies on magnetic reconnection in diverse plasma environments.

The preferential orientation of magnetic switchbacks and its implications for solar magnetic flux transport

Naïs **Fargette**¹, Benoit Lavraud^{1,2}, Alexis P. Rouillard¹, Victor Réville¹, Stuart D. Bale^{3,4} and Justin Kasper⁵

A&A 663, A109 (2022)

<https://www.aanda.org/articles/aa/pdf/2022/07/aa43537-22.pdf>

Context. Magnetic switchbacks in the solar wind are large deflections of the magnetic field vector, which often reverse their radial component, and are associated with a velocity spike consistent with their Alfvénic nature. The Parker Solar Probe (PSP) mission revealed them to be a dominant feature of the near-Sun solar wind. Where and how they are formed remains unclear and subject to discussion.

Aims. We investigate the orientation of the magnetic field deflections in switchbacks to determine if they are characterized by a possible preferential orientation.

Methods. We compute the deflection angles, $\psi = [\phi, \theta]T$, of the magnetic field relative to the theoretical Parker spiral direction for encounters 1 to 9 of the PSP mission. We first characterize the distribution of these deflection angles for quiet solar wind intervals and assess the precision of the Parker model as a function of distance from the Sun. We then assume that the solar wind is composed of two populations, the background quiet solar wind and the population of switchbacks, the latter of which is characterized by larger fluctuations. We model the total distribution of deflection angles we observe in the solar wind as a weighed sum of two distinct normal distributions, each corresponding to one of the populations. We fit the observed data with our model using a Monte Carlo Markov chain algorithm and retrieve the most probable mean vector and covariance matrix coefficients of the two Gaussian functions, as well as the population proportion. This method allows us to quantify the properties of both the quiet solar wind and the switchback populations without setting an arbitrary threshold on the magnetic field deflection angles.

Results. We first confirm that the Parker spiral is a valid model for quiet solar wind intervals at PSP distances. We observe that the accuracy of the spiral direction in the ecliptic is a function of radial distance, in a manner that is consistent with PSP being near the solar wind acceleration region. We then find that the fitted switchback population presents a systematic bias in its deflections, with a mean vector consistently shifted toward lower values of ϕ (-5.52° on average) and θ (-2.15° on average) compared to the quiet solar wind population. This results holds for all encounters but

encounter 6, and regardless of the magnetic field main polarity. This implies a marked preferential orientation of switchbacks in the clockwise direction in the ecliptic plane, and we discuss this result and its implications in the context of the existing switchback formation theories. Finally, we report the observation of a 12-hour patch of switchbacks that systematically deflect in the same direction, such that the magnetic field vector tip within the patch deflects and returns to the Parker spiral within a given plane. **1-10 Apr 2019**

Characteristic Scales of Magnetic Switchback Patches Near the Sun and Their Possible Association With Solar Supergranulation and Granulation

Naïs **Fargette**¹, Benoit Lavraud^{1,2}, Alexis P. Rouillard¹, Victor Réville¹, Thierry Dudok De Wit³, Clara Froment³, Jasper S. Halekas⁴, Tai D. Phan⁵, David M. Malaspina^{6,7}, Stuart D. Bale⁵ [Show full author list](#)
2021 ApJ 919 96

<https://doi.org/10.3847/1538-4357/ac1112>

Parker Solar Probe (PSP) data recorded within a heliocentric radial distance of 0.3 au have revealed a magnetic field dominated by Alfvénic structures that undergo large local variations or even reversals of the radial magnetic field. They are called magnetic switchbacks, they are consistent with folds in magnetic field lines within a same magnetic sector and are associated with velocity spikes during an otherwise calmer background. They are thought to originate either in the low solar atmosphere through magnetic reconnection processes or result from the evolution of turbulence or velocity shears in the expanding solar wind. In this work, we investigate the temporal and spatial characteristic scales of magnetic switchback patches. We define switchbacks as a deviation from the nominal Parker spiral direction and detect them automatically for PSP encounters 1, 2, 4, and 5. We focus in particular on a 5.1 day interval dominated by switchbacks during E5. We perform a wavelet transform of the solid angle between the magnetic field and the Parker spiral and find periodic spatial modulations with two distinct wavelengths, respectively consistent with solar granulation and supergranulation scales. In addition we find that switchback occurrence and spectral properties seem to depend on the source region of the solar wind rather than on the radial distance of PSP. These results suggest that switchbacks are formed in the low corona and modulated by the solar surface convection pattern.

A Machine Learning Approach to Understanding the Physical Properties of Magnetic Flux Ropes in the Solar Wind at 1 AU

Hameedullah **Farooki**, [Yasser Abdulllah](#), [Sung Jun Noh](#), [Hyomin Kim](#), [George Bizos](#), [Youra Shin](#), [Jason T. L. Wang](#), [Haimin Wang](#)

ApJ **961** 81 **2024**

<https://arxiv.org/pdf/2311.09345.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ad0c52/pdf>

Interplanetary magnetic flux ropes (MFRs) are commonly observed structures in the solar wind, categorized as magnetic clouds (MCs) and small-scale MFRs (SMFRs) depending on whether they are associated with coronal mass ejections. We apply machine learning to systematically compare SMFRs, MCs, and ambient solar wind plasma properties. We construct a dataset of 3-minute averaged sequential data points of the solar wind's instantaneous bulk fluid plasma properties using about twenty years of measurements from `{Wind}`. We label samples by the presence and type of MFRs containing them using a catalog based on Grad-Shafranov (GS) automated detection for SMFRs and NASA's catalog for MCs (with samples in neither labeled non-MFRs). We apply the random forest machine learning algorithm to find which categories can be more easily distinguished and by what features. MCs were distinguished from non-MFRs with an AUC of 94% and SMFRs with an AUC of 89% and had distinctive plasma properties. In contrast, while SMFRs were distinguished from non-MFRs with an AUC of 86%, this appears to rely solely on the $\langle B \rangle > 5$ nT threshold applied by the GS catalog. The results indicate that SMFRs have virtually the same plasma properties as the ambient solar wind, unlike the distinct plasma regimes of MCs. We interpret our findings as additional evidence that most SMFRs at 1 au are generated within the solar wind, and furthermore, suggesting that they should be considered a salient feature of the solar wind's magnetic structure rather than transient events.

Magnetic Field Dropouts at Near-Sun Switchback Boundaries: A Superposed Epoch Analysis

W. M. **Farrell**, R. J. MacDowall, J. R. Gruesbeck, S. D. Bale, and J. C. Kasper

2020 ApJS 249 28

<https://doi.org/10.3847/1538-4365/ab9eba>

During Parker Solar Probe's first close encounter with the Sun in early 2018 November, a large number of impulsive rotations in the magnetic field were detected within 50 R_s; these also occurred in association with short-lived impulsive solar wind bursts in speed. These impulsive features are now called "switchback" events. We examined a set of these

switchbacks where the boundary transition into and out of the switchback was abrupt, with fast B rotations and simultaneous solar wind speed changes occurring on timescales of less than ~ 10 s; these thus appear as step function-like changes in the radial component of B and V . Our objective was to search for any diamagnetic effects that might occur especially if the boundaries are associated with quick changes in density (i.e., a steep spatial density gradient at the switchback boundary). We identified 25 switchback entries where the radial component of B , B_r , quickly transitioned from large negative to positive values and V_r simultaneously abruptly increased (i.e., step-up transitions) and 28 switchback exits where B_r quickly transitioned from large positive to negative values and V_r simultaneously abruptly decreased (i.e., step-down transitions). We then performed a superposed epoch analysis on each of these sets of events. We found these fast-transitioning events typically had a clear and distinct decrease in the magnetic field magnitude by 7%–8% detected exactly at the boundary. The presence of the $|B|$ dropout suggests there is a diamagnetic current present at the boundary.

How Magnetic Reconnection May Affect the Coherence of Interplanetary Coronal Mass Ejections

C. J. **Farrugia**¹, B. J. Vasquez¹, N. Lugaz¹, N. A. Al-Haddad¹, I. G. Richardson^{2,3} +++

On **2020 April 19–20**, a solar ejection was seen by spacecraft in a radial alignment that included Solar Orbiter and Wind. The ejection contained a magnetic flux rope where magnetic field and plasma parameters were well correlated between spacecraft. This structure is called an "unperturbed magnetic flux rope" (UMFR). Ahead of the UMFR is a portion of the ejection (not sheath) that is referred to as "upstream" (US). We focus on the US and inquire why the correlation is so much weaker there. Specifically, we analyze data collected by Solar Orbiter at 0.81 au and Wind at L1. We show that a plausible cause for the lack of coherence in the US is a combination of front erosion and internal reconnection occurring there. Front erosion is inferred from an analysis of azimuthal magnetic flux balance in the UMFR. In the present case, we contend that the US, rather than the UMFR, is the source of the eroded field lines. The presence of erosion is supported further by a direct comparison of the magnetic field data at both spacecraft that shows, in particular, a massive shrinkage of the front portion of the US. Internal reconnection is also happening at thin current sheets inside the US. Strong nonradial flows are reconfiguring the structure. As a result of these reconnection processes, a whole section of the US is disrupted and field lines move down the flanks of the ejection and out of view of Wind.

A Study of a Magnetic Cloud Propagating Through Large-Amplitude Alfvén Waves

We discuss Wind observations of a long and slow magnetic cloud (MC) propagating through large-amplitude Alfvén waves (LAAWs). The MC axis has a strong component along GSE X , as also confirmed by a Grad-Shafranov reconstruction. It is overtaking the solar wind at a speed roughly equal to the upstream Alfvén speed, leading to a weak shock wave 17 hr ahead. We give evidence to show that the nominal sheath region is populated by LAAWs: (i) a well-defined de Hoffmann-Teller frame in which there is excellent correlation between the field and flow vectors, (ii) constant field and total pressure, and (iii) an Alfvén ratio (i.e., ratio of kinetic-to-magnetic energy of the fluctuations) near unity at frequencies much lower than the ion cyclotron frequency in the spacecraft frame. In the region where the LAAWs approach the MC's front boundary there are field and flow discontinuities. At the first, magnetic reconnection is taking place, as deduced from a stress balance test (Walén test). This severs connection of some field lines to the Sun and the solar wind strahl disappears. There follows a 2-hr interval where the magnetic field strength is diminished while pressure balance is maintained. Here the bidirectionality of the suprathermal electron flows is intermittently disrupted. This interval ends with a slow expansion fan downstream of which there is a dropout of halo electrons just inside the front boundary of the MC. This study illustrates an untypical case of a slow MC interacting with LAAWs in the slow solar wind. **3-5 Feb 1998**

Features of the interaction of interplanetary coronal mass ejections/magnetic clouds with the Earth's magnetosphere

C.J. **Farrugia**, N.V. Erkaev, V.K. Jordanova, N. Lugaz, P.E. Sandholt, S. Mühlbacher, R.B. Torbert

JASTP, 99, July 2013, Pages 14–26

The interaction of interplanetary coronal mass ejections (ICMEs) and magnetic clouds (MCs) with the Earth's magnetosphere exhibits various interesting features principally due to interplanetary parameters which change slowly and reach extreme values of long duration. These, in turn, allow us to explore the geomagnetic response to continued and extreme driving of the magnetosphere. In this paper we shall discuss elements of the following: (i) anomalous features of the flow in the terrestrial magnetosheath during ICME/MC passage and (ii) large geomagnetic disturbances when total or partial mergers of ICMEs/MCs pass Earth. In (i) we emphasize two roles played by the upstream Alfvén Mach number in solar wind–magnetosphere interactions: (i) It gives rise to wide plasma depletion layers. (ii) It enhances the magnetosheath flow speed on draped magnetic field lines. (By plasma depletion layer we mean a magnetosheath region adjacent to the magnetopause where magnetic forces dominate over hydrodynamic forces.) In (ii) we stress that the ICME mergers elicit geoeffects over and above those of the individual members. In addition, features of the non-linear behavior of the magnetosphere manifest themselves.

Deep Solar Activity Minimum 2007 – 2009: Solar Wind Properties and Major Effects on the Terrestrial Magnetosphere

C. J. [Farrugia](#), B. Harris, M. Leitner, C. Möstl, A. B. Galvin, K. D. C. Simunac, R. B. Torbert, M. B. Temmer, A. M. Veronig, N. V. Erkaev, ...

Solar Physics, November 2012, Volume 281, Issue 1, pp 461–489

We discuss the temporal variations and frequency distributions of solar wind and interplanetary magnetic field parameters during the solar minimum of 2007 – 2009 from measurements returned by the IMPACT and PLASTIC instruments on STEREO-A. We find that the density and total field strength were significantly weaker than in the previous minimum. The Alfvén Mach number was higher than typical. This reflects the weakness of magnetohydrodynamic (MHD) forces, and has a direct effect on the solar wind–magnetosphere interactions. We then discuss two major aspects that this weak solar activity had on the magnetosphere, using data from Wind and ground-based observations: i) the dayside contribution to the cross-polar cap potential (CPCP), and ii) the shapes of the magnetopause and bow shock. For i) we find a low interplanetary electric field of 1.3 ± 0.9 mV m⁻¹ and a CPCP of 37.3 ± 20.2 kV. The auroral activity is closely correlated to the prevalent stream–stream interactions. We suggest that the Alfvén wave trains in the fast streams and Kelvin–Helmholtz instability were the predominant agents mediating the transfer of solar wind momentum and energy to the magnetosphere during this three-year period. For ii) we determine 328 magnetopause and 271 bow shock crossings made by Geotail, Cluster 1, and the THEMIS B and C spacecraft during a three-month interval when the daily averages of the magnetic and kinetic energy densities attained their lowest value during the three years under survey. We use the same numerical approach as in Fairfield's (J. Geophys. Res. 76, 7600, 1971) empirical model and compare our findings with three magnetopause models. The stand-off distance of the subsolar magnetopause and bow shock were 11.8 R_E and 14.35 R_E, respectively. When comparing with Fairfield's (1971) classic result, we find that the subsolar magnetosheath is thinner by ~ 1 R_E. This is mainly due to the low dynamic pressure which results in a sunward shift of the magnetopause. The magnetopause is more flared than in Fairfield's model. By contrast the bow shock is less flared, and the latter is the result of weaker MHD forces.

Multiple, distant (40°) in situ observations of a magnetic cloud and a corotating interaction region complex

C.J. [Farrugia](#), , , D.B. Berdichevskyb, C. Möstlc, A.B. Galvina, M. Leitnerd, M.A. Popeckia, K.D.C. Simunaca, A. Opitze, B. Lavraude, K.W. Ogilvief, A.M. Veronigg, M. Temmerc, J.G. Luhmannh and J.A. Sauvaud

Journal of Atmospheric and Solar-Terrestrial Physics, Volume 73, Issue 10, 2011, Pages 1254–1269

We report a comprehensive analysis of in situ observations made by Wind and the STEREO probes (STA, STB) of a complex interaction between a magnetic cloud (MC) and a corotating interaction region (CIR) occurring near the heliospheric current sheet (HCS) on **November 19–21, 2007**. The probes were separated by 0.7 AU (40°) with a spread in heliographic latitudes (4.8°, 2.2°, and –0.4°, for STB, Wind and STA, respectively). We employ data from the MFI, SWE and 3DP instruments on Wind, and the PLASTIC and IMPACT suites on STEREO. STB, located east of Earth, observed a forward shock followed by signatures of a MC. The MC took the role of the HCS in that the polarity of the interplanetary magnetic field (IMF) on exit was the reverse of that on entry. A passage through a plasma sheet was observed. Along the Sun–Earth line Wind observed a stream interface (SI) between a forward and a reverse shock. A MC, compressed by the CIR, was entrained in this. STA, located 20° to the west of Earth, saw a MC which was not preceded by a shock. A SI trailed the transient. The shocks are examined using various methods and from this it is concluded that the forward shock at Wind—but not at STB—was driven by the MC. Examining the MC by Grad–Shafranov reconstruction, we find evidence of a double-flux rope structure at Wind and STA and possibly also at STB.

The orientations are at variance with the notion of a large-scale flux tube being observed at the three spacecraft. We find consistency of this with the directional properties of the solar wind “strahl” electrons. We examine aspects of the geomagnetic response and find a double-dip storm corresponding to the two interplanetary triggers. The minimum Dst phase was prolonged and the geoeffects were intensified due to the interaction. We conclude that while the formation of compound streams is a common feature of interplanetary space, understanding their components when CIRs are involved is a complicated matter needing numerical simulations and/or more in situ observations for its complete elucidation.

Research highlights

► Three-spacecraft observations and analysis of a complex interaction between a magnetic cloud (MC) and a corotating interaction region (CIR). ► A MC cloud consisting of two flux ropes and distorted by the interaction with the CIR. ► Force-free and Grad Shafranov modeling challenge the classic picture of a MC as a large-scale, bent coherent flux tube. ► An element of the geomagnetic response consists of a double-dip magnetic storm.

A two-ejecta event associated with a two-step geomagnetic storm

C. J. [Farrugia](#), C.J., Jordanova, V.K., Thomsen, M.F., Lu, G., Cowley, S.W.H., Ogilvie, K.W., JGR, VOL. 111, A11104, 2006

A new view on how large disturbances in the magnetosphere may be prolonged and intensified further emerges from a recently discovered interplanetary process: the collision/merger of interplanetary (IP) coronal mass ejections (ICMEs; ejecta) within 1 AU. As shown in a recent pilot study, the merging process changes IP parameters dramatically with respect to values in isolated ejecta. The resulting geoeffects of the coalesced (“complex”) ejecta reflect a superposition of IP triggers which may result in, for example, two-step, major geomagnetic storms. In a case study, we isolate the effects on ring current enhancement when two coalescing ejecta reached Earth on **31 March 2001**. The magnetosphere “senses” the presence of the two ejecta and responds with a reactivation of the ring current soon after it started to recover from the passage of the first ejection, giving rise to a double-dip (DD) great storm (each min $Dst < -250$ nT). A drift-loss global kinetic model of ring current buildup shows that in this case the major factor determining the intensity of the storm activity is the very high (up to ~ 10 cm⁻³) plasma sheet density. The plasma sheet density, in turn, is found to correlate well with the very high solar wind density, suggesting the compression of the leading ejecta as the source of the hot, superdense plasma sheet in this case. This correlation is similar to that obtained in a previous investigation extending over several years, but the present case study extends the range of plasma sheet densities from ~ 2 to ~ 10 cm⁻³. Since the features of the ejecta interaction in this example are fairly general, we propose that interacting ejecta are a new, important IP source of DD major storms. Peculiarities in the behavior of the magnetopause current during these extreme events are briefly discussed in the light of recent work. In a brief discussion of a second example (**21–23 October 2001**), we suggest that by strengthening the leading shock, the ejecta merger may have added to the “shock-driver gas” origin of DD geomagnetic storms by increasing the ability of the shock to compress preexisting $B_z < 0$ magnetic fields.

Relating near-Earth observations of an interplanetary coronal mass ejection to the conditions at its site of origin in the solar corona

Front. Phys., 12 May 2021 |

<https://doi.org/10.3389/fphy.2021.679780>

<https://www.frontiersin.org/articles/10.3389/fphy.2021.679780/full>

During solar eruptions, many closed magnetic flux ropes are ejected into interplanetary space, which contribute to the heliospheric magnetic field and have important space weather effect because of their coherent magnetic field. Therefore, understanding the evolution of these closed flux ropes in the interplanetary space is important. In this paper, we examined all the magnetic and plasma data measured in 1997 by the Wind spacecraft and identified 621 reconnection exhausts. Of the 621 reconnection events, 31 were observed at the boundaries of magnetic flux ropes and were thought to cause the opening or disconnection magnetic field lines of the adjacent ropes. Of the 31 magnetic reconnection events, 29 were interchange reconnections and the closed field lines of these related flux ropes were opened by them. Only 2 of the 31 magnetic reconnection events disconnected the opened field lines of the original flux ropes. These observations indicate that interchange reconnection and disconnection may be two important mechanisms changing the magnetic topology of the magnetic flux ropes during their propagation during the interplanetary space. **Nov 9, 1997, Nov 16, 1997**

Table 1. The magnetic reconnection exhausts and their related flux ropes. (1997)

Statistical Study of ICMEs with Low Mean Carbon Charge State Plasmas Detected from 1998 to 2011

Xuedong Feng^{1,2}, Shuo Yao¹, Dongni Li¹, Gang Li^{1,3}, and Xiaoli Yan⁴

2018 ApJ 868 124

<http://iopscience.iop.org/article/10.3847/1538-4357/aae92c/pdf>

We present a statistical study of 219 ICMEs measured by both ACE and WIND from 1998 to 2011. ICME plasmas are defined as possessing cold materials if the carbon average charge states are lower than those of the preceding solar wind by three standard deviations and the carbon ionic temperature is lower than 106.05 K. A total of 69 ICMEs were identified as containing cold materials. These ICMEs tend to have speeds in the range of 300–600 km s⁻¹, with durations between 2 and 6 hr. Cold materials tend to be present once or twice per ICME. We further identify two special types of cold materials: the ionic-cold type (IC) shows simultaneous lower average charge states of O, Mg, Si, and Fe ions than those of the preceding solar wind, while the carbon-only cold type (COC) shows a totally opposite trend in that these ions show higher average charge than in the preceding solar wind. We found that the IC has a higher proton temperature than the ICME mean value, whereas the COC has a lower proton temperature than the ICME mean value, and the COC is most often measured in magnetic cloud. A detailed examination of the IC and the COC material suggests that they are related to solar filaments. Their special mean charge indicates that the filaments are a mixture of coronal and chromospheric materials. Heating and collision processes beyond the carbon freeze-in height are crucial in generating the two distinct types.

Observations on the Magnetic Disconnections of a Magnetic Cloud from the Sun through Magnetic Reconnection

H. Q. Feng, J. M. Wang, G. Q. Zhao, and Y. Zhao

2018 ApJ 864 101

Most coronal mass ejections (CMEs) originally exhibit closed magnetic flux rope (MFR) structures near the Sun. Moreover, the amount of magnetic field magnitude in the heliosphere can continually increase when CMEs propagate from the Sun to interplanetary space. To solve the problem of increased magnetic field magnitude, the closed field lines of MFRs should be opened and disconnected through magnetic reconnections. Here, we report a magnetic cloud (MC) associated with a magnetic reconnection exhaust measured by Wind over the period of 2001 **October 31 to November 1**. Observations of unidirectional suprathermal electron strahls revealed that part of the field lines before the rear boundary of the MC was opened. The magnetic reconnection event was disconnecting the opened field lines of the MC by merging with open field lines after the MC. These observations indicated that MFRs could be opened or disconnected in no particular order.

Data-driven modeling of the solar wind from 1 Rs to 1 AU

Xueshang Feng, Xiaopeng Ma, Changqing Xiang

JGR 2016

We present here a time-dependent three-dimensional magnetohydrodynamic (MHD) solar wind simulation from the solar surface to the Earth's orbit driven by time-varying line-of-sight solar magnetic field data. The simulation is based on the three-dimensional (3-D) solar-interplanetary (SIP) adaptive mesh refinement (AMR) space-time conservation

element and solution element (CESE) MHD (SIP-AMR-CESE MHD) model. In this simulation, we first achieve the initial solar wind background with the time-relaxation method by inputting a potential field obtained from the synoptic photospheric magnetic field and then generate the time-evolving solar wind by advancing the initial 3-D solar wind background with continuously varying photospheric magnetic field. The model updates the inner boundary conditions by using the projected normal characteristic method, inputting the high-cadence photospheric magnetic field data corrected by solar differential rotation, and limiting the mass flux escaping from the solar photosphere. We investigate the solar wind evolution from **1 July to 11 August 2008** with the model driven by the consecutive synoptic maps from the Global Oscillation Network Group. We compare the numerical results with the previous studies on the solar wind, the solar coronal observations from the Extreme ultraviolet Imaging Telescope board on Solar and Heliospheric Observatory, and the measurements from OMNI at 1 astronomical unit (AU). Comparisons show that the present data-driven MHD model's results have overall good agreement with the large-scale dynamical coronal and interplanetary structures, including the sizes and distributions of the coronal holes, the positions and shapes of the streamer belts, the heliocentric distances of the Alfvénic surface, and the transitions of the solar wind speeds. However, the model fails to capture the small-sized equatorial holes, and the modeled solar wind near 1 AU has a somewhat higher density and weaker magnetic field strength than observed. Perhaps better preprocessing of high-cadence observed photospheric magnetic field (particularly 3-D global measurements), combined with plasma measurements and higher resolution grids, will enable the data-driven model to more accurately capture the time-dependent changes of the ambient solar wind for further improvements. In addition, other measures may also be needed when the model is employed in the period of high solar activity.

Counterstreaming electrons in small interplanetary magnetic flux ropes†

H. Q. Feng, G. Q. Zhao, J. M. Wang

JGR Volume 120, Issue 12 Pages 10,175–10,184 2015

<http://onlinelibrary.wiley.com/doi/10.1002/2015JA021643/full>

Small interplanetary magnetic flux ropes (SIMFRs) are commonly observed by spacecraft at 1 AU, and their origin still remains disputed. We investigated the counterstreaming suprathermal electron (CSE) signatures of 106 SIMFRs measured by Wind during 1995–2005. We found that 79 (75%) of the 106 flux ropes contain CSEs, and the percentages of counterstreaming vary from 8% to 98%, with a mean value of 51%. CSEs are often observed in magnetic clouds (MCs), and this indicates these MCs are still attached to the Sun at both ends. CSEs are also related to heliospheric current sheets (HCSs) and the Earth's bow shock. We divided the SIMFRs into two categories, as follows: The first category is far from HCSs, and the second category is in the vicinity of HCSs. The first category has 57 SIMFRs, and only 7 of 57 ropes have no CSEs. This ratio is similar to that of MCs. The second category has 49 SIMFRs, however, 20 of the 49 events have no CSEs. This ratio is larger than that of MCs. These two categories have different origins. One category originates from the solar corona, and most ropes are still connected to the Sun at both ends. The other category is formed near HCSs in the interplanetary space. **12 October 2004, 11 November 2005**

Table 1. Percent Counterstreaming in SIMFRs

Observations of Several Unusual Plasma Compositional Signatures within Small Interplanetary Magnetic Flux Ropes

H. Q. Feng¹ and J. M. Wang

2015 ApJ 809 112

Interplanetary coronal mass ejections (ICMEs) often show unusual plasma compositional signatures (high He/P ratio, high O^{7+}/O^{6+} ratio, and high Fe charge states), and their enhanced charge states of oxygen and iron are caused by flare-related heating in the corona. We investigated the abnormal plasma composition of small interplanetary magnetic flux ropes (IMFRs) in terms of He/P ratio, O^{7+}/O^{6+} ratio, and mean Fe charge state. We discover that 18 of the 24 small IMFRs showed high He/P ratios. In addition, 12 and 8 of the 24 events showed high Fe charge states and O^{7+}/O^{6+} ratios, respectively. This observation implies that these small IMFRs and ICMEs may be caused by the same coronal eruptions.

MORPHOLOGICAL EVOLUTION OF A THREE-DIMENSIONAL CORONAL MASS EJECTION CLOUD RECONSTRUCTED FROM THREE VIEWPOINTS

L. Feng^{1,2}, B. Inhester², Y. Wei², W. Q. Gan¹, T. L. Zhang³, and M. Y. Wang

2012 ApJ 751 18

The propagation properties of coronal mass ejections (CMEs) are crucial to predict its geomagnetic effect. A newly developed three-dimensional (3D) mask fitting reconstruction method using coronagraph images from three viewpoints

has been described and applied to the CME ejected on **2010 August 7**. The CME's 3D localization, real shape, and morphological evolution are presented. Due to its interaction with the ambient solar wind, the morphology of this CME changed significantly in the early phase of evolution. Two hours after its initiation, it was expanding almost self-similarly. The CME's 3D localization is quite helpful to link remote sensing observations to in situ measurements. The investigated CME was propagating to Venus with its flank just touching STEREO B. Its corresponding interplanetary CME in the interplanetary space shows a possible signature of a magnetic cloud with a preceding shock in Venus Express (VEX) observations, while from STEREO B only a shock is observed. We have calculated three principal axes for the reconstructed 3D CME cloud. The orientation of the major axis is, in general, consistent with the orientation of a filament (polarity inversion line) observed by SDO/AIA and SDO/HMI. The flux rope axis derived by the Minimal Variance Analysis from VEX indicates a radial-directed axis orientation. It might be that locally only the leg of the flux rope passed through VEX. The height and speed profiles from the Sun to Venus are obtained. We find that the CME speed possibly had been adjusted to the speed of the ambient solar wind flow after leaving the COR2 field of view and before arriving at Venus. A southward deflection of the CME from the source region is found from the trajectory of the CME geometric center. We attribute it to the influence of the coronal hole where the fast solar wind emanated from.

Magnetic reconnection exhausts at the boundaries of small interplanetary magnetic flux ropes

H. Q. **Feng**^{1,2}, D. J. Wu³, J. M. Wang¹ and J. W. Chao
A&A 527, A67 (2011)

Context. Small interplanetary magnetic flux ropes (SIMFRs) are commonly observed by spacecraft at 1 AU.

Aims. We provide a mechanism to decrease the dimensions of some SIMFRs as they propagate away from the Sun.

Methods. We carefully examined the high-resolution magnetic field and plasma data from the Wind spacecraft during the period 1995–2005 to identify X-line magnetic reconnection exhausts at the boundaries of SIMFRs.

Results. We identified nine X-line magnetic reconnection exhausts at the boundaries of SIMFRs, which were destroying the flux within the related SIMFRs.

Conclusions. These observational facts indicate that the boundaries of some SIMFRs were still evolving through interaction with the background solar wind, and their spatial scales would diminish gradually.

Are all leading shocks driven by magnetic clouds?,

Feng, H. Q., D. J. Wu, J. K. Chao, L. C. Lee, and L. H. Lyu (2010),
J. Geophys. Res., 115, A04107, doi:10.1029/2009JA014875

Magnetic clouds (MCs) are commonly observed in association with shocks at 1 AU, and many authors have claimed that the leading shocks are driven by MCs, without any direct evidence. In this work we surveyed the relations between MCs and their associated shocks. Using the interplanetary plasma and magnetic field data measured by Wind, we have identified 97 MCs near Earth during 1995 to 2007. Sixty-two (64%) of the MCs were associated with leading shocks. As Lepping et al. have pointed out, if a leading shock is driven by an MC, the axis of the driver should be approximately perpendicular to the shock normal. We calculated the angle between the axis of the MC and its leading shock normal and found that the angle for 21 of the 62 MCs deviates from 90° by more than 25°. Seventeen of the 21 MCs also have the following signatures: (1) The MC leading edge moves more slowly than the preceding shock; and (2) the time interval between the preceding shock and the front boundary of the MC is always long, with an average period of 15.4 h. The speed profiles of the other four events revealed that the leading shock was driven not directly by the MC but by the immediately subsequent flow, and their sheath durations are shorter than the time interval between the preceding shocks and the MC front boundaries. Therefore, at least 21 (34%) of 62 leading shocks were not directly driven by MCs.

An operational method for shock arrival time prediction by one-dimensional CESE-HD solar wind model

Feng, X. S., Y. Zhang, L. P. Yang, S.T. Wu, M. Dryer
J. Geophys. Res., Vol. 114, No. A10, A10103, 2009
<http://dx.doi.org/10.1029/2009JA014385>

With the purpose of operational real-time forecasting for arrival times of flare/coronal mass ejection associated shocks in the vicinity of the Earth, a one-dimensional hydrodynamic (HD) shock propagation model is established by a novel numerical scheme, the space-time conservation element and solution element (CESE) method. The required observational data inputs to this new one-dimensional CESE-HD model are the low coronal radio Type II drift speed, the duration estimation, and the background solar wind speed for a solar eruptive event. Applying this model to 137 solar events during the period of February 1997 to August 2002, it is found that our model could be practically

equivalent to the STOA, ISPM, HAFv.2, and SPM models in forecasting the shock arrival time. The absolute error in the transit time from our model is not larger than those of the other four models for the same set of events. These results may demonstrate the potential capability of our model in terms of improving real-time forecasting because the CESE method can be extended to three-dimensional magnetohydrodynamics (3D-MHD) from the solar photosphere to any heliospheric position.

A practical database method for predicting arrivals of average interplanetary shocks at Earth,

Feng, X. S., Y. Zhang, W. Sun, M. Dryer, C. D. Fry, and C. S. Deehr

J. Geophys. Res., 114, A01101, (2009), <http://dx.doi.org/10.1029/2008JA013499>

A practical database method for predicting the interplanetary shock arrival time at L1 point is presented here. First, a shock transit time database (hereinafter called Database-I) based on HAFv.1 (version 1 of the Hakamada-Akasofu-Fry model) is preliminarily established with hypothetical solar events. Then, on the basis of the prediction test results of 130 observed solar events during the period from February 1997 to August 2002, Database-I is modified to create a practical database method, named Database-II, organized on a multidimensional grid of source location, initial coronal shock speed, and the year of occurrence of the hypothetical solar event. The arrival time at L1 for any given solar event occurring in the 23rd solar cycle can be predicted by looking up in the grid of Database-II according to source location, the initial coronal shock speed, and the year of occurrence in cycle 23. Within the hit window of ± 12 h, the success rate of the Database-II method for 130 solar events is 44%. This could be practically equivalent to the shock time of arrival (STOA) model, the interplanetary shock propagation model (ISPM), and the HAFv.2 model. To explore the capability of this method, it is tested on new data sets. These tests give reasonable results. In particular, this method's performance for a set of events in other cycles is as good as that of the STOA and ISPM models. This gives us confidence in its application to other cycles. From the viewpoint of long-term periodicity for solar activity, it is expected that the Database-II method can be applicable to the next solar cycle 24.

Geoeffective Analysis of CMEs Under Current Sheet Magnetic Coordinates,

Xueshang **Feng** and Xinhua Zhao,

[Astrophysics and Space Science, Volume 305, Number 1](#), 37-47, 2006

Using 100 CME-ICME events during 1997.01-2002.11, based on the eruptive source locations of CMEs and solar magnetic field observations at the photosphere, a current sheet magnetic coordinate (CMC) system is established in order to statistically study the characteristics of the CME-ICME events and the corresponding geomagnetic storm intensity.

A New Prediction Method for the Arrival Time of Interplanetary Shocks,

Xueshang **Feng** and Xinhua Zhao,

Solar Physics, Volume 238 Number 1, p. 167-186, 2006. **File**

Solar transient activities such as solar flares, disappearing filaments, and coronal mass ejections (CMEs) are solar manifestations of interplanetary (IP) disturbances. Forecasting the arrival time at the near Earth space of the associated interplanetary shocks following these solar disturbances is an important aspect in space weather forecasting because the shock arrival usually marks the geomagnetic storm sudden commencement (SSC) when the IMF B_z component is appropriately southward and/or the solar wind dynamic pressure behind the shock is sufficiently large. Combining the analytical study for the propagation of the blastwave from a point source in a moving, steady-state, medium with variable density (Wei, 1982; Wei and Dryer, 1991) with the energy estimation method in the ISPM model (Smith and Dryer, 1990, 1995), we present a new shock propagation model (called SPM below) for predicting the arrival time of interplanetary shocks at Earth. The duration of the X-ray flare, the initial shock speed and the total energy of the transient event are used for predicting the arrival of the associated shocks in our model. Especially, the background speed, i.e., the convection effect of the solar wind is considered in this model. Applying this model to 165 solar events during the periods of January 1979 to October 1989 and February 1997 to August 2002, we found that our model could be practically equivalent to the prevalent models of STOA, ISPM and HAFv.2 in forecasting the shock arrival time. The absolute error in the transit time in our model is not larger than those of the other three models for the same sample events. Also, the prediction test shows that the relative error of our model is $\leq 10\%$ for 27.88% of all events, $\leq 30\%$ for 71.52%, and $\leq 50\%$ for 85.46%, which is comparable to the relative errors of the other models. These results might demonstrate a potential capability of our model in terms of real-time forecasting.

Numerical modeling of cosmic rays in the heliosphere: Analysis of proton data from AMS-02 and PAMELA

Emanuele [Fiandrini](#), [Nicola Tomassetti](#), [Bruna Bertucci](#), [Federico Donnini](#), [Maura Graziani](#), [Behrouz Khiali](#)
2020

<https://arxiv.org/pdf/2010.08649.pdf>

Galactic cosmic rays (GCRs) inside the heliosphere are affected by solar modulation. To investigate this phenomenon and its underlying physical mechanisms, we have performed a data-driven analysis of the temporal dependence of the GCR proton flux over the solar cycle. We have modeled the solar modulation effect by means of stochastic simulations of cosmic particles in the heliospheric plasma. We have constrained our model using the recent time-resolved measurements of GCR proton fluxes reported by AMS-02 and PAMELA experiments, on monthly basis, from mid-2006 to mid-2017. With a global statistical analysis, we have determined the key model parameters that rules the GCR transport, its dependence on the particle rigidity, and its evolution over the solar cycle. Our data sample comprises epochs of solar minimum, solar maximum, as well as epochs with magnetic reversal and opposite polarities. Along with the evolution of the GCR transport parameters, we study their relationship with solar activity proxies and interplanetary parameters. We find that the rigidity dependence of the parallel mean free path of GCR diffusion shows a remarkable time dependence, indicating a long-term variability in the interplanetary turbulence that interchanges across different regimes over the solar cycle. The evolution of GCR diffusion parameters show a delayed correlation with the sunspot number, reflecting the dynamics of the heliospheric plasma, and different dependencies for opposite states of magnetic polarity, reflecting the influence of charge-sign dependent drift in the GCR modulation.

Characterizing Auroral-Zone Absorption Based on Global Kp and Regional Geomagnetic Hourly Range Indices

R. A. D. [Fiori](#), [L. Trichtchenko](#), [C. Balch](#), [E. Spanswick](#), [S. Groleau](#)

Space Weather e2020SW002572 **2020**

<https://agupubs.onlinelibrary.wiley.com/doi/10.1029/2020SW002572>

Increased ionization in the auroral oval leads to the absorption of high-frequency radio waves in the auroral zone, or auroral absorption. Auroral absorption is typically characterized by global geomagnetic activity indices, such as the Kp index. In this paper the hourly range of the magnetic field (HR) is examined as an alternative to the 3-hr Kp index for describing the dynamic and localized features of auroral absorption represented by the hourly range of absorption (HRA). Kp, magnetometer, and riometer data were examined for a 3-year period for stations spread across typical auroral latitudes. A general linear relationship was shown to exist between Kp and LOG10(HRA) for Kp < 4; for Kp ≥ 4 the correlation was weaker. A stronger linear correlation was demonstrated between LOG10(HRA) and LOG10(HR) for HR > 50 nT, characterized by a correlation coefficient of R = 0.63. Increased variability in the relationship between HRA and Kp was attributed to the following factors: the variability of the magnetic field within the 3-hr window characterized by the Kp index, which was better represented by a 1-hr HR; the dependence of the Kp index on subauroral magnetic data, which is not subject to the geomagnetic variations typically experienced within the auroral region; and reduced statistics for Kp > 6.

Global Circulation of the Open Magnetic Flux of the Sun

L. A. [Fisk](#) and J. C. Kasper

2020 ApJL 894 L4

<https://doi.org/10.3847/2041-8213/ab8acd>

The global circulation of the open magnetic flux of the Sun, the component of the solar magnetic field that opens into the heliosphere, and the consequences of the global circulation were proposed by Fisk and coworkers in the early 2000s. The Parker Solar Probe, on its initial encounters with the Sun, has provided direct confirmation of both the global circulation and the physical mechanism by which the circulation occurs, transport by interchange reconnection between open magnetic flux and large coronal loops. The implications of this confirmation of the global circulation of open magnetic flux and the importance of interchange reconnection is discussed.

Data-driven solar wind model and prediction of type II bursts

M. S. L. [Florens](#), Iver H. Cairns, S. A. Knock, P. A. Robinson

GEOPHYSICAL RESEARCH LETTERS, VOL. 34, L04104, doi:10.1029/2006GL028522, **2007**

Type II solar radio bursts are produced by shock waves moving through the corona and solar wind. An existing theory predicts Type II dynamic spectra by considering electron acceleration at the shock, growth of Langmuir waves, and their conversion into radiation. Two contributions are presented, both relevant to space weather research and missions like STEREO. First, a more realistic 2-dimensional model for the solar wind is developed, based on spacecraft data at 1 AU, and illustrated for a specific period. It relates time to longitude and extrapolates to different heliocentric distances using MHD style equations and power-law temperature models. Second, the type II theory is combined with the data-driven solar wind model to predict the dynamic spectrum of a specific Type II burst. The results show reasonable semiquantitative agreement with observations. Issues and possible improvements are outlined.

Comparing the Properties of ICME-Induced Forbush Decreases at Earth and Mars

JGR [Volume125, Issue3](#) March 2020 e2019JA027662

sci-hub.ru/10.1029/2019JA027662

Forbush decreases (FDs), which are short-term drops in the flux of galactic cosmic rays, are caused by the shielding from strong and/or turbulent magnetic structures in the solar wind, especially interplanetary coronal mass ejections (ICMEs) and their associated shocks, as well as corotating interaction regions. Such events can be observed at Earth, for example, using neutron monitors, and also at many other locations in the solar system, such as on the surface of Mars with the Radiation Assessment Detector instrument onboard Mars Science Laboratory. They are often used as a proxy for detecting the arrival of ICMEs or corotating interaction regions, especially when sufficient in situ solar wind measurements are not available. We compare the properties of FDs observed at Earth and Mars, focusing on events produced by ICMEs. We find that FDs at both locations show a correlation between their total amplitude and the maximum hourly decrease, but with different proportionality factors. We explain this difference using theoretical modeling approaches and suggest that it is related to the size increase of ICMEs, and in particular their sheath regions, en route from Earth to Mars. From the FD data, we can derive the sheath broadening factor to be between about 1.5 and 1.9, agreeing with our theoretical considerations. This factor is also in line with previous measurements of the sheath evolution closer to the Sun.

2.2. [Catalogs](#) of FDs at Earth and Mars

Tracking and validating ICMEs propagating towards Mars using STEREO Heliospheric Imagers combined with Forbush decreases detected by MSL/RAD

Johan L. Freiherr von [Forstner](#), [Jingnan Guo](#), [Robert F. Wimmer-Schweingruber](#), [Manuela Temmer](#), [Mateja Dumbović](#), [Astrid Veronig](#), [Christian Möstl](#), [Donald M. Hassler](#), [Cary J. Zeitlin](#), [Bent Ehresmann](#)

Space Weather [Volume17, Issue4](#) Pages 586-598 2019

<http://sci-hub.se/10.1029/2018SW002138>

The Radiation Assessment Detector (RAD) instrument onboard the Mars Science Laboratory (MSL) mission's Curiosity rover has been measuring galactic cosmic rays (GCR) as well as solar energetic particles (SEP) on the surface of Mars for more than 6 years since its landing in August 2012. The observations include a large number of Forbush decreases (FD) caused by interplanetary coronal mass ejections (ICMEs) and/or their associated shocks shielding away part of the GCR particles with their turbulent and enhanced magnetic fields while passing Mars.

This study combines MSL/RAD FD measurements and remote tracking of ICMEs using the STEREO Heliospheric Imager (HI) telescopes in a statistical study for the first time. The large dataset collected by HI makes it possible to analyze 149 ICMEs propagating towards MSL both during its 8-month cruise phase and after its landing on Mars. We link 45 of the events observed at STEREO-HI to their corresponding FDs at MSL/RAD and study the accuracy of the ICME arrival time at Mars predicted from HI data using different methods.

The mean differences between the predicted arrival times and those observed using FDs range from -11 h to 5 h for the different methods, with standard deviations between 17 and 20 hours. These values for predictions at Mars are very similar compared to other locations closer to the Sun, and also comparable to the precision of some other modeling approaches.

Forecasting GOES 15 >2 MeV electron fluxes from solar wind data and geomagnetic indices

C. [Forsyth](#), [C. E. J. Watt](#), [M. K. Mooney](#), [I. J. Rae](#), [S. D. Walton](#), [R. B. Horne](#)

Space Weather e2019SW002416 2020

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2019SW002416>

The flux of > 2 MeV electrons at geosynchronous orbit is used by space weather forecasters as a key indicator of enhanced risk of damage to spacecraft in low, medium or geosynchronous Earth orbits. We present a methodology that uses the amount of time a single input dataset (solar wind data or geomagnetic indices) exceeds a given threshold to produce deterministic and probabilistic forecasts of the > 2 MeV flux at GEO exceeding 1000 or 10000 cm⁻² s⁻¹ sr⁻¹ within up to 10 days. By comparing our forecasts with measured fluxes from GOES 15 between 2014 and 2016, we determine the optimum forecast thresholds for deterministic and probabilistic forecasts by maximising the ROC and Brier Skill Scores respectively. The training dataset gives peak ROC scores of 0.71 to 0.87 and peak Brier Skill Scores of -0.03 to 0.32. Forecasts from AL give the highest skill scores for forecasts of up to 6-days. AL, solar wind pressure or SYM-H give the highest skill scores over 7-10 days. Hit rates range over 56-89% with false alarm rates of 11-53%. Applied to 2012, 2013 and 2017, our best forecasts have hit rates of 56-83% and false alarm rates of 10-20%. Further tuning of the forecasts may improve these. Our hit rates are comparable to those from operational fluence forecasts, that incorporate fluence measurements, but our false alarm rates are higher. This proof-of-concept shows that the geosynchronous electron flux can be forecast with a degree of success without incorporating a persistence element into the forecasts.

ICMES IN THE INNER HELIOSPHERE: ORIGIN, EVOLUTION AND PROPAGATION EFFECTS

Report of Working Group G

Space Science Reviews (2006) 123: 383–416; **File**

This report assesses the current status of research relating the origin at the Sun, the evolution through the inner heliosphere and the effects on the inner heliosphere of the interplanetary counterparts of coronal mass ejections (ICMEs). The signatures of ICMEs measured by in-situ spacecraft are determined both by the physical processes associated with their origin in the low corona, as observed by space-borne coronagraphs, and by the physical processes occurring as the ICMEs propagate out through the inner heliosphere, interacting with the ambient solar wind. The solar and in-situ observations are discussed as are efforts to model the evolution of ICMEs from the Sun out to 1 AU.

Travel time classification of extreme solar events: Two families and an outlier

Freed, A. J.; Russell, C. T.

Geophysical Research Letters, Volume 41, Issue 19, pp. 6590-6594, 2014; **File**

Extreme solar events are of great interest because of the extensive damage that could be experienced by technological systems such as electrical transformers during such periods. In studying geophysical phenomena, it is helpful to have a quantitative measure of event strength so that similar events can be intercompared. Such a measure also allows the calculation of the occurrence rates of events with varying strength. We use historical fast travel time solar events to develop a measure of strength based on the Sun-Earth trip time. We find that these fast events can be grouped into two distinct families with one even faster outlier. That outlier is not the Carrington event of 1859 but the extremely intense solar particle event of August 1972. **1 September 1859, 20 October 1989, 23 July 2012**

Neural network applications in geomagnetic storm prognosis based on the pre-storm occurrence of magnetic islands in the solar wind

Mikhail **Fridman**

EGU2020-1848 May 2020

<https://meetingorganizer.copernicus.org/EGU2020/displays/36057>

So far, the problem of a short-term forecast of geomagnetic storms can be considered as solved. Meanwhile, mid-term prognoses of geomagnetic storms with an advance time from 3 hours to 3 days are still unsuccessful (see <https://www.swpc.noaa.gov/sites/default/files/images/u30/Max%20Kp%20and%20GPRPRA.pdf>) This fact suggests a necessity of looking for specific processes in the solar wind preceding geomagnetic storms. Knowing that magnetic cavities filled with magnetic islands and current sheets are formed in front of high-speed streams of any type (Khabarova et al., 2015, 2016, 2018; Adhikari et al., 2019), we have performed an analysis of the corresponding ULF variations in the solar wind density observed at the Earth's orbit from hours to days before the arrival of a geoeffective stream or flow. The fact of the occurrence of ULF-precursors of geomagnetic storms was noticed a long time ago (Khabarova 2007; Khabarova & Yermolaev, 2007) and related prognostic methods were recently developed (Kogai et al. 2019), while the problem of automatization of the prognosis remained unsolved.

A new geomagnetic storm forecast method, which employs a Recurrent Neural Network (RNN) for an automatic pattern search, is proposed. An ability of self-teaching and extracting deeply hidden non-linear patterns is the main advantage of Deep Neural Networks (DNNs) with multiple layers over traditional Machine Learning methods. We show a success of the RNN method, using either the unprocessed solar wind density data or Wavelet analysis coefficients as the input parameter for a DNN to perform an automatic mid-term prognosis of geomagnetic storms.

Direct evidence for magnetic reconnection at the boundaries of magnetic switchbacks with Parker Solar Probe

Pulupa](#), [C. Revillet](#), [M. L. Stevens](#)

A&A, PSP special issue **2021**

<https://arxiv.org/pdf/2101.06279.pdf>

Parker Solar Probe's first encounters with the Sun revealed the presence of ubiquitous localised magnetic deflections in the inner heliosphere; these structures, often called switchbacks, are particularly striking in solar wind streams originating from coronal holes. We report the direct evidence for magnetic reconnection occurring at the boundaries of three switchbacks crossed by Parker Solar Probe (PSP) at a distance of 45 to 48 solar radii of the Sun during its first encounter. We analyse the magnetic field and plasma parameters from the FIELDS and SWEAP instruments. The three structures analysed all show typical signatures of magnetic reconnection. The ion velocity and magnetic field are first correlated and then anti-correlated at the inbound and outbound edges of the bifurcated current sheets with a central ion flow jet. Most of the reconnection events have a strong guide field and moderate magnetic shear but one current sheet shows indications of quasi anti-parallel reconnection in conjunction with a magnetic field magnitude decrease by 90%. Given the wealth of intense current sheets observed by PSP, reconnection at switchbacks boundaries appears to be rare. However, as the switchback boundaries accommodate currents one can conjecture that the geometry of these boundaries offers favourable conditions for magnetic reconnection to occur. Such a mechanism would thus contribute in reconfiguring the magnetic field of the switchbacks, affecting the dynamics of the solar wind and eventually contributing to the blending of the structures with the regular wind as they propagate away from the Sun. **1-2 Nov 2018**

Estimating the Open Solar Flux from In-Situ Measurements

[Anna Marie Frost](#), [Mathew Owens](#), [Allan Macneil](#) & [Mike Lockwood](#)
[Solar Physics](#) volume 297, Article number: 82 (2022)

<https://link.springer.com/content/pdf/10.1007/s11207-022-02004-6.pdf>

A fraction of the magnetic flux threading the solar photosphere extends to sufficient heliocentric distances that it is dragged out by the solar wind. Understanding this open solar flux (OSF) is central to space weather, as the OSF forms the heliosphere, magnetically connects the Sun to the planets, and dominates the motion of energetic particles. Quantification of OSF is also a key means of verifying global coronal models. However, OSF estimates derived from extrapolating the magnetic field from photospheric observations are consistently smaller than those based on heliospheric magnetic field (HMF) measurements, by around a factor two. It is therefore important to understand the uncertainties in estimating OSF from in-situ HMF measurements. This requires both an assumption of latitudinal invariance in the radial component of the HMF in the heliosphere, and that structures without an immediate connection to the Sun, such as local magnetic field inversions (or 'switchbacks'), can be correctly accounted for. In this study, we investigate the second assumption. Following an established methodology, we use in-situ electron and magnetic data to determine the global topology of the HMF and correct for inversions that would otherwise lead to an overestimation of the OSF. The OSF estimation is applied to the interval 1994 – 2021 and combines measurements from the Wind and ACE spacecraft. This extends the time range over which this methodology has previously been applied from 13 years

(1998 – 2011) to 27 years. We find that inversions cannot fully explain the discrepancy between heliospheric and photospheric OSF estimations, with the best heliospheric estimate of OSF still, on average, a factor 1.6 higher than the values extrapolated from photospheric observations.

The contribution and FIP bias of three types of materials inside ICMEs associated with different flare intensities

Hui Fu, [Xinzheng Shi](#), [Zhenghua Huang](#), [Youqian Qi](#), [Lidong Xia](#)

ApJ **956** 129 **2023**

<https://arxiv.org/pdf/2309.09434.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/acfa76/pdf>

The studies on the origination and generation mechanisms of ICME materials are crucial for understanding the connection between CMEs and flares. The materials inside ICMEs can be classified into three types, coming from corona directly (corona-materials), heated by magnetic reconnection in corona (heated-corona-materials), and generated by chromospheric evaporation (chromospheric-evaporation-materials). Here, the contribution and First Ionization Potential (FIP) bias of three types of materials inside ICMEs associated with different flare intensities are analyzed and compared. We find that the speeds and scales of near-Earth ICMEs both increase with flare intensities. The proportions of heated-corona-materials are nearly constant with flare intensities. The contributions of corona-materials (chromospheric-evaporation-materials) are significantly decreased (increased) with flare intensities. More than two-thirds of materials are chromospheric-evaporation-materials for ICMEs associated with strong flares. The FIP bias of corona-materials and heated-corona-materials is almost the same. The FIP bias of chromospheric-evaporation-materials is significantly higher than that of corona-materials and heated-corona-materials, and it is increased with flare intensities. The above characteristics of FIP bias can be explained reasonably by the origination and generation mechanisms of three types of ICME materials. The present study demonstrates that the origination and generation mechanisms of ICME materials are significantly influenced by flare intensities. The reasons for the elevation of FIP bias, if ICMEs are regarded as a whole, are that the FIP bias of chromospheric-evaporation-materials is much higher, and the chromospheric-evaporation-materials contributed significantly to the ICMEs which associated with strong flares.

Variations of the Galactic Cosmic Rays in the Recent Solar Cycles

Shuai Fu, [Xiaoping Zhang](#), [Lingling Zhao](#), [Yong Li](#)

Astrophysical Journal Supplement **254** 37 **2021**

<https://arxiv.org/pdf/2104.07862.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4365/abf936/pdf>

<https://doi.org/10.3847/1538-4365/abf936>

In this paper, we study the galactic cosmic ray (GCR) variations over the solar cycles 23 and 24, with measurements from the NASA's ACE/CRIS instrument and the ground-based neutron monitors (NMs). The results show that the maximum GCR intensities of heavy nuclei (nuclear charge 5-28, 50-500 MeV/nuc) at 1 AU during the solar minimum in 2019-2020 break their previous records, exceeding those recorded in 1997 and 2009 by ~25% and ~6%, respectively, and are at the highest levels since the space age. However, the peak NM count rates are lower than those in late 2009. The difference between GCR intensities and NM count rates still remains to be explained. Furthermore, we find that the GCR modulation environment during the solar minimum P24/25 are significantly different from previous solar minima in several aspects, including remarkably low sunspot numbers, extremely low inclination of the heliospheric current sheet, rare coronal mass ejections, weak interplanetary magnetic field and turbulence. These changes are conducive to reduce the level of solar modulation, providing a plausible explanation for the record-breaking GCR intensities in interplanetary space.

The high helium abundance and charge states of the interplanetary CME and its material source on the Sun

Hui Fu, [R.A. Harrison](#), [J.A. Davies](#), [LiDong Xia](#), [XiaoShuai Zhu](#), [Bo Li](#), [ZhengHua Huang](#), [D. Barnes](#)

ApJL **900** L18 **2020**

<https://arxiv.org/pdf/2008.08816.pdf>

<https://doi.org/10.3847/2041-8213/abb083>

Identifying the source of the material within coronal mass ejections (CMEs) and understanding CME onset mechanisms are fundamental issues in solar and space physics. Parameters relating to plasma composition, such as charge states and He abundance (λ_{He}), may be different for plasmas originating from differing processes or regions on the Sun. Thus, it is crucial to examine the relationship between in-situ measurements of CME composition and activity on the Sun. We

study the CME that erupted on **2014 September 10**, in association with an X1.6 flare, by analyzing AIA imaging and IRIS spectroscopic observations and its in-situ signatures detected by Wind and ACE. We find that during the slow expansion and intensity increase of the sigmoid, plasma temperatures of 9 MK, and higher, first appear at the footpoints of the sigmoid, associated with chromospheric brightening. Then the high-temperature region extends along the sigmoid. IRIS observations confirm that this extension is caused by transportation of hot plasma upflow. Our results show that chromospheric material can be heated to 9 MK, and above, by chromospheric evaporation at the sigmoid footpoints before flare onset. The heated chromospheric material can transport into the sigmoidal structure and supply mass to the CME. The aforementioned CME mass supply scenario provides a reasonable explanation for the detection of high charge states and elevated $\langle n_e \rangle$ in the associated ICME. The observations also demonstrate that the quasi-steady evolution in the precursor phase is dominated by magnetic reconnection between the rising flux rope and the overlying magnetic field structure.

Helium abundance and speed difference between helium ions and protons in the solar wind from coronal holes, active regions, and quiet Sun

Hui Fu, [Maria S. Madjarska](#), [Bo Li](#), [LiDong Xia](#), [ZhengHua Huang](#)

MNRAS **2018**

<https://arxiv.org/pdf/1805.02880.pdf>

Two main models have been developed to explain the mechanisms of release, heating and acceleration of the nascent solar wind, the wave-turbulence-driven (WTD) models and reconnection-loop-opening (RLO) models, in which the plasma release processes are fundamentally different. Given that the statistical observational properties of helium ions produced in magnetically diverse solar regions could provide valuable information for the solar wind modelling, we examine the statistical properties of the helium abundance (A_{He}) and the speed difference between helium ions and protons ($v_{\alpha,p}$) for coronal holes (CHs), active regions (ARs) and the quiet Sun (QS). We find bimodal distributions in the space of A_{He} and $v_{\alpha,p}/v_A$ (where v_A is the local Alfvén speed) for the solar wind as a whole. The CH wind measurements are concentrated at higher A_{He} and $v_{\alpha,p}/v_A$ values with a smaller A_{He} distribution range, while the AR and QS wind is associated with lower A_{He} and $v_{\alpha,p}/v_A$, and a larger A_{He} distribution range. The magnetic diversity of the source regions and the physical processes related to it are possibly responsible for the different properties of A_{He} and $v_{\alpha,p}/v_A$. The statistical results suggest that the two solar wind generation mechanisms, WTD and RLO, work in parallel in all solar wind source regions. In CH regions WTD plays a major role, whereas the RLO mechanism is more important in AR and QS.

Charge States and FIP Bias of the Solar Wind from Coronal Holes, Active Regions, and Quiet Sun

Hui Fu¹, Maria S. Madjarska^{2,1}, LiDong Xia¹, Bo Li¹, ZhengHua Huang¹, and Zhipeng Wangguan

2017 ApJ 836 169

10.3847/1538-4357/aa5cba

Connecting in situ measured solar-wind plasma properties with typical regions on the Sun can provide an effective constraint and test to various solar wind models. We examine the statistical characteristics of the solar wind with an origin in different types of source regions. We find that the speed distribution of coronal-hole (CH) wind is bimodal with the slow wind peaking at ~ 400 km s⁻¹ and the fast at ~ 600 km s⁻¹. An anti-correlation between the solar wind speeds and the O7+/O6+ ion ratio remains valid in all three types of solar wind as well during the three studied solar cycle activity phases, i.e., solar maximum, decline, and minimum. The range and its average values all decrease with the increasing solar wind speed in different types of solar wind. The range (0.06–0.40, first ionization potential (FIP) bias range 1–7) for active region wind is wider than for CH wind (0.06–0.20, FIP bias range 1–3), while the minimum value of (~ 0.06) does not change with the variation of speed, and it is similar for all source regions. The two-peak distribution of CH wind and the anti-correlation between the speed and O7+/O6+ in all three types of solar wind can be explained qualitatively by both the wave-turbulence-driven and reconnection-loop-opening (RLO) models, whereas the distribution features of in different source regions of solar wind can be explained more reasonably by the RLO models.

Coronal Sources and In Situ Properties of the Solar Winds Sampled by ACE During 1999 – 2008

Hui Fu, [Bo Li](#), [Xing Li](#), [Zhenghua Huang](#), [Chaozhou Mou](#), [Fangran Jiao](#), [Lidong Xia](#)

Solar Phys. May 2015, Volume 290, [Issue 5](#), pp 1399-1415 **2015**

We identify the coronal sources of the solar winds sampled by the ACE spacecraft during 1999 – 2008 and examine the in situ solar wind properties as a function of wind sources. The standard two-step mapping technique is adopted to establish the photospheric footpoints of the magnetic flux tubes along which the ACE winds flow. The footpoints are then placed in the context of EIT 284 Å images and photospheric magnetograms, allowing us to categorize the sources

into four groups: coronal holes (CHs), active regions (ARs), the quiet Sun (QS), and “undefined”. This practice also enables us to establish the response to solar activity of the fractions occupied by each type of solar wind, and of their speeds and O7+/O6+ ratios measured in situ. We find that during the maximum phase, the majority of ACE winds originate from ARs. During the declining phase, CHs and ARs are equally important contributors to the ACE solar winds. The QS contribution increases with decreasing solar activity and maximizes in the minimum phase when the QS appears to be the primary supplier of the ACE winds. With decreasing activity, the winds from all sources tend to become cooler, as represented by the increasingly low O7+/O6+ ratios. On the other hand, during each activity phase, the AR winds tend to be the slowest and are associated with the highest O7+/O6+ ratios, while the CH winds correspond to the other extreme, with the QS winds lying in between. Applying the same analysis method to the slow winds alone, here defined as the winds with speeds lower than 500 km s⁻¹, we find basically the same overall behavior, as far as the contributions of individual groups of sources are concerned. This statistical study indicates that QS regions are an important source of the solar wind during the minimum phase.

Relationship Between Solar Wind Speed and Coronal Magnetic Field Properties

Ken'ichi **Fujiki**, Munetoshi Tokumaru, Tomoya Iju, Kazuyuki Hakamada, Masayoshi Kojima
Solar Phys. Volume 290, Issue 9, pp 2491-2505 **2015**

<http://arxiv.org/pdf/1507.03301v2.pdf>

We have studied the relationship between the solar-wind speed [V] and the coronal magnetic-field properties (a flux expansion factor [f] and photospheric magnetic-field strength [Bs]) at all latitudes using data of interplanetary scintillation and solar magnetic field obtained for 24 years from 1986 to 2009. Using a cross-correlation analyses, we verified that V is inversely proportional to f and found that V tends to increase with Bs if f is the same. As a consequence, we find that V has extremely good linear correlation with Bs/f. However, this linear relation of V and Bs/f cannot be used for predicting the solar-wind velocity without information on the solar-wind mass flux. We discuss why the inverse relation between V and f has been successfully used for solar-wind velocity prediction, even though it does not explicitly include the mass flux and magnetic-field strength, which are important physical parameters for solar-wind acceleration.

PRECURSORS OF THE FORBUSH DECREASE ON 2006 DECEMBER 14 OBSERVED WITH THE GLOBAL MUON DETECTOR NETWORK (GMDN)

A. **Fushishita**, T. Kuwabara, C. Kato et al.

Astrophysical Journal, 715:1239–1247, **2010** June

We analyze the precursor of a Forbush decrease (FD) observed with the Global Muon Detector Network on **2006 December 14**. An intense geomagnetic storm is also recorded during this FD with the peak Kp index of 8+. By using the “two-dimensional map” of the cosmic ray intensity produced after removing the contribution from the diurnal anisotropy, we succeed in extracting clear signatures of the precursor. A striking feature of this event is that a weak loss-cone (LC) signature is first recorded more than a day prior to the storm sudden commencement (SSC) onset. This suggests that the LC precursor appeared only 7 hr after the coronal mass ejection eruption from the Sun, when the interplanetary (IP) shock driven by the interplanetary coronal mass ejection was located at 0.4 AU from the Sun. We find the precursor being successively observed with multiple detectors in the network according to the Earth’s spin and confirmed that the precursor continuously exists in space. The long lead time (15.6 hr) of this precursor which is almost twice the typical value indicates that the interplanetary magnetic field (IMF) was more quiet in this event than a typical power spectrum assumed for the IMF turbulence. The amplitude (−6.45%) of the LC anisotropy at the SSC onset is more than twice the FD size, indicating that the maximum intensity depression behind the IP shock is much larger than the FD size recorded at the Earth in this event. We also find the excess intensity from the sunward IMF direction clearly observed during ~10 hr preceding the SSC onset. It is shown that this excess intensity is consistent with the measurement of the particles accelerated by the head-on collisions with the approaching shock. This is the first detailed observation of the precursor due to the shock reflected particles with muon detectors.

To the question about perturbations of solar-terrestrial characteristics

E. A. **Gavryuseva** (Institute for Nuclear Research RAS)

2018

<https://arxiv.org/pdf/1802.04348.pdf>

Data obtained over the last three solar cycles have been analysed to reveal the relationships between the intensity of the photospheric field measured along the line of sight by the WSO group at heliolatitudes from -75 to 75 degrees and the

intensity of the interplanetary magnetic field and absolute values of the perturbations of the different characteristics of the solar wind at the Earth orbit, and geomagnetic parameters. provided by the OMNI team.
The heliospheric and geomagnetic data are found to be divided into two groups characterized by their response to variability of the solar magnetic field latitudinal structures on short and on long time scales.

Relations between variability of the photospheric and interplanetary magnetic fields, solar wind and geomagnetic characteristics

E. A. [Gavryuseva](#) (Institute for Nuclear Research RAS)

2018

<https://arxiv.org/pdf/1802.03135.pdf>

Large scale solar magnetic field topology has a great influence on the structure of the corona, heliosphere and geomagnetic perturbations.

Data obtained over the last three solar cycles have been analysed to reveal the relationships between the photospheric field measured along the line of sight by the WSO group at 30 levels of heliolatitudes from -75 to 75 degrees and the interplanetary magnetic field. The main aim of this first paper is to make a direct comparison between the basic structure and dynamics of the photospheric magnetic field and components and intensity of the interplanetary magnetic field, solar wind and geomagnetic parameters without using theoretical assumptions, models, physical expectations, etc.

The second paper by Gavryuseva, 2018d presents the reports between different characteristics of the solar wind at the Earth orbit, and geomagnetic parameters provided by the OMNI team. % Data obtained over the last three solar cycles have been analysed % to reveal the relationships % between the photospheric field measured along the line of sight % by the WSO group % at heliolatitudes from -75 to 75 degrees averaged over one year % and the interplanetary magnetic field, different characteristics % of the solar wind at the Earth orbit, and geomagnetic parameters. % provided by the OMNI team.

The heliospheric and geomagnetic data are found to be divided into two groups characterized by their response to variability of the solar magnetic field latitudinal structures on short and on long time scales.

High-Speed Solar Wind Streams and Geomagnetic Storms During Solar Cycle 24

M. [Gerontidou](#), H. Mavromichalaki, T. Daglis

[Solar Physics](#) September 2018, 293:131

<https://link.springer.com/article/10.1007/s11207-018-1348-8>

An updated catalog is created of 303 well-defined high-speed solar wind streams that occurred in the time period 2009 – 2016. These streams are identified from solar and interplanetary measurements obtained from the OMNIWeb database as well as from the Solar and Heliospheric Observatory (SOHO) database. This time interval covers the deep minimum observed between the last two Solar Cycles 23 and 24, as well as the ascending, the maximum, and part of the descending phases of the current Solar Cycle 24. The main properties of solar-wind high-speed streams, such as their maximum velocity, their duration, and their possible sources are analyzed in detail. We discuss the relative importance of all those parameters of high-speed solar wind streams and especially of their sources in terms of the different phases of the current cycle. We carry out a comparison between the characteristic parameters of high-speed solar wind streams in the present solar cycle with those of previous solar cycles to understand the dependence of their long-term variation on the cycle phase. Moreover, the present study investigates the varied phenomenology related to the magnetic interactions between these streams and the Earth's magnetosphere. These interactions can initiate geomagnetic disturbances resulting in geomagnetic storms at Earth that may have impact on technology and endanger human activity and health.

Table : An updated catalogue of High-Speed Solar Wind Streams (HSSWSs) from 2009 to 2016.

Structure of the Photospheric Magnetic Field During Sector Crossings of the Heliospheric Magnetic Field

Tibebu [Getachew](#), Ilpo Virtanen, Kalevi Mursula

[Solar Physics](#) November **2017**, 292:174

The photospheric magnetic field is the source of the coronal and heliospheric magnetic fields (HMF), but their mutual correspondence is non-trivial and depends on the phase of the solar cycle. The photospheric field during the HMF sector crossings observed at 1 AU has been found to contain enhanced field intensities and definite polarity ordering, forming regions called Hale boundaries. Here we separately study the structure of the photospheric field during the HMF sector crossings during Solar Cycles 21 – 24 for the four phases of each solar cycle. We use a refined version of Svalgaard's list of major HMF sector crossings, mapped to the Sun using the solar wind speed observed at Earth, and the daily level-3 magnetograms of the photospheric field measured at the Wilcox Solar Observatory in 1976 – 2016. We find that the structure of the photospheric field corresponding to the HMF sector crossings and the existence and properties of the corresponding Hale bipolar regions varies significantly with solar cycle, solar cycle phase, and hemisphere. The Hale boundaries in more than half of the ascending, maximum, and declining phases are clear and statistically significant. The clearest Hale boundaries are found during the (+,-) HMF crossings in the northern hemisphere of odd Cycles 21 and 23, but less systematic during the (+,-) crossings in the southern hemisphere of even Cycles 22 and 24. No similar difference between odd and even cycles is found for the (-,+) crossings. This shows that the northern hemisphere has a more organized Hale pattern overall. The photospheric field distribution also depicts a larger area for the field of the northern hemisphere during the declining and minimum phases, in a good agreement with the bashful ballerina phenomenon.

Interaction of a coronal mass ejection and a stream interaction region: A case study

<https://www.aanda.org/articles/aa/pdf/2023/04/aa45433-22.pdf>

We investigated the interaction of a coronal mass ejection (CME) and a coronal hole (CH) in its vicinity using remote-sensing and 1 AU in situ data. We used extreme-ultraviolet images and magnetograms to identify coronal structures and coronagraph images to analyze the early CME propagation. The Wind spacecraft and the Advanced Composition Explorer (ACE) provide plasma and magnetic field data of near-Earth interplanetary space. We applied various diagnostic tools to the images and to the time-series data. We find that the CME erupts under a streamer and causes the evacuation of material at its far end, which is observable as dimming and subsequent CH formation. The CME is likely deflected in its early propagation and travels southwest of the Sun-Earth line. In situ data lack signatures of a large magnetic cloud, but show a small flux rope at the trailing edge of the interplanetary CME (ICME), followed by an Alfvénic wave. This wave is identified as exhaust from a Petschek-type reconnection region following the successful application of a Walén test. We infer that the two spacecraft at 1 AU most likely traverse the ICME leg that is in the process of reconnection along the heliospheric current sheet that separates the ICME and the high-speed stream outflowing from the CH. **2014: January 25, February 4-10, February 17**

Properties of stream interaction regions at Earth and Mars during the declining phase of SC 24

<https://doi.org/10.1051/0004-6361/202040162>

We inspect the evolution of SIRs from Earth to Mars (distance range 1-1.5 AU) over the declining phase of solar cycle 24 (2014-2018). So far, studies only analyzed SIRs measured at Earth and Mars at different times. We compare existing catalogs for both heliospheric distances and arrive at a clean dataset for the identical time range. This allows a well-sampled statistical analysis and for the opposition phases of the planets an in-depth analysis of SIRs as they evolve with distance. We use in-situ solar wind data from OMNI and the MAVEN spacecraft as well as remote sensing data from

SDO. A superposed epoch analysis is performed for bulk speed, proton density, temperature, magnetic field magnitude and total perpendicular pressure. Additionally, a study of events during the two opposition phases of Earth and Mars in the years 2016 and 2018 is conducted. SIR related coronal holes with their area as well as their latitudinal and longitudinal extent are extracted and correlated to the maximum bulk speed and duration of the corresponding high speed solar wind streams following the stream interaction regions. We find that while the entire solar wind HSS shows no expansion as it evolves from Earth to Mars, the crest of the HSS profile broadens by about 17%, and the magnetic field and total pressure by about 45% around the stream interface. The difference between the maximum and minimum values in the normalized superposed profiles increases slightly or stagnates from 1-1.5 AU for all parameters, except for the temperature. A sharp drop at zero epoch time is observed in the superposed profiles for the magnetic field strength at both heliospheric distances. Maximum solar wind speed has a stronger dependence on the latitudinal extent of the respective coronal hole than on its longitudinal extent. We arrive at an occurrence rate of fast forward shocks three times as high at Mars than at Earth. **2016-06-03, 06-29, 07-26, 08-21, 09-17**

The role of extreme geomagnetic storms in the Forbush decrease profile observed by neutron monitors

Ghag, K ; Tari, P ; Raghav, A ; +++

JOURNAL OF ATMOSPHERIC AND SOLAR-TERRESTRIAL PHYSICS V. 252, Article 106146, **2023**

DOI 10.1016/j.jastp.2023.106146

<https://arxiv.org/pdf/2112.09918.pdf>

The Forbush decrease (FD) and Geomagnetic storm (GS) are the two distinct space weather events having common causing agents like interplanetary coronal mass ejection (ICME) or corotating interacting region (CIR). Generally, large-amplitude FDs and extreme GSs are caused by ICME. Here, we studied eight ICME induced extreme storms and their effects on respective FD profiles as observed by neutron monitors. We observed the sudden storm commencement of the GS coincides with the FD onset. Interestingly, we also noted a gradual increase in neutron counts during the main and recovery phases of GS. The maximum enhancement in neutron counts coincides with the minimum value of the Sym-H index. The enhancement is visible primarily in all the neutron monitors but significantly pronounced in high-energy neutrons compared to low-energy neutrons. We observed that the enhancement in cosmic ray flux during Forbush decrease as observed by neutron monitors is contributed by magnetospheric disturbance of geomagnetic storm. Thus we conclude that the weakening of Earth's magnetic shield due to ICME-Magnetosphere interaction allows more cosmic rays to reach the ground. Thus, we conclude that the geomagnetic storm conditions highly influence the FD profile along with the external causing agent. Therefore, it is essential to include the effect of geomagnetic field variation in the models that are used to reproduce the FD profile. **13 July 1992 and 10 May 1991 , 24th November 2001 , 20 November 2003, 26 August 2018**

Distinct polytropic behavior of plasma during ICME-HSS Interaction

Kalpesh **Ghag**, [Anil Raghav](#), [Zubair Shaikh](#), [Georgios Nicolaou](#), [Omkar Dhamane](#), [Utsav Panchal](#) **2022**

<https://arxiv.org/pdf/2210.04065.pdf>

Interplanetary Coronal Mass Ejections (ICMEs) and High Speed Streams (HSSs) are noteworthy drivers of disturbance of interplanetary space. Interaction between them can cause several phenomena, such as; generation of waves, enhanced geo-effectiveness, particle acceleration, etc. However, how does thermodynamic properties vary during the ICME-HSS interaction remain an open problem. In this study, we investigated the polytropic behavior of plasma during an ICME-HSS interaction observed by STEREO and Wind spacecraft. We find that the ICME observed by the STEREO-A has polytropic index $\alpha=1.0$, i.e., exhibiting isothermal process. Moreover, Wind spacecraft observed the HSS region, non-interacting ICME, and ICME-HSS interaction region. During each regions we found $\alpha=1.8$, $\alpha=0.7$, and $\alpha=2.5$, respectively. It implies that the HSS region exhibits a nearly adiabatic behaviour, ICME region is closely isothermal, and the ICME-HSS interaction region exhibits super-adiabatic behaviour. The insufficient expansion of the ICME due to the interaction with HSS triggers the system for heating and cooling mechanisms which dependent on the degrees of freedom of plasma components.

ICME pancaking: a cause of two-step severe storm (Dst \sim -187 nT) of 25th solar cycle observed on 23 April 2023

Kalpesh **Ghag**, [Anil Raghav](#), [Ankush Bhaskar](#), [Shirish Soni](#), [Bhagyashri Sathe](#), [Zubair Shaikh](#), [Omkar Dhamane](#), [Prathmesh Tari](#)

JGR: Space Weather **2023**

<https://arxiv.org/pdf/2305.05381.pdf>

Interplanetary Coronal Mass Ejections (ICMEs) are prominent drivers of space weather disturbances and mainly lead to intense or extreme geomagnetic storms. The reported studies suggested that the planar ICME sheath and planar magnetic clouds (MCs) cause extreme storms. Here, we investigated the severe two-step geomagnetic storm ($Dst \sim -187$ nT) of 25th solar cycle. Our analysis demonstrates flattened (pancaked) ICME structures, i.e., quasi-planar magnetic structures (PMS). The study corroborates our earlier reported finding that the less adiabatic expansion in quasi-PMS transformed ICME enhanced the strength of the southward magnetic field component. It contributes to the efficient transfer of plasma and energy in the Earth's magnetosphere to cause the observed severe storm.

Galactic Cosmic Rays Modulation in the Vicinity of Corotating Interaction Regions: Observations During the Last Two Solar Minima

Keyvan **Ghanbari**^{1,2}, Vladimir Florinski^{1,2}, Xiaocheng Guo³, Qiang Hu^{1,2}, and Richard Leske⁴

2019 ApJ 882 54

<https://doi.org/10.3847/1538-4357/ab31a5>

[sci-hub.se/10.3847/1538-4357/ab31a5](https://arxiv.org/abs/1905.05381)

Corotating interaction regions (CIRs) are responsible for short-term recurrent cosmic-ray modulation, prominent near solar minima. Using the OMNI data sets for two periods of low solar activity near the beginning and end of solar cycle 24, superposed epoch analysis was performed on the solar wind plasma features for 53 and 43 events during periods 2007–2008 and 2017–2018, respectively. Turbulent properties of the solar wind were studied using the variance method for each CIR. Power spectra have been constructed for overlapped subintervals in the vicinity of stream interfaces (SIs). Using measured correlation lengths and turbulent energies, parallel and perpendicular diffusion mean free paths for cosmic-ray ions have been inferred based on two distinct theoretical formulations. For the two periods with opposite solar polarities, our results show that unlike solar wind speed, magnetic field strength, flow pressure, and proton density are relatively higher during the latest period. Increased turbulent energy and reduced parallel transport coefficients of energetic particles at the SIs are observed. The diffusion coefficients follow the same trends during both periods. The perpendicular diffusion starts increasing nearly a day before SIs and is higher in the fast wind. Superposed epoch analysis is performed on the >120 MeV proton count rate obtained from the CRIS instrument on board the ACE spacecraft for the same events. The recorded proton rates have peaks half a day before a SI and reach their minimum more than a day after a SI and have a high anticorrelation with the perpendicular diffusion coefficient.

Anomalous Cosmic Rays and Heliospheric Energetic Particles

Review

J. **Giacalone**, **H. Fahr**, **H. Fichtner**, **V. Florinski**, **B. Heber**, **M. E. Hill**, **J. Kóta**, **R. A. Leske**, **M. S. Potgieter** & **J. S. Rankin**

[Space Science Reviews](https://arxiv.org/abs/2201.00001) volume 218, Article number: 22 (2022)

<https://link.springer.com/content/pdf/10.1007/s11214-022-00890-7.pdf>

We present a review of Anomalous Cosmic Rays (ACRs), including the history of their discovery and recent insights into their acceleration and transport in the heliosphere. We focus on a few selected topics including a discussion of mechanisms of their acceleration, escape from the heliosphere, their effects on the dynamics of the heliosheath, transport in the inner heliosphere, and their solar cycle dependence. A discussion concerning their name is also presented towards the end of the review. We note that much is known about ACRs and perhaps the term Anomalous Cosmic Ray is not particularly descriptive to a non specialist. We suggest that the more-general term: “Heliospheric Energetic Particles”, which is more descriptive, for which ACRs and other energetic particle species of heliospheric origin are subsets, might be more appropriate.

Energetic Particles Associated with a Coronal Mass Ejection Shock Interacting with a Convected Magnetic Structure

2021 ApJ 921 102

<https://doi.org/10.3847/1538-4357/ac1ce1>

On **2020 November 30**, Parker Solar Probe (PSP) was crossed by a coronal mass ejection (CME)-driven shock, which we suggest was also crossing a convected, isolated magnetic structure (MS) at about the same time. By analyzing PSP/FIELDS magnetic field measurements, we find that the leading edge of the MS coincided with the crossing of the shock, while its trailing edge, identified as a crossing of a current sheet, overtook PSP about 7 minutes later. Prior to the

arrival of the shock, the flux of 30 keV–3 MeV ions and electrons, as measured by PSP/Integrated Science Investigation of the Sun (ISOIS)/Energetic Particle Instrument (EPI-Lo), increased gradually, peaking at the time of the shock passage. However, during the crossing of the MS downstream of the shock, the energetic-ion flux dropped dramatically, before recovering at about the time of the crossing of the trailing edge of the MS. Afterwards, the ion fluxes remained approximately constant within the sheath region of the CME shock. We interpret this depletion of energetic ions within the MS as the result of insufficient time to accelerate particles at the shock within the MS, given that the structure moves along the shock surface owing to its advection with the solar wind. We present results from a quantitative numerical model of the interaction of an idealized MS with a shock, which supports this interpretation.

Partially ejected flux ropes: Implications for interplanetary coronal mass ejections,

Gibson, S. E., and Y. Fan,

E-print, March 2007; *J. Geophys. Res.*, 113, A09103 (2008), **File**

<http://dx.doi.org/10.1029/2008JA013151>

Connecting interplanetary coronal mass ejections (ICMEs) to their solar pre-eruption source requires a clear understanding of how that source may have evolved during eruption. Gibson and Fan (2006a) have presented a three-dimensional numerical magnetohydrodynamic simulation of a CME, which showed how, in the course of eruption, a coronal flux rope may writhe and reconnect both internally and with surrounding fields in a manner that leads to a partial ejection of only part of the rope as a CME. In this paper, we will explicitly describe how the evolution during eruption found in that simulation leads to alterations of the magnetic connectivity, helicity, orientation, and topology of the ejected portion of the rope so that it differs significantly from that of the pre-eruption rope. Moreover, because a significant part of the magnetic helicity remains behind in the lower portion of the rope that survives the eruption, the region is likely to experience further eruptions. These changes would complicate how ICMEs embedded in the solar wind relate to their solar source. In particular, the location and evolution of transient coronal holes, topology of magnetic clouds ("tethered spheromak"), and likelihood of interacting ICMEs would differ significantly from what would be predicted for a CME which did not undergo writhing and partial ejection during eruption.

Forming tori: Implications and possible origins of a "tethered spheromak" topology for magnetic clouds

Gibson, S. E.; Fan, Y.

American Geophysical Union, Spring Meeting 2008, abstract #SH31C-06, **2008**

We present a "tethered spheromak" model for magnetic clouds. The proposed topology differs from previous magnetic cloud models invoking spheromaks in that large portions of the field remain connected to the sun. This magnetic configuration may explain observed departures from the standard magnetic cloud model of a cylindrically-symmetric magnetic flux rope, such as magnetic fields which rotate more than 180 degrees. It is also topologically complex enough to include intermingled detached, doubly attached, and apparently open fields in a manner consistent with observations of sporadic heat flux dropouts within otherwise bidirectional or unidirectional streaming electrons. We use a numerical simulation to demonstrate how, for solar eruptions where the kink instability drives significant rotation of an erupting flux rope, such a tethered spheromak may form during that rope's partial ejection. It does so because writhing motions and reconnections create twist about two distinct axes of rotation: the first associated with the rotated portion of the original rope axis, and the second formed in situ via reconnections between the erupting rope and surrounding coronal arcade fields.

Partially-ejected flux ropes: implications for space weather

Sarah E. **Gibson**¹ and Yuhong Fan

Solar Activity and its Magnetic Origin, Proc.IAU Symposium No. 233, **2006**, Volker Bothmer, ed., **File**

The structure and evolution of the sources of solar activity directly affects the nature of space weather disturbances that reach the Earth. We have previously demonstrated that the loss of equilibrium and partial ejection of a coronal magnetic flux rope matches observations of coronal mass ejections (CMEs) and their precursors. In this paper we discuss the significance of such a partially-ejected rope for space weather. We will consider how the evolution and bifurcation of the rope modifies it from its initial, source configuration. In particular, we will consider how reconnections and writhing motions lead to an escaping rope which has an axis rotated counterclockwise from the original rope axis orientation, and which is rooted in transient coronal holes external to the original source region.

Solar-MACH: An open-source tool to analyze solar magnetic connection configurations

Jan [Gieseler](#), [Nina Dresing](#), [Christian Palmroos](#), [Johan L. Freiherr von Forstner](#), [Daniel J. Price](#), [Rami Vainio](#), [Athanasios Kouloumvakos](#), [Laura Rodríguez-García](#), [Domenico Trotta](#), [Vincent Génot](#), [Arnaud Masson](#), [Markus Roth](#), [Astrid Veronig](#)

2022

<https://arxiv.org/pdf/2210.00819.pdf>

The Solar MAGnetic Connection HAUS tool (Solar-MACH) is an open-source tool completely written in Python that derives and visualizes the spatial configuration and solar magnetic connection of different observers (i.e., spacecraft or planets) in the heliosphere at different times. For doing this, the magnetic connection in the interplanetary space is obtained by the classic Parker Heliospheric Magnetic Field (HMF). In close vicinity of the Sun, a Potential Field Source Surface (PFSS) model can be applied to connect the HMF to the solar photosphere. Solar-MACH is especially aimed at providing publication-ready figures for the analyses of Solar Energetic Particle events (SEPs) or solar transients such as Coronal Mass Ejections (CMEs). It is provided as an installable Python package (listed on PyPI and conda-forge), but also as a web tool at [this http URL](#) that completely runs in any web browser and requires neither Python knowledge nor installation. The development of Solar-MACH is open to everyone and takes place on GitHub, where the source code is publicly available under the BSD 3-Clause License. Established Python libraries like sunpy and pfsspy are utilized to obtain functionalities when possible. In this article, the Python code of Solar-MACH is explained, and its functionality is demonstrated using real science examples. In addition, we introduce the overarching SERPENTINE project, the umbrella under which the recent development took place. **9 October 2021, 28 October 2021**

Analysis of Geoeffective Impulsive Events on the Sun During the First Half of Solar Cycle 24

Agnieszka [Gil](#), [Monika Berendt-Marchel](#), [Renata Modzelewska](#), [Agnieszka Siluszyk](#), [Marek Siluszyk](#), [Anna Wawrzaszek](#) & [Anna Wawrzynczak](#)

[Solar Physics](#) volume 298, Article number: 26 (2023)

<https://link.springer.com/content/pdf/10.1007/s11207-023-02119-4.pdf>

A coronal mass ejection (CME) is an impulsive event that emerges rapidly from the Sun. We observed a quiet Sun without many spectacular episodes during the last decade. Although some fast halo and partial halo CMEs had taken place, among them was the backside CME on 23 July 2012. In this work, we verify the link between the variability of solar-wind, heliospheric and geomagnetic parameters and the transmission grid failures registered in southern Poland during 2010 – 2014 when many geomagnetic storms appeared, caused by halo and partial halo CMEs. We aim to apply three machine learning methods: Principal Components Analysis, Self-Organizing Maps, and Hierarchical Agglomerative Clustering to analyze sources on the Sun and the impacts of the intense geomagnetic storms in the first half of Solar Cycle 24. The conducted analyzes underline the importance of solar-wind proton temperature and point out other solar-wind and geomagnetic parameters independently indicated by all the methods used in this study. **26 – 27.09.2011, 19.02.2014**

The Solar Event of 14 – 15 July 2012 and Its Geoeffectiveness

Agnieszka [Gil](#), [Renata Modzelewska](#), [Szczepan Moskwa](#), [Agnieszka Siluszyk](#), [Marek Siluszyk](#), [Anna Wawrzynczak](#), [Mariusz Pozoga](#) & [Lukasz Tomasiak](#)

[Solar Physics](#) volume 295, Article number: 135 (2020)

<https://link.springer.com/content/pdf/10.1007/s11207-020-01703-2.pdf>

During Solar Cycle 24, which started at the end of 2008, the Sun was calm, and there were not many spectacular geoeffective events. In this article, we analyze the geomagnetic storm that happened on **15 July 2012** during the 602nd anniversary of the Polish Battle of Grunwald, thus we propose this event to be called the “Battle of Grunwald Day Storm”. According to NOAA scale, it was a G3 geomagnetic storm with a southward component of the heliospheric magnetic field, BzBz, falling to -20 nT, minimum Dst index of -139 nT, AE index of 1368 nT, and Ap index of 132 nT. It was preceded by a solar flare class X1.4 on **12 July**. This geomagnetic storm was associated with the fast halo coronal mass ejection at 16:48:05 UT on 12 July, first appearance in the Large Angle and Spectroscopic Coronagraph C2, with a plane-of-sky speed of 885 km s $^{-1}$ and maximum of 1415 km s $^{-1}$. This geomagnetic storm was classified as the fourth strongest geomagnetic storm of Solar Cycle 24. At that time, a significant growth in the failures of the Polish electric transmission lines was observed, which could have a solar origin.

An Anisotropic Cosmic-Ray Enhancement Event on 07-June-2015: A Possible Origin

Agnieszka [Gil](#), Gennady A. Kovaltsov, Vladimir V. Mikhailov, Alexander Mishev, Stepan Poluianov, Ilya G. Usoskin

[Solar Physics](#) November 2018, 293:154

<https://link.springer.com/content/pdf/10.1007%2Fs11207-018-1375-5.pdf>
sci-hub.tw/10.1007/s11207-018-1375-5

A usual event, called anisotropic cosmic-ray enhancement (ACRE), was observed as a small increase ($\leq 5\%$) in the count rates of polar neutron monitors during 12 – 19 UT on **07 June 2015**. The enhancement was highly anisotropic, as detected only by neutron monitors with asymptotic directions in the southwest quadrant in geocentric solar ecliptic (GSE) coordinates. The estimated rigidity of the corresponding particles is ≤ 1 GV. No associated detectable increase was found in the space-borne data from the Geostationary Operational Environmental Satellite (GOES), the Energetic and Relativistic Nuclei and Electron (ERNE) on board the Solar and Heliospheric Observatory (SOHO), or the Payload for Antimatter Matter Exploration and Light-nuclei Astrophysics (PAMELA) instruments, whose sensitivity was not sufficient to detect the event. No solar energetic particles were present during that time interval. The heliospheric conditions were slightly disturbed, so that the interplanetary magnetic field strength gradually increased during the event, followed by an increase of the solar wind speed after the event. It is proposed that the event was related to a crossing of the boundary layer between two regions with different heliospheric parameters, with a strong gradient of low-rigidity (< 1 GV) particles. It was apparently similar to another cosmic-ray enhancement (e.g., on **22 June 2015**) that is thought to have been caused by the local anisotropy of Forbush decreases, with the difference that in our case, the interplanetary disturbance was not observed at Earth, but passed by southward for this event.

Comparing two intervals of exceptionally strong solar rotation recurrence of galactic cosmic rays

A. **Gil** and K. Mursula

JGR **2018** DOI 10.1029/2018JA025523

<http://sci-hub.tw/https://onlinelibrary.wiley.com/doi/abs/10.1029/2018JA025523>

Two intervals of exceptionally strong recurrence of galactic cosmic ray (GCR) intensity at solar rotation period stand out in recent history, one in 2007-2008, the other in 2014-2015. We use neutron monitor data from Oulu and Hermanus, solar wind (SW) data and coronal images to study these intervals. We find that in both cases the source of solar rotation period recurrence was a coronal hole (CH), but CH structures were different. While a large, longitudinally asymmetric CH existed at high southern latitudes in 2014-2015, a low-latitude CH caused the recurrence in 2007-2008. Spectral properties of GCR and SW parameters reflect these differences. In 2014-2015 the GCR power spectrum density was broad and peaked at a period of 28.9 days, longer than the simultaneous recurrence period of SW speed. In 2007-2008 the GCR power spectrum was narrow and peaked at 27.5 days, exactly the same as for SW speed. The effect of CHs to GCRs was somewhat different in the two cases because of opposite solar polarities in the two intervals. In 2014-2015, during positive polarity when GCRs drift inward from high latitudes, the convection of fast SW from CH reduces the inward GCR drift over a wide range of high heliolatitudes at certain heliolongitudes. In 2007-2008, during negative polarity when GCRs drift inward via the heliospheric current sheet (HCS), a low-latitude CH depletes the GCR flux not only by convection but also by deflecting HCS away from the ecliptic, whence GCR drift to higher latitudes in a limited longitude range. **25 September 2007, 30 January 2015**

FIRST MEASUREMENTS OF THE COMPLETE HEAVY-ION CHARGE STATE DISTRIBUTIONS OF C, O, AND Fe ASSOCIATED WITH INTERPLANETARY CORONAL MASS EJECTIONS

J. A. **Gilbert**, S. T. Lepri, E. Landi, and T. H. Zurbuchen

2012 ApJ 751 20

We present the first analysis of the complete charge state distributions of heavy ions in interplanetary coronal mass ejections (CMEs), from singly charged to fully ionized. We develop a novel analysis technique that requires the combination and cross-calibration of two different data sets from the Solar Wind Ion Composition Spectrometer on the Advanced Composition Explorer. The first contains ions of higher charge states, and includes an identification of their mass, mass-per-charge, and energy-per-charge. The second data set contains singly and low-charge ions, and identifies only their mass-per-charge and energy-per-charge. Focusing on C, O, and Fe, we find ionic charge states representative of temperatures from $\leq 60,000$ K to over 5,000,000 K contained within interplanetary CMEs observed near 1 AU. We interpret these data in the context of near-Sun observations of filament material associated with CMEs. We find that singly charged ions are embedded within selected interplanetary CMEs, and we examine their densities and durations. These data thus provide the most unambiguous in situ diagnostic of solar prominence plasma in the heliosphere.

Multi-fractal Analysis of Cosmic Rays over Mid- and High-Latitude Stations During Severe Geomagnetic Storms.

Giri, A., Adhikari, B., Dahal, S. et al.

Sol Phys 299, 148 (2024).

<https://doi.org/10.1007/s11207-024-02393-w>

This study explores the multi-fractal properties of cosmic-ray (CR) counts collected from two mid-latitude neutron-monitor stations, Newark (NEWK) and Irkutsk 3 (IRK3), and two high-latitude stations, Thule (THUL) and Inuvik (INVK), during periods of severe geomagnetic storms. By employing multi-fractal along with time-series analysis, we did an in-depth examination of CR count variations to demonstrate the effectiveness of these methods in analyzing complex signals associated with astrophysical and solar phenomena. The findings reveal that CR count rates across stations at different latitudes exhibit multi-fractal characteristics, reflecting a range of scaling exponents that capture varying degrees of correlation and variability within the system. The results underscore that solar activity, geomagnetic events, and interactions with Earth's magnetic field play a more crucial role in determining multi-fractality than the geographic location of the measurement station. Moreover, the study shows that geomagnetic events exert a stronger influence on the multi-fractal properties of CR count rate than the geographic location of station, underscoring the impact of solar storms and Earth's magnetic field on the distribution and intensity of CRs. This work emphasizes the value of multi-fractal analysis as a powerful tool for investigating the complex nature of CR counts and its sensitivity to both extraterrestrial and terrestrial factors.

A 30-Year Simulation of the Outer Electron Radiation Belt

S. A. [Glauert](#) [R. B. Horne](#) [N. P. Meredith](#)

Space Weather Volume16, Issue10 October 2018 Pages 1498-1522

<https://doi.org/10.1029/2018SW001981>

As society becomes more reliant on satellite technology, it is becoming increasingly important to understand the radiation environment throughout the Van Allen radiation belts. Historically most satellites have operated in low Earth orbit or geostationary orbit (GEO), but there are now over 100 satellites in medium Earth orbit (MEO). Additionally, satellites using electric orbit raising to reach GEO may spend hundreds of days on orbits that pass through the heart of the radiation belts. There is little long-term data on the high-energy electron flux, responsible for internal charging in satellites, available for MEO. Here we simulate the electron flux between the outer edge of the inner belt and GEO for 30 years. We present a method that converts the >2-MeV flux measured at GEO by the Geostationary Operational Environmental Satellites spacecraft into a differential flux spectrum to provide an outer boundary condition. The resulting simulation is validated using independent measurements made by the Galileo In-Orbit Validation Element-B spacecraft; correlation coefficients are in the range 0.72 to 0.88, and skill scores are between 0.6 and 0.8 for a range of L* and energies. The results show a clear solar cycle variation and filling of the slot region during active conditions and that the worst case spectrum overlaps that derived independently for the limiting extreme event. The simulation provides a resource that can be used by satellite designers to understand the MEO environment, by space insurers to help resolve the cause of anomalies and by satellite operators to plan for the environmental extremes.

Variations in Energetic Particle Fluxes around Significant Geomagnetic Storms Observed by the Low-Altitude DEMETER Spacecraft.

Gohl, S.; N'emece, F.; Parrot, M.

Universe 2021, 7, 260.

<https://www.mdpi.com/2218-1997/7/8/260/htm>

<https://doi.org/10.3390/universe7080260>

A superposed epoch analysis is conducted for five geomagnetic storms in the years 2005 and 2006 with the aim to understand energetic particle flux variations as a function of L-shell, energy and time from the Dst minimum. Data measured by the low-altitude DEMETER spacecraft were used for this purpose. The storms were identified by a Dst index below -100 nT, as well as their being isolated events in a seven-day time window. It is shown that they can be categorized into two types. The first type shows significant variations in the energetic particle fluxes around the Dst minimum and increased fluxes at high energies (>1.5 MeV), while the second type only shows increased fluxes around the Dst minimum without the increased fluxes at high energies. The first type of storm is related to more drastic but shorter-lasting changes in the solar wind parameters than the second type. One storm does not fit either category, exhibiting features from both storm types. Additionally, we investigate whether the impenetrable barrier for ultra-relativistic electrons also holds in extreme geomagnetic conditions. For the highest analyzed energies, the obtained barrier L-shells do not go below 2.6, consistent with previous findings. **15 May 2005, 13 June 2005, 24 August 2005, 31 August 2005, 15 December 2006**

Dependence of Radiation Belt Flux Depletions at Geostationary Orbit on Different Solar Drivers During Intense Geomagnetic Storms

Sneha **Gokani**, De-Sheng Han, R Selvakumaran, R Selvakumaran, and Tarun Pant

Front. Astron. Space Sci. 9:952486. 2022

doi: 10.3389/fspas.2022.952486

<https://www.frontiersin.org/articles/10.3389/fspas.2022.952486/pdf>

The loss of electron flux of the outer radiation belt has been widely studied in terms of the mechanism that brings in these losses. There are a few studies which have attempted to explain the interplanetary conditions that favor the depletions. As the Sun is the prime cause of any change happening in the magnetosphere, it is important to look at the solar drivers that bring in such changes. In this study, we attempt to understand the effect of solar structures and substructures on the loss of radiation belt high-energy electrons during intense geomagnetic storms. The superposed epoch analysis is used to observe any peculiar changes in GOES electron flux data during the storms that are associated with solar structures such as CME and CIR, ICME substructures such as the magnetic cloud, magnetic cloud with sheath, ejecta, ejecta with sheath, and only sheath. The long-term data also give an opportunity to compare the flux decrease during solar cycles 23 and 24. It has been observed that 1) CIR-associated storms cause a comparatively higher flux decrease than CME-associated storms, 2) sheath-related storms bring out a higher flux decrease, and 3) there is no significant change in flux for the storms of both the solar cycles. The flux decrease in intense storms at the geostationary orbit is essentially triggered by the “Dst effect.” Apart from this, the minimum IMF Bz and northward IMF Bz before turning southward add to the flux decrease. These results hold true for the electron depletions occurring only during intense geomagnetic storms and may alter otherwise.

Extended MHD modeling of the steady solar corona and the solar wind

Review

Tamas I. **Gombosi**, Bart van der Holst, Ward B. Manchester, Igor V. Sokolov

[Living Reviews in Solar Physics](#) December 2018, 15:4

<https://link.springer.com/content/pdf/10.1007%2Fs41116-018-0014-4.pdf>

<https://arxiv.org/pdf/1807.00417.pdf>

The history and present state of large-scale magnetohydrodynamic modeling of the solar corona and the solar wind with steady or quasi-steady coronal physics is reviewed. We put the evolution of ideas leading to the recognition of the existence of an expanding solar atmosphere into historical context. The development and main features of the first generation of global corona and solar wind models are described in detail. This historical perspective is also applied to the present suite of global corona and solar wind models. We discuss the evolution of new ideas and their implementation into numerical simulation codes. We point out the scientific and computational challenges facing these models and discuss the ways various groups tried to overcome these challenges. Next, we discuss the latest, state-of-the-art models and point to the expected next steps in modeling the corona and the interplanetary medium. 29 March 2006, 2011 March 7

Clustering of fast Coronal Mass Ejections during the solar cycles 23 and 24 and implications for CME-CME interactions

[Jenny M. Rodríguez Gómez](#), [Tatiana Podladchikova](#), [Astrid Veronig](#), [Alexander Ruzmaikin](#), [Joan Feynman](#), [Anatoly Petrukovich](#)

ApJ 2020

<https://arxiv.org/pdf/2006.10404.pdf>

We study the clustering properties of fast Coronal Mass Ejections (CMEs) that occurred during solar cycles 23 and 24. We apply two methods: the Max spectrum method can detect the predominant clusters and the de-clustering threshold time method provides details on the typical clustering properties and time scales. Our analysis shows that during the different phases of solar cycles 23 and 24, CMEs with speed ≥ 1000 km/s preferentially occur as isolated events and in clusters with on average two members. However, clusters with more members appear particularly during the maximum phases of the solar cycles. Over the total period and in the maximum phases of solar cycles 23 and 24, about 50% are isolated events, 18% (12%) occur in clusters with 2 (3) members, and another 20% in larger clusters ≥ 4 , whereas in solar minimum fast CMEs tend to occur more frequently as isolated events (62%). During different solar cycle phases, the typical de-clustering time scales of fast CMEs are $\tau_c = 28-32$ hrs, irrespective of the very different occurrence frequencies of CMEs during solar minimum and maximum. These findings suggest that τ_c for extreme events may reflect the characteristic energy build-up time for large flare and CME-prolific active ARs. Associating statistically the clustering properties of fast CMEs with the Disturbance storm index $\{Dst\}$ at Earth suggests that fast CMEs occurring in clusters tend to produce larger geomagnetic storms than isolated fast CMEs. This may be related to CME-

CME interaction producing a more complex and stronger interaction with the Earth magnetosphere. **2000-11-23-25, 2005-08-22-23, 2017-09-09-10**

Sunward-propagating Solar Energetic Electrons inside Multiple Interplanetary Flux Ropes

Raúl **Gómez-Herrero**¹, Nina Dresing², Andreas Klassen², Bernd Heber², Manuela Temmer³, Astrid Veronig³, Radoslav Bučík^{4,5}, Miguel A. Hidalgo¹, Fernando Carcaboso¹, Juan J. Blanco

2017 ApJ 840 85

<http://sci-hub.cc/10.3847/1538-4357/aa6c5c>

On **2013 December 2 and 3**, the SEPT and STE instruments on board STEREO-A observed two solar energetic electron events with unusual sunward-directed fluxes. Both events occurred during a time interval showing typical signatures of interplanetary coronal mass ejections (ICMEs). The electron timing and anisotropies, combined with extreme-ultraviolet solar imaging and radio wave spectral observations, are used to confirm the solar origin and the injection times of the energetic electrons. The solar source of the ICME is investigated using remote-sensing observations and a three-dimensional reconstruction technique. In situ plasma and magnetic field data combined with energetic electron observations and a flux-rope model are used to determine the ICME magnetic topology and the interplanetary electron propagation path from the Sun to 1 au. Two consecutive flux ropes crossed the STEREO-A location and each electron event occurred inside a different flux rope. In both cases, the electrons traveled from the solar source to 1 au along the longest legs of the flux ropes still connected to the Sun. During the December 2 event, energetic electrons propagated along the magnetic field, while during the December 3 event they were propagating against the field. As found by previous studies, the energetic electron propagation times are consistent with a low number of field line rotations $N < 5$ of the flux rope between the Sun and 1 au. The flux rope model used in this work suggests an even lower number of rotations. **2013 November 29**

On Short-Duration Intense and Strongly Geoeffective (ICME) Sheath Magnetic Fields

Walter D. **Gonzalez**

JGR [Volume 129, Issue 4](#) April **2024** e2023JA032222

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2023JA032222>

This Commentary article deals with the important role of large-amplitude, short-duration (<1 hr) and southwardly directed magnetic field incursions within the Sheath region of an interplanetary coronal mass ejection, which were recently shown to have led to extreme auroral activity during the early part of the Halloween storm (Ohtani, 2022, <https://doi.org/10.1029/2022ja030596>). For such largely geoeffective magnetic field structures some suggestions are given toward their possible interplanetary causes, which could also be associated with the origin of similar Sheath-structures observed during other events with very intense geomagnetic activity. A particular attention is given to a Sheath-incorporated and largely geoeffective flux rope-hypothesis. At the end we add some comments on further related magnetospheric and space weather issues. **29–30 Oct 2003**

Using sunRunner3D to interpret the global structure of the heliosphere from in situ measurements

José Juan **González-Avilés**^{1*}, Pete Riley², Michal Ben-Nun², Prateek Mayank³ and Bhargav Vaidya³

J. Space Weather Space Clim. **2024**, 14, 12

<https://www.swsc-journal.org/articles/swsc/pdf/2024/01/swsc230061.pdf>

Understanding the large-scale three-dimensional structure of the inner heliosphere, while important in its own right, is crucial for space weather applications, such as forecasting the time of arrival and propagation of coronal mass ejections (CMEs). This study uses sunRunner3D (3D), a 3-D magnetohydrodynamic (MHD) model, to simulate solar wind (SW) streams and generate background states. SR3D employs the boundary conditions generated by corona-heliosphere (CORHEL) and the PLUTO code to compute the plasma properties of the SW with the MHD approximation up to 1.1 AU in the inner heliosphere. We demonstrate that SR3D reproduces global features of corotating interaction regions (CIRs) observed by Earth-based spacecraft (OMNI) and the Solar Terrestrial Relations Observatory (STEREO)-A for a set of Carrington rotations (CRs) that cover a period that lays in the late declining phase of solar cycle 24. Additionally, we demonstrate that the model solutions are valid in the corotating and inertial frames of references. Moreover, a comparison between SR3D simulations and in situ measurements shows reasonable agreement with the observations, and our results are comparable to those achieved by Predictive Science Inc.'s Magnetohydrodynamic Algorithm outside a Sphere (MAS) code. We have also undertaken a comparative analysis with the Space Weather Adaptive Simulation Framework for Solar Wind (SWASTi-SW), a PLUTO physics-based model, to evaluate the precision of various initial boundary conditions. Finally, we discuss the disparities in the solutions derived from inertial and rotating frames.

Observations of Low-Latitude Red Aurora in Mexico During the 1859 Carrington Geomagnetic Storm

González-Esparza, J. A.; Cuevas-Cardona, M. C.

Space Weather, Volume 16, Issue 6, pp. 593-600, 2018

<http://sci-hub.tw/10.1029/2017SW001789>

One of the most intense geomagnetic storm that has been documented in recent history occurred on 1 September 1859. This storm is known as the Carrington Event. In the morning of 1 September at around 11:15 UT, Richard Carrington and Richard Hodgson observed in England, independently and for the first time, an intense white light solar flare. About 17 hr after this solar event, there occurred the strongest geomagnetic perturbation ever recorded as well as a greatly extended red aurora, which covered unusually at low latitudes. The red auroral display on 2 September was reported in regions where this kind of phenomena is very rare, like in Cuba and Hawaii. Until now however, it was not known to scientists that the low-latitude red aurora is also registered in Mexico. At that time, Mexico was in a civil war, and there were very difficult conditions in where to establish astronomical and magnetic observatories. Nevertheless, the geomagnetic storm was observed with a maximum intensity between 7:00 and 8:00 UTC and was reported to a Mexican newspaper from five different locations (Mexico City, Querétaro, Guadalajara, Hidalgo, and Guanajuato) and registered also from at least in two additional sites (Michoacán and San Luis Potosí) in other historical documents. These records confirm that the Carrington geomagnetic storm was a global event with planetary repercussions, and that the Mexican low-latitude region is susceptible to significant effects associated with intense space weather events.

See Space Weather Quarterly Vol. 15, Issue 2, 2018 <https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1002/swq.18>

Study of Corotating Interaction Regions in the Ascending Phase of the Solar Cycle: Multi-spacecraft Observations

J. A. Gonzalez-Esparza, E. Romero-Hernandez, P. Riley

Solar Physics, July 2013, Volume 285, Issue 1-2, pp 201-216

We combined simultaneous solar wind observations from five different spacecraft: Helios 1, Helios 2, IMP-8, Voyager 1 and Voyager 2, from November 1977 to February 1978 (Carrington rotations 1661 – 1664, ascending phase of Solar Cycle 21). The concurrence of the five trajectories makes this interval unique for the purpose of studying solar wind dynamics during this phase of the cycle. We analyzed the observations identifying five corotating interaction regions (CIRs) and produced maps of interplanetary large-scale features, unifying and summarizing the data. The maps show the compressive events and the magnetic sectors associated with the solar wind streams causing the CIRs. We analyzed the relative position of the stream interfaces immersed within the CIRs. About 70 % of the stream interfaces in this study were located closer to the forward edge of the CIR. From the analysis of the geometry of the stream interfaces, we found that all the CIRs presented latitudinal tilts, having their fronts pointing towards the ecliptic plane and their tails northwards or southwards. These results are in agreement with the origin of the fast streams coming from mid-latitude coronal holes and the predominance of forward shocks over reverse shocks bounding the CIRs, which characterize this phase of the cycle. From the analysis of the ratio of dynamic pressures between fast and slow solar wind streams associated with the CIRs, we found that in about 60 % of the cases the fast stream was transferring momentum to the slow one ahead, but in the rest of the cases the momentum was flowing sunward. This result indicates significant inhomogeneities in the solar wind streams during the ascending phase of the cycle that affect the local form and evolution of CIR events. We did a limited comparison between a global magneto-hydrodynamic (MHD) model of SW flows and the orientation of the SI from in-situ observations, we found, in general, a qualitative agreement between the pressure profiles at 1 AU predicted by the model and the inclinations of the stream interfaces deduced from the data analysis.

Extreme geomagnetic storms, recent Gleissberg cycles and space era-superintense storms

W.D. Gonzalez, , E. Echera, , A.L. Clúa de Gonzalez, , B.T. Tsurutanib, , and G.S. Lakhinac, Journal of Atmospheric and Solar-Terrestrial Physics, Volume 73, Issues 11-12, 2011, Pages 1447-1453 sci-hub.se/10.1016/j.jastp.2010.07.023

http://ac.els-cdn.com/S1364682610002191/1-s2.0-S1364682610002191-main.pdf?_tid=1bbe6824-a9ab-11e3-ac70-0000aab0f27&acdnat=1394603992_13c70fe75e41148720b352c2e9055341

Extreme historical and space era geomagnetic storms (ΔH or ΔI) are studied in terms of their sunspot and Gleissberg solar cycle distributions. Interplanetary and magnetospheric processes associated with the Carrington storm are summarized and the intense storm of August 4, 1972 is discussed in the context of the possibility of having occurred as an extreme storm instead, if the polarity of the related magnetic cloud would have been opposite. We also discuss about

superintense geomagnetic storms () that occurred in the space era, showing their solar cycle and seasonal distributions and also providing averages for the peak values of their main associated interplanetary parameters. A discussion about the possible occurrence of more Carrington type storms is also addressed.

Table 1
List of superstorms ($Dst \leq -250$ nT) during the space era.

Interplanetary Origin of Intense, Superintense and Extreme Geomagnetic Storms Review

Walter D. [Gonzalez](#) · Ezequiel Echer · Bruce T. Tsurutani · Alicia L. Clúa de Gonzalez · Alisson Dal Lago
Space Sci Rev (2011) 158: 69–89, [File](#)

We present a review on the interplanetary causes of intense geomagnetic storms

($Dst \leq -100$ nT), that occurred during solar cycle 23 (1997–2005). It was reported that the most common interplanetary structures leading to the development of intense storms were: magnetic clouds, sheath fields, sheath fields followed by a magnetic cloud and corotating interaction regions at the leading fronts of high speed streams. However, the relative importance of each of those driving structures has been shown to vary with the solar cycle phase.

Superintense storms ($Dst \leq -250$ nT) have been also studied in more detail for solar cycle 23, confirming initial studies done about their main interplanetary causes. The storms are associated with magnetic clouds and sheath fields following interplanetary shocks, although they frequently involve consecutive and complex ICME structures. Concerning extreme storms ($Dst \leq -400$ nT), due to the poor statistics of their occurrence during the space era, only some indications about their main interplanetary causes are known. For the most extreme events, we review the Carrington event and also discuss the distribution of historical and space era extreme events in the context of the sunspot and Gleissberg solar activity cycles, highlighting a discussion about the eventual occurrence of more Carrington type storms.

Interplanetary origin of intense geomagnetic storms ($Dst < -100$ nT) during solar cycle 23,

[Gonzalez](#), W. D., E. Echer, A. L. Clua-Gonzalez, and B. T. Tsurutani
Geophys. Res. Lett., 34, L06101, doi:10.1029/2006GL028879, (2007), [File](#).

We study the interplanetary causes of intense geomagnetic storms ($Dst < -100$ nT) that occurred during solar cycle 23 (1997–2005). It was found that the most common interplanetary structures leading to the development of an intense storm were: magnetic clouds, sheath fields, sheath fields followed by a magnetic cloud and corotating interaction regions leading high speed streams. However, the relative importance of each of those driving structures was found to vary with the solar cycle phase. We divide the cycle in three phases (rising, maximum and declining) and explain the differences. We also discuss about the geoeffectiveness of each of the four main interplanetary driving structures.

[sci-hub.se/10.1029/93ja02867](https://doi.org/10.1029/93ja02867)

After a brief review of magnetospheric and interplanetary phenomena for intervals with enhanced solar wind-magnetosphere interaction, an attempt is made to define a geomagnetic storm as an interval of time when a sufficiently intense and long-lasting interplanetary convection electric field leads, through a substantial energization in the magnetosphere-ionosphere system, to an intensified ring current sufficiently strong to exceed some key threshold of the quantifying storm time Dst index. The associated storm/substorm relationship problem is also reviewed. Although the physics of this relationship does not seem to be fully understood at this time, basic and fairly well established mechanisms of this relationship are presented and discussed. Finally, toward the advancement of geomagnetic storm research, some recommendations are given concerning future improvements in monitoring existing geomagnetic indices as well as the solar wind near Earth.

Impact of Inner Heliospheric Boundary Conditions on Solar Wind Predictions at Earth

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2020SW002499>

Predictions of the physical parameters of the solar wind at Earth are at the core of operational space weather forecasts. Such predictions typically use line-of-sight observations of the photospheric magnetic field to drive a heliospheric model. The models Wang-Sheeley-Arge (WSA) and ENLIL for the transport in the heliosphere are commonly used for these respective tasks. Here we analyse the impact of replacing the potential field coronal boundary conditions from WSA with two alternative approaches. The first approach uses a more realistic non-potential rather than potential approach, based on the Durham Magneto Frictional Code (DUMFRIC) model. In the second approach the ENLIL inner boundary conditions are based on Inter Planetary Scintillation observations (IPS). We compare predicted solar wind speed, plasma density and magnetic field magnitude with observations from the WIND spacecraft for two six-months intervals in 2014 and 2016. Results show that all models tested produce fairly similar output when compared to the observed time series. This is not only reflected in fairly low correlation coefficients (<0.3) but also large biases. For example for solar wind speed some models have average biases of more than 150 (km/s). On a positive note, the choice of coronal magnetic field model has a clear influence on the model results when compared to the other models in this study. Simulations driven by IPS data have a high success rate with regard to detection of the high speed solar wind. Our results also indicate that model forecasts do not degrade for longer forecast times.

Turbulence Properties of Interplanetary Coronal Mass Ejections in the Inner Heliosphere: Dependence on Proton Beta and Flux Rope Structure

S. W. **Good**, [O. K. Rantala](#), [A.-S. M. Jylhä](#), [C. H. K. Chen](#), [C. Möstl](#), [E. K. J. Kilpua](#)

ApJ **2023**

<https://arxiv.org/pdf/2307.09800.pdf>

Interplanetary coronal mass ejections (ICMEs) have low proton beta across a broad range of heliocentric distances and a magnetic flux rope structure at large scales, making them a unique environment for studying solar wind fluctuations. Power spectra of magnetic field fluctuations in 28 ICMEs observed between 0.25 and 0.95 au by Solar Orbiter and Parker Solar Probe have been examined. At large scales, the spectra were dominated by power contained in the flux ropes. Subtraction of the background flux rope fields reduced the mean spectral index from $-5/3$ to $-3/2$ at $k\Delta l \leq 10-3$. Rope subtraction also revealed shorter correlation lengths in the magnetic field. The spectral index was typically near $-5/3$ and radially invariant in the inertial range regardless of rope subtraction, and steepened to values consistently below -3 with transition to kinetic scales. The high-frequency break point terminating the inertial range evolved almost

linearly with radial distance and was closer in scale to the proton inertial length than the proton gyroscale, as expected for plasma at low proton beta. Magnetic compressibility at inertial scales did not grow with radial distance, in contrast to the solar wind generally. In ICMEs, the distinctive spectral properties at injection scales appear mostly determined by the global flux rope structure while transition-kinetic properties are more influenced by the low proton beta; the intervening inertial range appears independent of both ICME features, indicative of a system-independent scaling of the turbulence. **2019-03-24**

<https://watermark.silverchair.com/stac1388.pdf>

Interplanetary coronal mass ejections (ICMEs) contain magnetic field and velocity fluctuations across a wide range of scales. These fluctuations may be interpreted as Alfvénic wave packets propagating parallel or anti-parallel to the background magnetic field, with the difference in power between counter-propagating fluxes quantified by the cross helicity. We have determined the cross helicity of inertial range fluctuations at 10^{-3} – 10^{-2} Hz in 226 ICME flux ropes and 176 ICME sheaths observed by the Wind spacecraft at 1 au during 1995-2015. The flux ropes and sheaths had mean, normalised cross helicities of 0.18 and 0.24, respectively, with positive values here indicating net anti-sunward fluxes. While still tipped towards the anti-sunward direction on average, fluxes in ICMEs tend to be more balanced than in the solar wind at 1 au, where the mean cross helicity is larger. Superposed epoch profiles show cross helicity falling sharply in the sheath and reaching a minimum inside the flux rope near the leading edge. More imbalanced, solar wind-like cross helicity was found towards the trailing edge and laterally further from the rope axis. The dependence of cross helicity on flux rope orientation and the presence of an upstream shock are considered. Potential origins of the low cross helicity in ICMEs at 1 au include balanced driving of the closed-loop flux rope at the Sun and ICME-solar wind interactions in interplanetary space. We propose that low cross helicity of fluctuations is added to the standard list of ICME signatures. **3-5 Apr 2004**

Cross Helicity of the November 2018 Magnetic Cloud Observed by the Parker Solar Probe

<https://doi.org/10.3847/2041-8213/abb021>

Magnetic clouds are large-scale transient structures in the solar wind with low plasma β , low-amplitude magnetic field fluctuations, and twisted field lines with both ends often connected to the Sun. Their inertial-range turbulent properties have not been examined in detail. In this Letter, we analyze the normalized cross helicity, σ_c , and residual energy, σ_r , of plasma fluctuations in the November 2018 magnetic cloud observed at 0.25 au by the Parker Solar Probe. A low value of $|\sigma_c|$ was present in the cloud core, indicating that wave power parallel and anti-parallel to the mean field was approximately balanced, while the cloud's outer layers displayed larger amplitude Alfvénic fluctuations with high $|\sigma_c|$ values and $\sigma_r \sim 0$. These properties are discussed in terms of the cloud's solar connectivity and local interaction with the solar wind. We suggest that low $|\sigma_c|$ is likely a common feature of magnetic clouds given their typically closed field structure. Anti-sunward fluctuations propagating immediately upstream of the cloud had strongly negative σ_r values. **November 11-12, 2018**

Radial Evolution of Magnetic Field Fluctuations in an Interplanetary Coronal Mass Ejection Sheath

S. W. [Good](#)¹, [M. Ala-Lahti](#)¹, [E. Palmerio](#)^{1,2}, [E. K. J. Kilpua](#)¹, and [A. Osmane](#)¹

2020 ApJ **893** 110

<https://arxiv.org/pdf/2003.05760.pdf>

<https://doi.org/10.3847/1538-4357/ab7fa2>

The sheaths of compressed solar wind that precede interplanetary coronal mass ejections (ICMEs) commonly display large-amplitude magnetic field fluctuations. As ICMEs propagate radially from the Sun, the properties of these fluctuations may evolve significantly. We have analyzed magnetic field fluctuations in an ICME sheath observed by MESSENGER at 0.47 au and subsequently by STEREO-B at 1.08 au while the spacecraft were close to radial alignment. Radial changes in fluctuation amplitude, compressibility, inertial-range spectral slope, permutation entropy,

Jensen–Shannon complexity, and planar structuring are characterized. These changes are discussed in relation to the evolving turbulent properties of the upstream solar wind, the shock bounding the front of the sheath changing from a quasi-parallel to quasi-perpendicular geometry, and the development of complex structures in the sheath plasma. **5-7 Nov 2010**

Self-Similarity of ICME Flux Ropes: Observations by Radially Aligned Spacecraft in the Inner Heliosphere

S. W. [Good](#), [E. K. J. Kilpua](#), [A. T. LaMoury](#), [R. J. Forsyth](#), [J. P. Eastwood](#), [C. Möstl](#)

JGR [Volume 124, Issue 7](#) July 2019 Pages 4960-4982

[sci-hub.se/10.1029/2019JA026475](https://doi.org/10.1029/2019JA026475)

Interplanetary coronal mass ejections (ICMEs) are a significant feature of the heliospheric environment and the primary cause of adverse space weather at the Earth. ICME propagation and the evolution of ICME magnetic field structure during propagation are still not fully understood. We analyze the magnetic field structures of **18 ICME** magnetic flux ropes observed by radially aligned spacecraft in the inner heliosphere. Similarity in the underlying flux rope structures is determined through the application of a simple technique that maps the magnetic field profile from one spacecraft to the other. In many cases, the flux ropes show very strong underlying similarities at the different spacecraft. The mapping technique reveals similarities that are not readily apparent in the unmapped data and is a useful tool when determining whether magnetic field time series observed at different spacecraft are associated with the same ICME. Lundquist fitting has been applied to the flux ropes, and the rope orientations have been determined; macroscale differences in the profiles at the aligned spacecraft may be ascribed to differences in flux rope orientation. Assuming that the same region of the ICME was observed by the aligned spacecraft in each case, the fitting indicates some weak tendency for the rope axes to reduce in inclination relative to the solar equatorial plane and to align with the solar east-west direction with heliocentric distance.

[Solar Physics](#) March 2018, 293:52

<https://link.springer.com/content/pdf/10.1007%2Fs11207-018-1264-y.pdf>

The magnetic field structures of two interplanetary coronal mass ejections (ICMEs), each observed by a pair of spacecraft close to radial alignment, have been analysed. The ICMEs were observed in situ by MESSENGER and STEREO-B in November 2010 and November 2011, while the spacecraft were separated by more than 0.6 AU in heliocentric distance, less than 4° in heliographic longitude, and less than 7° in heliographic latitude. Both ICMEs took approximately two days to travel between the spacecraft. The ICME magnetic field profiles observed at MESSENGER have been mapped to the heliocentric distance of STEREO-B and compared directly to the profiles observed by STEREO-B. Figures that result from this mapping allow for easy qualitative assessment of similarity in the profiles. Macroscale features in the profiles that varied on timescales of one hour, and which corresponded to the underlying flux rope structure of the ICMEs, were well correlated in the solar east–west and north–south directed components, with Pearson’s correlation coefficients of approximately 0.85 and 0.95, respectively; microscale features with timescales of one minute were uncorrelated. Overall correlation values in the profiles of one ICME were increased when an apparent change in the flux rope axis direction between the observing spacecraft was taken into account. The high degree of similarity seen in the magnetic field profiles may be interpreted in two ways. If the spacecraft sampled the same region of each ICME (i.e. if the spacecraft angular separations are neglected), the similarity indicates that there was little evolution in the underlying structure of the sampled region during propagation. Alternatively, if the spacecraft observed different, nearby regions within the ICMEs, it indicates that there was spatial homogeneity across those different regions. The field structure similarity observed in these ICMEs points to the value of placing in situ space weather monitors well upstream of the Earth. **5-6 November 2010, 5-6 November 2011**

Interplanetary Coronal Mass Ejections Observed by MESSENGER and Venus Express

S. W. [Good](#), [R. J. Forsyth](#)

[Solar Phys.](#) January 2016, Volume 291, [Issue 1](#), pp 239-263 **Open Access**

Interplanetary coronal mass ejections (ICMEs) observed by the MESSENGER and Venus Express spacecraft have been catalogued and analysed. The ICMEs were identified by a relatively smooth rotation of the magnetic field direction consistent with a flux rope structure, coinciding with a relatively enhanced magnetic field strength. A total of 35 ICMEs were found in the surveyed MESSENGER data (primarily from March 2007 to April 2012), and 84 ICMEs in the

surveyed Venus Express data (from May 2006 to December 2013). The ICME flux rope configurations have been determined. Ropes with northward leading edges were about four times more common than ropes with southward leading edges, in agreement with a previously established solar cycle dependence. Ropes with low inclinations to the solar equatorial plane were about four times more common than ropes with high inclinations, possibly an observational effect. Left- and right-handed ropes were observed in almost equal numbers. In addition, data from MESSENGER, Venus Express, STEREO-A, STEREO-B and ACE were examined for multipoint signatures of the catalogued ICMEs. For spacecraft separations below 15° in heliocentric longitude, the second spacecraft observed the ICME flux rope in 82 % of cases; this percentage dropped to 49 % for separations between 15 and 30°, to 18 % for separations between 30 and 45°, and to 12 % for separations between 45 and 60°. As the spacecraft separation increased, it became increasingly likely that only the sheath and not the flux rope of the ICME was observed, in agreement with the notion that ICME flux ropes are smaller in longitudinal extent than the shocks or discontinuities that they often drive. Furthermore, this study has identified 23 ICMEs observed by pairs of spacecraft close to radial alignment. A detailed analysis of these events could lead to a better understanding of how ICMEs evolve during propagation.

Table 1 The MESSENGER (200501- 201203) and *Venus Express* (200601-201312) ICME catalogue. Parenthesised table entries indicate uncertainty in the stated values.

Radial Evolution of a Magnetic Cloud: MESSENGER, STEREO, and Venus Express Observations

S. W. [Good](#)¹, R. J. Forsyth¹, J. M. Raines², D. J. Gershman³, J. A. Slavin², and T. H. Zurbuchen
2015 *ApJ* 807 177

The Solar Orbiter and Solar Probe Plus missions will provide observations of magnetic clouds closer to the Sun than ever before, and it will be good preparation for these missions to make full use of the most recent in situ data sets from the inner heliosphere—namely, those provided by MERcury Surface, Space ENvironment, GEochemistry, and RANGing (MESSENGER) and Venus Express—for magnetic cloud studies. We present observations of the same magnetic cloud made by MESSENGER at Mercury and later by Solar TERrestrial RElations Observatory-B (STEREO-B), while the spacecraft were radially aligned in **2011 November**. Few such radial observations of magnetic clouds have been previously reported. Estimates of the solar wind speed at MESSENGER are also presented, calculated through the application of a previously established technique. The cloud's flux rope has been analyzed using force-free fitting; the rope diameter increased from 0.18 to 0.41 AU (corresponding to an $r_H^{0.94}$ dependence on heliocentric distance, r_H), and the axial magnetic field strength dropped from 46.0 to 8.7 nT (an $r_H^{-1.84}$ dependence) between the spacecraft, clear indications of an expanding structure. The axial magnetic flux was ~ 0.50 nT AU² at both spacecraft, suggesting that the rope underwent no significant erosion through magnetic reconnection between MESSENGER and STEREO-B. Further, we estimate the change in the cloud's angular width by assuming helicity conservation. It has also been found that the rope axis rotated by 30° between the spacecraft to lie close to the solar equatorial plane at STEREO-B. Such a rotation, if it is a common feature of coronal mass ejection propagation, would have important implications for space weather forecasting.

Intense Geomagnetic Storms during Solar Cycles 23-25

N. [Gopalswamy](#), [S. Akiyama](#), [S. Yashiro](#), [P. Makela](#), [H. Xie](#)

Proceedings of the Fifteenth Workshop Solar Influences on the Magnetosphere, Ionosphere and Atmosphere, June, 2023 **2024**

<https://arxiv.org/ftp/arxiv/papers/2401/2401.03524.pdf> **File**

Intense geomagnetic storms are characterized by a minimum value of the Dst index at or below -100 nT. It is well known that these storms are caused by the southward magnetic fields in coronal mass ejections (CMEs) and corotating interaction regions (CIRs). While CIR storms are confined to Dst values at or above -150 nT, CME storms can reach Dst -500 nT or lower. In this report, we illustrate the need to understand the storm evolution based on solar source and solar wind parameters using a recent storm (**2023 April 24**) by way of providing the motivation to catalog such events for a better understanding of the main phase time structure of geomagnetic storms

The Solar Cause of the 2022 February 3 Geomagnetic Storm that Led to the Demise of the Starlink Satellites

Nat [Gopalswamy](#), [Hong Xie](#), [Seiji Yashiro](#), [Sachiko Akiyama](#)

Sun and Geosphere **2023**

<https://arxiv.org/ftp/arxiv/papers/2303/2303.02330.pdf>

We report on the solar source of the **2022 February 3** geomagnetic storm of moderate strength that contributed to the loss of 39 Starlink satellites. The geomagnetic storm was caused by the **2022 January 29** halo coronal mass ejection (CME) that was of moderate speed (about 690 km/s) originating from NOAA active region 12936 located in the northeast quadrant (N18E06) of the Sun. The eruption was marked by an M1.1 flare, which started at 22:45 UT, peaked at 23:32 UT on January 29 and ended at 00:24 UT the next day. The CME ended up as a shock-driving magnetic cloud (MC) observed at Sun-Earth L1 and at STEREO-Ahead (STA) located about 34 deg behind Earth. The geomagnetic storm was caused by a strong southward component of the MC that was boosted by a high speed solar wind stream behind the MC. Even though Earth and STA were separated by only about 34 deg, the MC appeared quite different at Earth and L1. One possibility is that the MC was writhed reflecting the curved neutral line at the Sun. In-situ observations suggest that the MC was heading closer to STA than to Earth because of the earlier arrival at STA. However, the shock arrived at STA and Earth around the same time, suggesting a weaker shock at Earth due to flank passage.

What is Unusual about the Third Largest Geomagnetic Storm of Solar Cycle 24?

[N. Gopalswamy](#), [S. Yashiro](#), [S. Akiyama](#), [H. Xie](#), [P. Mäkelä](#), [M.-C. Fok](#), [C. P. Ferradas](#)

JGR **Volume127, Issue8** e2022JA030404 2022

<https://arxiv.org/ftp/arxiv/papers/2207/2207.11630.pdf>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2022JA030404>

We report on the solar and interplanetary (IP) causes of the third largest geomagnetic storm (**2018 August 26**) in solar cycle 24. The underlying coronal mass ejection (CME) originating from a quiescent filament region becomes a 440 km/s magnetic cloud (MC) at 1 au after ~5 days. The prolonged CME acceleration (for about 24 hrs) coincides with the time profiles of the post-eruption arcade intensity and reconnected flux. Chen et al. (2019) obtain lower speed since they assumed that the CME does not accelerate after about 12 hrs. The presence of multiple coronal holes near the filament channel and the high-speed wind from them seem to have the combined effect of producing complex rotation in the corona and IP medium resulting in a high-inclination MC. The Dst time profile in the main phase steepens significantly (rapid increase in storm intensity) coincident with the density increase (prominence material) in the second half of the MC. Simulations using the Comprehensive Inner Magnetosphere-Ionosphere (CIMI) model shows that a higher ring current energy results from larger dynamic pressure in MCs. Furthermore, the Dst index is highly correlated with the main-phase time integral of the ring current injection that includes density, consistent with the simulations. A complex temporal structure develops in the storm main phase if the underlying MC has a complex density structure during intervals of southward interplanetary magnetic field. We conclude that the high intensity of the storm results from the prolonged CME acceleration, complex rotation, and the high density in the 1-au MC.

Table 2 List of 32 Storms Considered for Correlation Analysis, the First 17 Being Very Intense 1998-2018

The Multiview observatory for solar terrestrial science (MOST),

Gopalswamy, N., Christe, S., Fung, S. F., Gong, Q., Jian, L., Kanekal, S. G., et al.

in The decadal survey for solar and space physics (Heliophysics), 2024–2033. Submitted White Paper. (2022).

https://ntrs.nasa.gov/api/citations/20220013621/downloads/GopalswamyNat_MOST_WP.pdf

Understanding the emergence of magnetic flux from the solar interior through the photosphere and its global impact on the inner heliosphere is a key scientific goal of the heliophysics community. This white paper outlines the concept of the Multiview Observatory for Solar Terrestrial Science (MOST) mission, which will make measurements of solar variability from the solar interior, atmosphere, and the interplanetary (IP) medium. MOST will be a 4- spacecraft mission with one each at L4 (MOST1) and L5 (MOST2) and the other two (MOST3 and MOST4) at variable locations along Earth orbit. MOST1 and MOST2 will each carry seven remote-sensing and 3 in-situ instruments. All four spacecraft will carry elements of a novel radio package known as the Faraday Effect Tracker of Coronal and Heliospheric structures (FETCH). FETCH will systematically probe the magnetic content of transient IP structures including coronal mass ejections (CMEs) and stream interaction regions (SIRs). The Faraday rotation measurements will provide magnetic information of these structures at various heliocentric distances from the outer corona to Earth's vicinity. Photospheric and chromospheric magnetograms will cover >70% of the solar surface providing synchrotron maps needed for accurately modeling the corona and solar wind. EUV, coronagraph, radio spectrograph, and heliospheric imager (HI) observations from multiple viewpoints provide 3-d information on CMEs/CME-driven shocks, SIRs, and other solar wind structures. The Hard X-ray imagers will provide the flare aspects of solar eruptions to complement the CME aspects. MOST, a 10-year mission, is well aligned with NASA's Heliophysics objectives and will

provide an unprecedented opportunity to achieve these objectives with broad participation from the heliophysics community.

Effect of the Weakened Heliosphere in Solar Cycle 24 on the Properties of Coronal Mass Ejections

N. [Gopalswamy](#), [S. Akiyama](#), [S. Yashiro](#), [G. Michalek](#), [H. Xie](#), [P. Mäkelä](#)

Proc. 19th International Astrophysics Conference held in Santa Fe, New Mexico, March 9 - 13, 2020

<https://arxiv.org/ftp/arxiv/papers/2007/2007.08291.pdf>

Solar cycle (SC) 24 has come to an end by the end of 2019, providing information on two full cycles to understand the manifestations of SC 24, the smallest cycle in the Space Age that has resulted in a weak heliospheric state indicated by the reduced pressure. The backreaction of the heliospheric state is to make the coronal mass ejections (CMEs) appear physically bigger than in SC 23, but their magnetic content has been diluted resulting in a lower geoeffectiveness. The heliospheric magnetic field is also lower in SC 24, leading to the dearth of high-energy solar energetic particle (SEP) events. These space weather events closely follow fast and wide (FW) CMEs. All but FW CMEs are higher in number in SC 24. The CME rate vs. sunspot number (SSN) correlation is high in both cycles but the rate increases faster in SC 24. We revisit the study of limb CMEs (those with source regions within 30 degrees from the limb) previously studied over partial cycles. We find that limb CMEs are slower in SC 24 as in the general population but wider. Limb halo CMEs follow the same trend of slower SC-24 CMEs. However, the SC-24 CMEs become halos at a shorter distance from the Sun. Thus, slower CMEs becoming halos sooner is a clear indication of the backreaction of the weaker heliospheric state on CMEs. We can further pin down the heliospheric state as the reason for the altered CME properties because the associated flares have similar distributions in the two cycles, unaffected by the heliospheric state. **2002-09-06**

Table 3. Halo CMEs originating within 30° from the limb in solar cycles 23 and 24

The State of the Heliosphere Revealed by Limb Halo Coronal Mass Ejections in Solar Cycles 23 and 24

Nat [Gopalswamy](#), [Sachiko Akiyama](#), [Seiji Yashiro](#)

ApJL 897:L1 2020

<https://arxiv.org/ftp/arxiv/papers/2006/2006.05844.pdf>

<https://iopscience.iop.org/article/10.3847/2041-8213/ab9b7b/pdf>

We compare the properties of halo coronal mass ejections (CMEs) that originate close to the limb (within a central meridian distance range of 60 to 90 deg) during solar cycles 23 and 24 to quantify the effect of the heliospheric state on CME properties. There are 44 and 38 limb halos in the cycles 23 and 24, respectively. Normalized to the cycle-averaged total sunspot number, there are 42 percent more limb halos in cycle 24. Although the limb halos as a population is very fast (average speed 1464 km s⁻¹), cycle-24 halos are slower by 26 percent than the cycle-23 halos. We introduce a new parameter, the heliocentric distance of the CME leading edge at the time a CME becomes a full halo; this height is significantly shorter in cycle 24 (by 20 percent) and has a lower cutoff at 6 Rs. These results show that cycle-24 CMEs become halos sooner and at a lower speed than the cycle-23 ones. On the other hand, the flare sizes are very similar in the two cycles, ruling out the possibility of eruption characteristics contributing to the differing CME properties. In summary, this study reveals the effect of the reduced total pressure in the heliosphere that allows cycle-24 CMEs expand more and become halos sooner than in cycle 23. Our findings have important implications for the space-weather consequences of CMEs in cycle 25 (predicted to be similar to cycle 24) and for understanding the disparity in halo counts reported by automatic and manual catalogs. **2011 September 22**

We investigate the propagation of the **2015 June 21** CME-driven shock as revealed by the type II bursts at metric and longer wavelengths and coronagraph observations. The CME was associated with the second largest geomagnetic storm of solar cycle 24 and a large solar energetic particle (SEP) event. The eruption consisted of two M-class flares, with the first one being confined, with no metric or interplanetary radio bursts. However, there was intense microwave burst, indicating accelerated particles injected toward the Sun. The second flare was eruptive that resulted in a halo CME. The CME was deflected primarily by an equatorial coronal hole that resulted in the modification of the intensity profile of the associated SEP event and the duration of the CME at Earth. The interplanetary type II burst was particularly intense

and was visible from the corona all the way to the vicinity of the Wind spacecraft with fundamental-harmonic structure. We computed the shock speed using the type II drift rates at various heliocentric distances and obtained information on the evolution of the shock that matched coronagraph observations near the Sun and in-situ observations near Earth. The depth of the geomagnetic storm is consistent with the 1-AU speed of the CME and the magnitude of the southward component.

A New Technique to Provide Realistic Input to CME Forecasting Models

Proc. IAU [Volume 13, Symposium S335](#) July 2017 , pp. 258-262

[sci-hub.se/10.1017/S1743921317011048](https://doi.org/10.1017/S1743921317011048)

We report on a technique to construct a flux rope (FR) from eruption data at the Sun. The technique involves line-of-sight magnetic fields, post-eruption arcades in the corona, and white-light coronal mass ejections (CMEs) so that the FR geometric and magnetic properties can be fully defined in addition to the kinematic properties. We refer to this FR as FRED (Flux Rope from Eruption Data). We illustrate the FRED construction using the **2012 July 12** eruption and compare the coronal and interplanetary properties of the FR. The results indicate that the FRED input should help make realistic predictions of the components of the FR magnetic field in the heliosphere.

Extreme Solar Eruptions and their Space Weather Consequences

Solar eruptions generally refer to coronal mass ejections (CMEs) and flares. Both are important sources of space weather. Solar flares cause sudden change in the ionization level in the ionosphere. CMEs cause solar energetic particle (SEP) events and geomagnetic storms. A flare with unusually high intensity and/or a CME with extremely high energy can be thought of examples of extreme events on the Sun. These events can also lead to extreme SEP events and/or geomagnetic storms. Ultimately, the energy that powers CMEs and flares are stored in magnetic regions on the Sun, known as active regions. Active regions with extraordinary size and magnetic field have the potential to produce extreme events. Based on current data sets, we estimate the sizes of one-in-hundred and one-in-thousand year events as an indicator of the extremeness of the events. We consider both the extremeness in the source of eruptions and in the consequences. We then compare the estimated 100-year and 1000-year sizes with the sizes of historical extreme events measured or inferred.

J. Atmos. Solar-Terr. Phys. 2017 **File**

<https://arxiv.org/pdf/1705.08912.pdf>

We report on a study comparing coronal flux ropes inferred from eruption data with their interplanetary counterparts constructed from in situ data. The eruption data include the source-region magnetic field, post-eruption arcades, and coronal mass ejections (CMEs). Flux ropes were fit to the interplanetary CMEs (ICMEs) considered for the 2011 and 2012 Coordinated Data Analysis Workshops (CDAWs). We computed the total reconnected flux involved in each of the associated solar eruptions and found it to be closely related to flare properties, CME kinematics, and ICME properties. By fitting flux ropes to the white-light coronagraph data, we obtained the geometric properties of the flux ropes and added magnetic properties derived from the reconnected flux. We found that the CME magnetic field in the corona is significantly higher than the ambient magnetic field at a given heliocentric distance. The radial dependence of the flux-rope magnetic field strength is faster than that of the ambient magnetic field. The magnetic field strength of the coronal flux rope is also correlated with that in interplanetary flux ropes constructed from in situ data, and with the observed peak magnetic field strength in ICMEs. The physical reason for the observed correlation between the peak field strength in MCs is the higher magnetic field content in faster coronal flux ropes and ultimately the higher reconnected flux in the

eruption region. The magnetic flux ropes constructed from the eruption data and coronagraph observations provide a realistic input that can be used by various models to predict the magnetic properties of ICMEs at Earth and other destination in the heliosphere. **1999 June 24**

Estimation of Reconnection Flux using Post-eruption Arcades and Its Relevance to 1-au Magnetic Clouds

Solar Phys. 292: 65. **2017**

<https://arxiv.org/pdf/1701.01943v1.pdf> **File**

We report on a new method to compute the flare reconnection (RC) flux from post-eruption arcades (PEAs) and the underlying photospheric magnetic fields. In previous work, the RC flux has been computed using cumulative flare ribbon area. Here we obtain the RC flux as half of that underlying the PEA associated with the eruption using an image in EUV taken after the flare maximum. We apply this method to a set of 21 eruptions that originated near the solar disk center in solar cycle 23. We find that the RC flux from the arcade method (Φ_{rA}) has excellent agreement with that from the ribbon method (Φ_{rR}) according to: $\Phi_{rA} = 1.24(\Phi_{rR})^{0.99}$. We also find Φ_{rA} to be correlated with the poloidal flux (Φ_P) of the associated magnetic cloud at 1 au: $\Phi_P = 1.20(\Phi_{rA})^{0.85}$. This relation is nearly identical to that obtained by Qiu et al. (2007) using a set of only 9 eruptions. Our result supports the idea that flare reconnection results in the formation of flux rope and PEA as a common process.

DOI 10.1186/s40562-016-0039-2

Coronal mass ejections (CMEs) are relatively a recently discovered phenomenon—in 1971, some 15 years into the Space Era. It took another two decades to realize that CMEs are the most important players in solar terrestrial relationship as the root cause of severe weather in Earth's space environment. CMEs are now counted among the major natural hazards because they cause large solar energetic particle (SEP) events and major geomagnetic storms, both of which pose danger to humans and their technology in space and ground. Geomagnetic storms discovered in the 1700s, solar flares discovered in the 1800s, and SEP events discovered in the 1900s are all now found to be closely related to CMEs via various physical processes occurring at various locations in and around CMEs, when they interact with the ambient medium. This article identifies a number of key developments that preceded the discovery of white-light CMEs suggesting that CMEs were waiting to be discovered. The last two decades witnessed an explosion of CME research following the launch of the Solar and Heliospheric Observatory mission in 1995, resulting in the establishment of a full picture of CMEs.

Short-term variability of the Sun-Earth system: an overview of progress made during the CAWSES-II period

Review

Progress in Earth and Planetary Science, Volume 2, article id. #13, 41 pp., **2015**

<http://arxiv.org/pdf/1504.06332v1.pdf> **File**

sci-hub.se/10.1186/s40645-015-0043-8

This paper presents an overview of results obtained during the CAWSES-II period on the short-term variability of the Sun and how it affects the near-Earth space environment. CAWSES-II was planned to examine the behavior of the solar-terrestrial system as the solar activity climbed to its maximum phase in solar cycle 24. After a deep minimum following cycle 23, the Sun climbed to a very weak maximum in terms of the sunspot number in cycle 24 (MiniMax24), so many of the results presented here refer to this weak activity in comparison with cycle 23. The short-term variability that has immediate consequence to Earth and geospace manifests as solar eruptions from closed-field regions and high-speed streams from coronal holes. Both electromagnetic (flares) and mass emissions (coronal mass ejections - CMEs) are

involved in solar eruptions, while coronal holes result in high-speed streams that collide with slow wind forming the so-called corotating interaction regions (CIRs). Fast CMEs affect Earth via leading shocks accelerating energetic particles and creating large geomagnetic storms. CIRs and their trailing high-speed streams (HSSs), on the other hand, are responsible for recurrent small geomagnetic storms and extended days of auroral zone activity, respectively. The latter leads to the acceleration of relativistic magnetospheric 'killer' electrons. One of the major consequences of the weak solar activity is the altered physical state of the heliosphere that has serious implications for the shock-driving and storm-causing properties of CMEs. Finally, a discussion is presented on extreme space weather events prompted by the **23 July 2012** super storm event that occurred on the backside of the Sun. Many of these studies were enabled by the simultaneous availability of remote sensing and in situ observations from multiple vantage points with respect to the Sun-Earth line.

sci-hub.tw/10.1002/2015JA021446

We report on a study that compares the properties of magnetic clouds (MCs) during the first 73 months of solar cycles 23 and 24 in order to understand the weak geomagnetic activity in cycle 24. We find that the number of MCs did not decline in cycle 24, although the average sunspot number is known to have declined by ~40%. Despite the large number of MCs, their geoeffectiveness in cycle 24 was very low. The average Dst index in the sheath and cloud portions in cycle 24 was -33 nT and -23 nT, compared to -66 nT and -55 nT, respectively in cycle 23. One of the key outcomes of this investigation is that the reduction in the strength of geomagnetic storms as measured by the Dst index is a direct consequence of the reduction in the factor VBz (the product of the MC speed and the out-of-the-ecliptic component of the MC magnetic field). The reduction in MC-to-ambient total pressure in cycle 24 is compensated for by the reduction in the mean MC speed, resulting in the constancy of the dimensionless expansion rate at 1 AU. However, the MC size in cycle 24 was significantly smaller, which can be traced to the anomalous expansion of coronal mass ejections near the Sun reported by Gopalswamy et al. (2014a). One of the consequences of the anomalous expansion seems to be the larger heliocentric distance where the pressure balance between the CME flux ropes and the ambient medium occurs in cycle 24.

CMEs during the Two Activity Peaks in Cycle 24 and their Space Weather Consequences

N. **Gopalswamy**, P. Mäkelä, S. Akiyama, S. Yashiro, N. Thakur

Sun and Geosphere, **2015**

<http://arxiv.org/pdf/1509.04216v1.pdf> **File**

We report on a comparison between space weather events that occurred around the two peaks in the sunspot number (SSN) during solar cycle 24. The two SSN peaks occurred in the years 2012 and 2014. Even though SSN was larger during the second peak, we find that there were more space weather events during the first peak. The space weather events we considered are large solar energetic particle (SEP) events and major geomagnetic storms associated with coronal mass ejections (CMEs). We also considered interplanetary type II radio bursts, which are indicative of energetic CMEs driving shocks. When we compared the CME properties between the two SSN peaks, we find that more energetic CMEs occurred during the 2012 peak. In particular, we find that CMEs accompanying IP type II bursts had an average speed of 1543 km/s during the 2012 peak compared to 1201 km/s during the 2014 peak. This result is consistent with the reduction in the average speed of the general population of CMEs during the second peak. All SEP events were associated with the interplanetary type II bursts, which are better than halo CMEs as indicators of space weather. The comparison between the two peaks also revealed the discordant behavior CME rate and SSN is more pronounced during the second peak. None of the 14 disk-center halo CMEs was associated with a major storm in 2014. The lone major storm in 2014 was due to the intensification of the (southward) magnetic field in the associated magnetic cloud by a shock that caught up and propagated into the magnetic cloud. **23-24 Apr 2012; 18-19 Feb 2014**

The Mild Space Weather in Solar Cycle 24

Nat **Gopalswamy**, [Sachiko Akiyama](#), [Seiji Yashiro](#), [Hong Xie](#), [Pertti Makela](#), [Grzegorz Michalek](#)

Proc. 14th International Ionospheric Effects Symposium on 'Bridging the gap between applications and research involving ionospheric and space weather disciplines' May 12-14, **2015**, Alexandria, VA

<http://arxiv.org/ftp/arxiv/papers/1508/1508.01603.pdf>

The space weather is extremely mild during solar cycle 24: the number of major geomagnetic storms and high-energy solar energetic particle events are at the lowest since the dawn of the space age. Solar wind measurements at 1 AU using Wind and ACE instruments have shown that there is a significant drop in the density, magnetic field, total pressure, and Alfvén speed in the inner heliosphere as a result of the low solar activity. The drop in large space weather events is disproportionately high because the number of energetic coronal mass ejections that cause these events has not decreased significantly. For example, the rate of halo CMEs, which is a good indicator of energetic CMEs, is similar to that in cycle 23, even though the sunspot number has declined by about 40%. The mild space weather seems to be a consequence of the anomalous expansion of CMEs due to the low ambient pressure in the heliosphere. The anomalous expansion results in the dilution of the magnetic contents of CMEs, so the geomagnetic storms are generally weak. CME driven shocks propagating through the weak heliospheric field are less efficient in accelerating energetic particles, so the particles do not attain high energies. Finally, we would like to point out that extreme events such as the 2012 July 23 CMEs that occurred on the backside of the Sun and did not affect Earth except for a small proton event. **March 17, 2015**

The Peculiar Behavior of Halo Coronal Mass Ejections in Solar Cycle 24

N. **Gopalswamy**, H. Xie, S. Akiyama, P. Mäkelä, S. Yashiro, G. Michalek

ApJL **2015**

<http://arxiv.org/ftp/arxiv/papers/1504/1504.01797.pdf>

We report on a remarkable finding that the halo coronal mass ejections (CMEs) in cycle 24 are more abundant than in cycle 23, although the sunspot number in cycle 24 has dropped by about 40%. We also find that the distribution of halo-CME source locations is different in cycle 24: the longitude distribution of halos is much flatter with the number of halos originating at central meridian distance ≥ 60 degrees twice as large as that in cycle 23. On the other hand, the average speed and the associated soft X-ray flare size are the same in the two cycles, suggesting that the ambient medium into which the CMEs are ejected is significantly different. We suggest that both the higher abundance and larger central meridian longitudes of halo CMEs can be explained as a consequence of the diminished total pressure in the heliosphere in cycle 24 (Gopalswamy et al. 2014). The reduced total pressure allows CMEs expand more than usual making them appear as halos.

Anomalous Expansion of Coronal Mass Ejections during Solar Cycle 24 and its Space Weather Implications

Nat **Gopalswamy**, Sachiko Akiyama, Seiji Yashiro, Hong Xie, and Pertti Mäkelä, Grzegorz Michalek
E-print, April **2014**; GRL 41:2673-2680

<http://arxiv.org/pdf/1404.0252v1.pdf>

<http://sci-hub.tw/10.1002/2014GL059858>

The familiar correlation between the speed and angular width of coronal mass ejections (CMEs) is also found in solar cycle 24, but the regression line has a larger slope: for a given CME speed, cycle 24 CMEs are significantly wider than those in cycle 23. The slope change indicates a significant change in the physical state of the heliosphere, due to the weak solar activity. The total pressure in the heliosphere (magnetic + plasma) is reduced by $\sim 40\%$, which leads to the anomalous expansion of CMEs explaining the increased slope. The excess CME expansion contributes to the diminished effectiveness of CMEs in producing magnetic storms during cycle 24, both because the magnetic content of the CMEs is diluted and also because of the weaker ambient fields. The reduced magnetic field in the heliosphere may contribute to the lack of solar energetic particles accelerated to very high energies during this cycle.

Testing the empirical shock arrival model using quadrature observations

N. **Gopalswamy**^{1,*}, P. Mäkelä^{1,2}, H. Xie^{1,2}, S. Yashiro

Space Weather, Volume 11, Issue 11, pages 661–669, November **2013**

http://cdaw.gsfc.nasa.gov/publications/gopal/gopal2013SW_testESA.pdf

The empirical shock arrival (ESA) model was developed based on quadrature data from Helios (in situ) and P-78 (remote sensing) to predict the Sun-Earth travel time of coronal mass ejections (CMEs). The ESA model requires

earthward CME speed as input, which is not directly measurable from coronagraphs along the Sun-Earth line. The Solar Terrestrial Relations Observatory (STEREO) and the Solar and Heliospheric Observatory (SOHO) were in quadrature during 2010–2012, so the speeds of Earth-directed CMEs were observed with minimal projection effects. We identified a set of 20 full halo CMEs in the field of view of SOHO that were also observed in quadrature by STEREO. We used the earthward speed from STEREO measurements as input to the ESA model and compared the resulting travel times with the observed ones from L1 monitors. We find that the model predicts the CME travel time within about 7.3 h, which is similar to the predictions by the ENLIL model. We also find that CME-CME and CME-coronal hole interaction can lead to large deviations from model predictions. **2011 February 15, 2012 July 12**

The Solar Connection of Enhanced Heavy Ion Charge States in the Interplanetary Medium: Implications for the Flux-rope Structure of CMEs

N. **Gopalswamy**, P. Mäkelä, S. Akiyama, H. Xie, S. Yashiro, and A. A. Reinard
Solar Physics, Volume 284, Issue 1, pp 17-46, **2013**, **File**

We investigated a set of 54 interplanetary coronal mass ejection (ICME) events whose solar sources are very close to the disk center (within ± 15 degrees from the central meridian). The ICMEs consisted of 23 magnetic cloud (MC) events and 31 non-MC events. Our analyses suggest that the MC and non-MC ICMEs have more or less the same eruption characteristics at the Sun in terms of soft X-ray flares and CMEs. Both types have significant enhancements in charge states, although the non-MC structures have slightly lower levels of enhancement. The overall duration of charge state enhancement is also considerably smaller than that in MCs as derived from solar wind plasma and magnetic signatures. We find very good correlation between the Fe and O charge state measurements and the flare properties such as soft X-ray flare intensity and flare temperature for both MCs and non-MCs. These observations suggest that both MC and non-MC ICMEs are likely to have a flux-rope structure and the unfavorable observational geometry may be responsible for the appearance of non-MC structures at 1 AU. We do not find any evidence for active region expansion resulting in ICMEs lacking a flux rope structure because the mechanism of producing high charge states and the flux rope structure at the Sun is the same for MC and non-MC events.

Energetic Particle and Other Space Weather Events of Solar Cycle 24

N. **Gopalswamy**

E-print, Jan 2013,; In Space Weather: The space Radiation Environment, Ed. Q. Hu, G. Li, G. P. Zank, X. Ao, O. Verkhoglyadova, J. H. Adama, AIP Conf Proc. 1500, pp. 14-19, **2012**; **File**

We report on the space weather events of solar cycle 24 in comparison with those during a similar epoch in cycle 23. We find major differences in all space weather events: solar energetic particles, geomagnetic storms, and interplanetary shocks. Dearth of ground level enhancement (GLE) events and major geomagnetic storms during cycle 24 clearly stand out. The space weather events seem to reflect the less frequent solar eruptions and the overall weakness of solar cycle 24.

Radio-loud CMEs from the disk center lacking shocks at 1 AU

N. **Gopalswamy**, P. Makela, S. Akiyama, S. Yashiro, H. Xie, R. J. MacDowall, M. L. Kaiser
E-print, June **2012**, JGR, 117, A08106, **2012**

A coronal mass ejection (CME) associated with a type II burst and originating close to the center of the solar disk typically results in a shock at Earth in 2-3 days and hence can be used to predict shock arrival at Earth. However, a significant fraction (about 28%) of such CMEs producing type II bursts were not associated with shocks at Earth. We examined a set of 21 type II bursts observed by the Wind/WAVES experiment at decameter-hectometric (DH) wavelengths that had CME sources very close to the disk center (within a central meridian distance of 30 degrees), but did not have a shock at Earth. We find that the near-Sun speeds of these CMEs average to ~644 km/s, only slightly higher than the average speed of CMEs associated with radio-quiet shocks. However, the fraction of halo CMEs is only ~30%, compared to 54% for the radio-quiet shocks and 91% for all radio-loud shocks. We conclude that the disk-center radio-loud CMEs with no shocks at 1 AU are generally of lower energy and they drive shocks only close to the Sun and dissipate before arriving at Earth. There is also evidence for other possible processes that lead to the lack of shock at 1 AU: (i) overtaking CME shocks merge and one observes a single shock at Earth, and (ii) deflection by nearby coronal holes can push the shocks away from the Sun-Earth line, such that Earth misses these shocks. The probability of observing a shock at 1 AU increases rapidly above 60% when the CME speed exceeds 1000 km/s and when the type II bursts propagate to frequencies below 1 MHz.

Universal Heliophysical Processes

Gopalswamy, N.

In: *The Sun, the Solar Wind, and the Heliosphere*, ed. M. P. Miralles and J. Sanchez Almeida, IAGA Special Sopron Book Series, Vol 4, Chapter 2, Springer, pp 9-20, **2011, File**, DOI: 10.1007/978/90-481-9787-3_2

The physical processes in the heliospace are a direct consequence of the influenced by Sun's mass and electromagnetic emissions. There has been enormous progress in studying these processes since the dawn of the space age half a century ago. The heliospace serves as a great laboratory to study numerous physical processes, using the vast array of ground and space-based measurements of various physical quantities. The observational capabilities collectively form the Great Observatory to make scientific investigations not envisioned by individual instrument teams. The International Heliophysical Year (IHY) program has been promoting scientific investigations on the universality of physical processes such as shocks, particle acceleration, dynamo, magnetic reconnection, magnetic flux ropes, plasma-neutral matter interactions, turbulence, and so on. This paper highlights scientific deliberations on these and related topics that took place during the IAGA sessionon "Universal Heliophysical Processes" in Sopron, Hungary. The session featured several invited and contributed papers that focused on observations, theory and modeling of the universal heliophysical processes.

Earth-Affecting Solar Causes Observatory (EASCO): A Potential International Living with a Star Mission from Sun-Earth L5*

This paper describes the scientific rationale for an L5 mission and a partial list of key scientific instruments the mission should carry. The L5 vantage point provides an unprecedented view of the solar disturbances and their solar sources that can greatly advance the science behind space weather. A coronagraph and a heliospheric imager at L5 will be able to view CMEs broadsided, so space speed of the Earth-directed CMEs can be measured accurately and their radial structure discerned. In addition, an inner coronal imager and a magnetograph from L5 can give advance information on active regions and coronal holes that will soon rotate on to the solar disk. Radio remote sensing at low frequencies can provide information on shock-driving CMEs, the most dangerous of all CMEs. Coordinated helioseismic measurements from the Sun-Earth line and L5 provide information on the physical conditions at the base of the convection zone, where solar magnetism originates. Finally, in situ measurements at L5 can provide information on the large-scale solar wind structures (corotating interaction regions (CIRs)) heading towards Earth that potentially result in adverse space weather.

Solar Sources of "Driverless" Interplanetary Shocks,

INTERPLANETARY SHOCKS LACKING TYPE II RADIO BURSTS

N. [Gopalswamy](#)¹, H. Xie², P. Mäkelä², S. Akiyama², S. Yashiro³, M. L. Kaiser¹, R. A. Howard⁴, and J.-L. Bougeret⁵

Astrophysical Journal, 710:1111–1126, 2010 February, [File](#)

We report on the radio-emission characteristics of 222 interplanetary (IP) shocks detected by spacecraft at Sun–Earth L1 during solar cycle 23 (1996 to 2006, inclusive). A surprisingly large fraction of the IP shocks (~34%) was radio quiet (RQ; i.e., the shocks lacked type II radio bursts). We examined the properties of coronal mass ejections (CMEs) and soft X-ray flares associated with such RQ shocks and compared them with those of the radio-loud (RL) shocks. The CMEs associated with the RQ shocks were generally slow (average speed ~535 km s⁻¹) and only ~40% of the CMEs were halos. The corresponding numbers for CMEs associated with RL shocks were 1237 km s⁻¹ and 72%, respectively. Thus, the CME kinetic energy seems to be the deciding factor in the radio-emission properties of shocks. The lower kinetic energy of CMEs associated with RQ shocks is also suggested by the lower peak soft X-ray flux of the associated flares (C3.4 versus M4.7 for RL shocks). CMEs associated with RQ CMEs were generally accelerating within the coronagraph field of view (average acceleration ~+6.8 m s⁻²), while those associated with RL shocks were decelerating (average acceleration ~-3.5 m s⁻²). This suggests that many of the RQ shocks formed at large distances from the Sun, typically beyond 10 Rs, consistent with the absence of metric and decameter–hectometric (DH) type II radio bursts. A small fraction of RL shocks had type II radio emission solely in the kilometric (km) wavelength domain. Interestingly, the kinematics of the CMEs associated with the km type II bursts is similar to those of RQ shocks, except that the former are slightly more energetic. Comparison of the shock Mach numbers at 1 AU shows that the RQ shocks are mostly subcritical, suggesting that they were not efficient in accelerating electrons. The Mach number values also indicate that most of these are quasi-perpendicular shocks. The radio-quietness is predominant in the rise phase and decreases through the maximum and declining phases of solar cycle 23. About 18% of the IP shocks do not have discernible ejecta behind them. These shocks are due to CMEs moving at large angles from the Sun–Earth line and hence are not blast waves. The solar sources of the shock-driving CMEs follow the sunspot butterfly diagram, consistent with the higher-energy requirement for driving shocks.

Advances in Geosciences, Volume 21: Solar Terrestrial (ST). Edited by Marc Duldig. Singapore: World Scientific, 2010, p.71, 2010, [File](#)

http://arxiv.org/pdf/0903.2776.pdf?origin=publication_detail

Solar cycle 23 witnessed the observation of hundreds of halo coronal mass ejections (CMEs), thanks to the high dynamic range and extended field of view of the Large Angle and Spectrometric Coronagraph (LASCO) on board the Solar and Heliospheric Observatory (SOHO) mission. More than two thirds of halo CMEs originating on the front side of the Sun have been found to be geoeffective ($Dst \leq -50$ nT). The delay time between the onset of halo CMEs and the peak of ensuing geomagnetic storms has been found to depend on the solar source location (Gopalswamy et al., 2007). In particular, limb halo CMEs (source longitude $> 45^\circ$) have a 20% shorter delay time on the average. It was suggested that the geomagnetic storms due to limb halos must be due to the sheath portion of the interplanetary CMEs (ICMEs) so that the shorter delay time can be accounted for. We confirm this suggestion by examining the sheath and ejecta portions of ICMEs from Wind and ACE data that correspond to the limb halos. Detailed examination showed that three pairs of limb halos were interacting events. Geomagnetic storms following five limb halos were actually produced by other disk halos. The storms followed by four isolated limb halos and the ones associated with interacting limb halos, were all due to the sheath portions of ICMEs.

CME link to the geomagnetic storms

Nat **Gopalswamy**

Solar and Stellar Variability: Impact on Earth and Planets, Proceedings IAU Symposium No. 264, 2009, p. 326-335, A.G. Kosovichev, A.H. Andrei & J.-P. Rozelot, eds.; **File**

sci-hub.tw/10.1017/S1743921309992870

The coronal mass ejection (CME) link to geomagnetic storms stems from the southward component of the interplanetary magnetic field contained in the CME flux ropes and in the sheath between the flux rope and the CME-driven shock. A typical storm-causing CME is characterized by (i) high speed, (ii) large angular width (mostly halos and partial halos), and (iii) solar source location close to the central meridian. For CMEs originating at larger central meridian distances, the storms are mainly caused by the sheath field. Both the magnetic and energy contents of the storm-producing CMEs can be traced to the magnetic structure of active regions and the free energy stored in them.

Coronal mass ejections and space weather

Nat **Gopalswamy**

Climate and Weather of the Sun-Earth System(CAWSES):Selected Papers from the2007 KyotoSymposium, Edited by T. Tsuda, R. Fujii, K. Shibata, and M. A. Geller, pp. 77–120.

c_TERRAPUB, Tokyo, 2009, **File**.

Solar energetic particles (SEPs) and geomagnetic storms are the two primary space weather consequences of coronal mass ejections (CMEs) and their interplanetary counterparts (ICMEs). I summarize the observed properties of CMEs and ICMEs, paying particular attention to those properties that determine the ability of CMEs in causing space weather. Then I provide observational details of two the central issues: (i) for producing geomagnetic storms, the solar source location and kinematics along with the magnetic field structure and intensity are important, and (ii) for SEPs, the shock-driving ability of CMEs, the Alfvén speed in the ambient medium, and the connectivity to Earth are crucial parameters.

CME Interaction with Coronal Holes and their Interplanetary Consequences

N. **Gopalswamy**¹, P. Mäkelä^{1,2}, H. Xie^{1,2}, S. Akiyama^{1,2}, and S. Yashiro^{1,2}

JGR, 2009; **File**; J. Geophys. Res., Vol. 114, No. A3, A00A22

A significant number of interplanetary (IP) shocks (~17%) during cycle 23 were not followed by drivers. The number of such “driverless” shocks steadily increased with the solar cycle with 15%, 33%, and 52% occurring in the rise, maximum, and declining phase of the solar cycle. The solar sources of 15% of the driverless shocks were very close to the central meridian of the Sun (within ~15°), which is quite unexpected. More interestingly, all the driverless shocks with their solar sources near the solar disk center occurred during the declining phase of solar cycle 23. When we investigated the coronal environment of the source regions of driverless shocks, we found that in each case there was at least one coronal hole nearby suggesting that the coronal holes might have deflected the associated coronal mass ejections (CMEs) away from the Sun-Earth line. The presence of abundant low-latitude coronal holes during the declining phase further explains why CMEs originating close to the disk center mimic the limb CMEs, which normally lead to driverless shocks due to purely geometrical reasons. We also examined the solar source regions of shocks with drivers. For these, the coronal holes were located such that they either had no influence on the CME trajectories, or they deflected the CMEs towards the Sun-Earth line. We also obtained the open magnetic field distribution on the Sun by performing a potential field source surface extrapolation to the corona. It was found that the CMEs generally move away from the open magnetic field regions. The CME-coronal hole interaction must be widespread in the declining phase, and may have a significant impact on the geoeffectiveness of CMEs.

Halo coronal mass ejections and geomagnetic storms

Nat **Gopalswamy**

Earth Planets Space, 61, 1–3, 2009, **File**

In this letter, I show that the discrepancies in the geoeffectiveness of halo coronal mass ejections (CMEs) reported in the literature arise due to the varied definitions of halo CMEs used by different authors. In particular, I show that the low geoeffectiveness rate is a direct consequence of including partial halo CMEs. The geoeffectiveness of partial halo CMEs is lower because they are of low speed and likely to make a glancing impact on Earth

Large Geomagnetic Storms: Introduction to Special Section

Nat [Gopalswamy](#)

J. Geophys. Res., 114, A00A00, 2009 File

Solar cycle 23 witnessed the accumulation of rich data sets that reveal various aspects of geomagnetic storms in unprecedented detail both at the Sun where the storm causing disturbances originate and in geospace where the effects of the storms are directly felt. During two recent coordinated data analysis workshops (CDAWs) the large geomagnetic storms ($Dst \leq -100$ nT) of solar cycle 23 were studied in order to understand their solar, interplanetary, and geospace connections. This special section grew out of these CDAWs with additional contributions relevant to these storms. Here I provide a brief summary of the results presented in the special section.

Solar connections of geoeffective magnetic structures

Nat [Gopalswamy](#)

[Journal of Atmospheric and Solar-Terrestrial Physics](#)

[Volume 70, Issue 17](#), December 2008, Pages 2078-2100, File

Coronal mass ejections (CMEs) and high-speed solar wind streams (HSS) are two solar phenomena that produce large-scale structures in the interplanetary (IP) medium. CMEs evolve into interplanetary CMEs (ICMEs) and the HSS result in corotating interaction regions (CIRs) when they interact with preceding slow solar wind. This paper summarizes the properties of these structures and describes their geoeffectiveness. The primary focus is on the intense storms of solar cycle 23 because this is the first solar cycle during which simultaneous, extensive, and uniform data on solar, IP, and geospace phenomena exist. After presenting illustrative examples of coronal holes and CMEs, I discuss the internal structure of ICMEs, in particular the magnetic clouds (MCs). I then discuss how the magnetic field and speed correlate in the sheath and cloud portions of ICMEs. CME speed measured near the Sun also has significant correlations with the speed and magnetic field strengths measured at 1 AU. The dependence of storm intensity on MC, sheath, and CME properties is discussed pointing to the close connection between solar and IP phenomena. I compare the delay time between MC arrival at 1AU and the peak time of storms for the cloud and sheath portions and show that the internal structure of MCs leads to the variations in the observed delay times.

Finally, we examine the variation of solar-source latitudes of IP structures as a function of the solar cycle and find that they have to be very close to the disk center.

Comment on “Prediction of the 1-AU arrival times of CME associated interplanetary shocks: Evaluation of an empirical interplanetary shock propagation model” by K.-H. Kim et al.

N. [Gopalswamy](#)¹ and H. Xie²

JOURNAL OF GEOPHYSICAL RESEARCH, VOL. 113, A10105, doi:10.1029/2008JA013030, 2008, File

Table 1. List of Events With Solar Sources Used for Testing the ESA Model

Recently, Kim et al. [2007] (hereinafter referred to as KMC) have evaluated the empirical shock arrival (ESA) model and found only about 60% of the observed shocks arrived within ± 112 h of the model prediction. They also found the deviations of shock travel times from the ESA model strongly correlate with the CME initial speeds (VCME), suggesting that the constant interplanetary (IP) acceleration used in the ESA model may not be applicable to all CMEs. KMC further concluded that faster CMEs decelerate and slower CMEs accelerate more than that what is considered in the ESA model. We point out that such systematic deviations in arrival time arise owing to projection effects.

Solar Sources and Geospace Consequences of Interplanetary Magnetic Clouds Observed During Solar Cycle 23

Solar sources and geospace consequences of interplanetary magnetic clouds observed during solar cycle 23

A preprint of this paper can be downloaded as a [pdf file](#) ([an online supplement table](#)).

We present results of a statistical investigation of 99 magnetic clouds (MCs) observed during 1995-2005. The MC-associated coronal mass ejections (CMEs) are faster and wider on the average and originate within ± 30 deg from the Sun center. The solar sources of MCs also followed the butterfly diagram. The correlation between the magnetic field strength

and speed of MCs was found to be valid over a much wider range of speeds. The number of south-north (SN) MCs was dominant and decreased with solar cycle, while the number of north-south (NS) MCs increased confirming the odd-cycle behavior. Two-thirds of MCs were geoeffective; the Dst index was highly correlated with speed and magnetic field in MC as well as their product. Many (55%) fully northward (FN) MCs were geoeffective solely due to their sheaths. The non-geoeffective MCs were slower (average speed 382 km/s), had a weaker southward magnetic field (average -5.2 nT), and occurred mostly during the rise phase of the solar activity cycle.

Erratum to “Solar sources and geospace consequences of interplanetary magnetic clouds observed during solar cycle 23”(Paper 1) [J. Atmos. Sol.-Terr. Phys. 70(2?4) (2008) 245-253]

E-print, July 2009

Journal of Atmospheric and Solar-Terrestrial Physics, Volume 71, Issue 8-9, p. 1005-1009, 2009

One of the figures (Fig. 4) in “Solar sources and geospace consequences of interplanetary magnetic clouds observed during solar cycle 23” Paper 1?? by Gopalswamy et al.(2008, JASTP, Vol.70, Issues 2?4, February 2008, pp. 245-253) is incorrect because of a software error in the routine that was used to make the plot. The source positions of various magnetic cloud (MC) types are therefore not plotted correctly. Fig. 1 replaces Fig.4 in Paper 1 and is now plotted correctly.

Energetic Phenomena on the Sun

Nat [Gopalswamy](#)

Coronal mass ejections and space weather due to extreme events

N. [Gopalswamy](#), S. Yashiro and S. Akiyama

in "Solar Influence on the Heliosphere and Earth's Environment: Recent Progress and Prospects", ed. N. Gopalswamy and A. Battacharyya, Quest Publications, Mumbai, p. 79, 2006.

This paper summarizes the extreme solar activity and its space weather implications during the declining phase of the solar cycle 23: October-November 2003 (AR 486), November 2004 (AR 696), January 2005 (AR 720), and September 2005 (AR 808). We have compiled and compared the properties of eruptions and the underlying active regions. All these are super active regions, but the flare and CME productivity varied significantly. While the CMEs from all the regions kept the level of solar energetic particles (SEPs) at storm level for several days, their geoeffectiveness (the ability to produce geomagnetic storms) was significantly different, probably due to the location of the eruptions on the Sun.

Solar source of the largest geomagnetic storm of cycle 23

N. [Gopalswamy](#)¹, S. Yashiro^{1,2}, G. Michalek, H. Xie^{1,2}, R. P. Lepping¹, and R. A. Howard³

Geophys. Res. Lett. 32, 12, **2005**, [File](#)

The largest geomagnetic storm of solar cycle 23 occurred on 2003 November 20 with a Dst index of -472 nT, due to a coronal mass ejection (CME) from active region 0501. The CME near the Sun had a sky-plane speed of ~1660 km/s, but the associated magnetic cloud (MC) arrived with a speed of only 730 km/s. The MC at 1 AU (ACE Observations) had a high magnetic field (~56 nT) and high inclination to the ecliptic plane. The southward component of the MC's magnetic field was made up almost entirely of its axial field because of its east-south-west (ESW) chirality. We suggest that the southward pointing strong axial field of the MC reconnected with Earth's front-side magnetic field, resulting in the largest storm of the solar cycle 23.

An empirical model to predict the 1 - AU arrival of interplanetary shocks,

[Gopalswamy](#), N., A. Lara, P. K. Manoharan, and R. Howard,

Adv. Space Res., 36, 2289–2294, **(2005)**.

We extend the empirical coronal mass ejection (CME) arrival model of Gopalswamy et al. [Gopalswamy, N. et al. Predicting the 1-AU arrival times of coronal mass ejections, J. Geophys. Res. 106, 29207, 2001] to predict the 1-AU arrival of interplanetary (IP) shocks. A set of 29 IP shocks and the associated magnetic clouds observed by the Wind spacecraft are used for this study. The primary input to this empirical shock arrival model is the initial speed of white-light CMEs obtained using coronagraphs. We use the gas dynamic piston–shock relationship to derive the ESA model which provides a simple means of obtaining the 1-AU speed and arrival times of interplanetary shocks using CME speeds.

Predicting the 1-AU Arrival Times of Coronal Mass Ejections

N. [Gopalswamy](#), A. Lara, S. Yashiro, M. L. Kaiser, and R. A. Howard

Journal of Geophysical Research, Vol. 106 , No. A12 , p. 29,207 **(2001)** ; [File](#)

We describe an empirical model to predict the 1-AU arrival of coronal mass ejections (CMEs). This model is based on an effective interplanetary (IP) acceleration described in Gopalswamy et al. [2000b] that the CMEs are subject to, as they propagate from the Sun to 1 AU. We have improved this model (i) by minimizing the projection effects (using data from spacecraft in quadrature) in determining the initial speed of CMEs, and (ii) by allowing for the cessation of the interplanetary acceleration before 1 AU. The resulting effective IP acceleration was higher in magnitude than what was obtained from CME measurements from spacecraft along the Sun-Earth line. We evaluated the predictive capability of the CME arrival model using recent two-point measurements from the Solar and Heliospheric Observatory (SOHO), Wind and ACE spacecraft. We found that an acceleration cessation distance of 0.76 AU is in reasonable agreement with the observations. The new prediction model reduces the average prediction error from 15.4 to 10.7 hrs. The model is in good agreement with the observations for high speed CMEs. For slow CMEs, the model as well as observations show a flat arrival time of ~4.3 days. Use of quadrature observations minimized the projection effects naturally without the need to assume the width of the CMEs. However, there is no simple way of estimating the projection effects based on the surface location of the Earth-directed CMEs observed by a spacecraft (such as SOHO) located along the Sun-Earth line because it is impossible to measure the width of these CMEs. The standard assumption that the CME is a rigid cone may not be correct. In fact, the predicted arrival times have a better agreement with the observed arrival times when no projection correction is applied to the SOHO CME measurements. The results presented in this work suggest that CMEs expand and accelerate near the Sun (inside 0.7 AU) more than our model supposes; these aspects will have to be included in future models.

Interplanetary acceleration of coronal mass ejections.

[Gopalswamy](#), N.; Lara, A.; Lepping, R. P.; Kaiser, M. L.; Berdichevsky, D.; St. Cyr, O. C.

Geophys. Res. Lett. 27, 145–148 **(2000)**.

<http://onlinelibrary.wiley.com/doi/10.1029/1999GL003639/pdf>

Using an observed relation between speeds of CMEs near the Sun and in the solar wind, we determine an “effective” acceleration acting on the CMEs. We found a linear relation between this effective acceleration and the initial speed of the CMEs. The acceleration is similar to that of the slow solar wind in magnitude. The average solar wind speed naturally divides CMEs into fast and slow ones. Based on the relation between the acceleration and initial speed, we derive an empirical model to predict the arrival of CMEs at 1 AU.

Identification of Hot Plasma Anomalies in Solar Wind Using Fe Ion Charge Distributions

Farid F. **Goryaev**, Vladimir Slemzin, and Denis Rodkin

2020 ApJL 905 L17

<https://doi.org/10.3847/2041-8213/abcc76>

A presence of high Fe charge states in the ionic charge state distributions of the solar wind (SW) plasma, commonly characterized by the mean charge Q_{Fe} , provides valuable information on heating processes in the SW sources. We study the relationship between the parameter Q_{Fe} and the charge state distributions of Fe ions using the Solar TERrestrial Relations Observatory/PLASMA and SupraThermal Ion Composition data on the beginning of the 24th Cycle (2010 January–2011 July). We find that the Fe charge state distributions related to SW with $Q_{\text{Fe}} \approx 8\text{--}10$ have a uni-modal shape peaked around Fe⁸⁺–Fe⁹⁺. When the Q_{Fe} value increases, the distributions change: at first, the profile extends to higher charge states and then transforms into a bi-modal shape with a second maximum around Fe¹⁶⁺ and a minimum around Fe¹²⁺. We discuss possible reasons for such bi-modality through the example of the interplanetary coronal mass ejection (ICME) event on **2011 February 24–26**, where it was related to the heating of an eruptive prominence. For such an analysis, it is informative to have a special measure of the fraction of highly charged ions for the Fe ion charge distribution in SW. In addition to Q_{Fe} , we introduce a parameter q_{12} equal to a fraction of Fe ions with charges $Q \geq 12$ and show that this parameter can be applied for identifying both the large-scale hot plasma enhancements associated with ICMEs and small hot fragments of SW plasma, which may be associated with small-scale solar activity in various coronal structures.

Magnetic reconnection in the heliosphere: new insights from observations in the solar wind

J. T. **Gosling**

Proceedings of the International Astronomical Union / Volume 4 / Symposium S257, pp 367 – 377,

Published online: 16 May 2009

<http://journals.cambridge.org/action/displayIssue?iid=4866212>

Magnetic reconnection plays a central role in the interpretation of a wide variety of observed solar, space, astrophysical, and laboratory plasma phenomena. The relatively recent discovery that reconnection is common at thin current sheets in the solar wind opens up a new laboratory for studying this fundamental plasma process and its after-effects. Here we provide a brief overview of some of the new insights on reconnection derived from observations of reconnection exhaust jets in the solar wind.

Multiple magnetic reconnection sites associated with a coronal mass ejection in the solar wind

Gosling, J. T.; Eriksson, S.; McComas, D. J.; Phan, T. D.; Skoug, R. M.

J. Geophys. Res., Vol. 112, No. A8, A08106, 2007

<http://dx.doi.org/10.1029/2007JA012418>

Occasionally, an exhaust is observed at the interface between ambient solar wind and the leading edge of an ICME where reconnection serves to erode away some of the magnetic flux carried by the ICME. More often the exhausts are observed at thin current sheets within the interiors of ICMEs or near their trailing edges. We have examined an unusually large set of seven reconnection exhausts, including both sunward and antisunward directed events, observed within the interior of and near the trailing edge of an ICME.

Formation and evolution of corotating interaction regions and their three dimensional structure. **Review**

Gosling, J.T., Pizzo, V.J.:

1999, Space Sci. Rev. 89, 21.

sci-hub.se/10.1023/A:1005291711900

Corotating interaction regions are a consequence of spatial variability in the coronal expansion and solar rotation, which cause solar wind flows of different speeds to become radially aligned. Compressive interaction regions are produced where high-speed wind runs into slower plasma ahead. When the flow pattern emanating from the Sun is roughly time-stationary these compression regions form spirals in the solar equatorial plane that corotate with the Sun, hence the name corotating interaction regions, or CIRs. The leading edge of a CIR is a forward pressure wave that propagates into the slower plasma ahead, while the trailing edge is a reverse pressure wave that propagates back into the trailing high-speed flow. At large heliocentric distances the pressure waves bounding a CIR commonly steepen into forward and reverse shocks. Spatial variation in the solar wind outflow from the Sun is a consequence of the solar magnetic field, which modulates the coronal expansion. Because the magnetic equator of the Sun is commonly both warped and tilted with respect to the heliographic equator, CIRs commonly have substantial north-south tilts that are opposed in the northern

and southern hemispheres. Thus, with increasing heliocentric distance the forward waves in both hemispheres propagate toward and eventually across the solar equatorial plane, while the reverse shocks propagate poleward to higher latitudes. This paper provides an overview of observations and numerical models that describe the physical origin and radial evolution of these complex three-dimensional (3-D) heliospheric structures.

The solar flare myth.

Gosling, J.T.,

1993. J. Geophys. Res. 98, 18937–18950. **File**

<https://sci-hub.ru/10.1029/93JA01896>

Many years of research have demonstrated that large, nonrecurrent geomagnetic storms, shock wave disturbances in the solar wind, and energetic particle events in interplanetary space often occur in close association with large solar flares. This result has led to a paradigm of cause and effect - that large solar flares are the fundamental cause of these events in the near-Earth space environment. This paradigm, which I call "the solar flare myth," dominates the popular perception of the relationship between solar activity and interplanetary and geomagnetic events and has provided much of the pragmatic rationale for the study of the solar flare phenomenon. Yet there is good evidence that this paradigm is wrong and that flares do not generally play a central role in producing major transient disturbances in the near-Earth space environment. In this paper I outline a different paradigm of cause and effect that removes solar flares from their central position in the chain of events leading from the Sun to near-Earth space. Instead, this central role is given to events known as coronal mass ejections

Difference in the parameters of ICMEs in Ejecta and Sheath region and their impact on Dst index during 1997–2014

A.Goswami

[Advances in Space Research](#) **Volume 62, Issue 3**, 1 August 2018, Pages 692-706

<https://reader.elsevier.com/reader/sd/A2E30781C7C222DE3DCD5CBF00E17585D5634341A3EB75BA96844FB1E60B83753DBD8508EE05ACA454D926ADDCE9675F>

The comparisons in respect of mean parameters in [ejecta](#) and sheath region during 1997–2014 have been studied here. The results from statistical analysis indicate that all the parameters, are more powerful (in respect of amplitude) in the sheath region than that of ejecta, whether there is magnetic cloud (MC) structure or not. Probably, a shock plays the key role to such increases. The inter-relation of parameters in the sheath is higher than that of ejecta. In addition, I also discuss the nature of storm influence parameters variation in the sheath and ejecta separately for MC or non MC. The results in respect of t-test and correlations confirm that, associated with the shock, the [magnetic field](#) in the sheath region are opened up and sheath parameters are more energetic for producing geomagnetic storm. I have proposed multiple linear regression model for the prediction of response variable (Dst index) by using mean of the total magnetic field, southward magnetic field, velocity of the [solar wind](#). About 61% of the observed value can be predicted using this model for MC. The correlation becomes strong in case of addition and multiplication functions from the dependent components of [multiple regression](#) line equation with Dst index than that of individual parameters of MC and non MC with Dst index. Thus it is preferable to investigate accumulated effect of ICMEs causing successive geomagnetic storms as compared to their isolated effects. One ultimate finding is that, there is a higher correlation between Dst index and solar wind parameters (individually or combined) in the sheath than the ones in the ejecta, for both MCs and non-MCs.

Properties and Geoeffectiveness of Solar Wind High-Speed Streams and Stream Interaction Regions During Solar Cycles 23 and 24

Maxime [Grandin](#), [Anita T. Aikio](#), [Alexander Kozlovsky](#)

JGR [Volume124, Issue6](#) June 2019 Pages 3871-3892

sci-hub.se/10.1029/2018JA026396

We study the properties and geoeffectiveness of solar wind high-speed streams (HSSs) emanating from coronal holes and associated with stream interaction regions (SIRs). This paper presents a statistical study of 588 SIR/HSS events with solar wind speed at 1 AU exceeding 500 km/s during 1995–2017, encompassing the decline of solar cycle 22 to the decline of cycle 24. Events are detected using measurements of the solar wind speed and the interplanetary magnetic field. Events misidentified as or interacting with interplanetary coronal mass ejections are removed by comparison with an existing interplanetary coronal mass ejection list. Using this SIR/HSS event catalog (list given in the [supporting information](#)), a superposed epoch analysis of key solar wind parameters is carried out. It is found that the number of SIR/HSSs peaks during the late declining phase of solar cycle (SC) 23, as does their velocity, but that their geoeffectiveness in terms of the AE and SYM-H indices is low. This can be explained by the anomalously low values of

magnetic field during the extended solar minimum. Within SC23 and SC24, the highest geoeffectiveness of SIR/HSSs takes place during the early declining phases. Geoeffectiveness of SIR/HSSs continues to be up to 40% lower during SC24 than SC23, which can be explained by the solar wind properties. **6-24 June 2008**

A Geoeffective CME Caused by the Eruption of a Quiescent Prominence on 29 September 2013

V. V. [Grechnev](#) & [I. V. Kuzmenko](#)

[Solar Physics](#) volume 295, Article number: 55 (2020) **File**

<https://link.springer.com/content/pdf/10.1007/s11207-020-01619-x.pdf>

The eruption of a large prominence that occurred away of active regions in the SOL**2013-09-29** event produced a fast coronal mass ejection (CME) and a shock wave. The event caused considerable geospace disturbances, including a proton enhancement that have been addressed in previous studies. Continuing with the analysis of this event, we focus on the development of the CME and shock wave, assess an expected geospace impact using simplest considerations, and compare the expectations with in situ measurements near Earth. The high CME speed in this non-flare-associated event was determined by a considerable reconnected flux that corresponds to a pattern established by different authors. Estimations based on a few approaches showed the reconnection flux in this event to be comparable with a typical value in flare-associated eruptions. The shock wave was most likely impulsively excited by the erupting prominence in the same way as in flare-associated events and changed to the bow-shock regime later. The trajectory calculated for this scenario reproduces the Type II emission observed from 30 MHz to 70 kHz; its interruptions were probably caused by propagation effects. Properties of the near-Earth proton enhancement are discussed considering the results of recent studies

A Challenging Solar Eruptive Event of 18 November 2003 and the Causes of the 20 November Geomagnetic Superstorm. IV. Unusual Magnetic Cloud and Overall Scenario

<http://arxiv.org/pdf/1409.0283v1.pdf>

The geomagnetic superstorm of 20 November 2003 with Dst = -422 nT, one of the most intense in history, is not well understood. The superstorm was caused by a moderate solar eruptive event on 18 November, comprehensively studied in our preceding Papers I-III. The analysis has shown a number of unusual and extremely complex features, which presumably led to the formation of an isolated right-handed magnetic-field configuration. Here we analyze the interplanetary disturbance responsible for the 20 November superstorm, compare some of its properties with the extreme 28-29 October event, and reveal a compact size of the magnetic cloud (MC) and its disconnection from the Sun. Most likely, the MC had a spheromak configuration and expanded in a narrow angle of < 14 degree. A very strong magnetic field in the MC up to 56 nT was due to the unusually weak expansion of the disconnected spheromak in an enhanced-density environment constituted by the tails of the preceding ICMEs. Additional circumstances favoring the superstorm were (i) the exact impact of the spheromak on the Earth's magnetosphere and (ii) the almost exact southward orientation of the magnetic field, corresponding to the original orientation in its probable source region near the solar disk center.

II. CMEs, Shock Waves, and Drifting Radio Bursts

V.V. [Grechnev](#), A.M. Uralov, I.M. Chertok, V.A. Slemzin, B.P. Filippov, Ya.I. Egorov, V.G. Fainshtein, A.N. Afanasyev, N.P. Prestage, M. Temmer

E-print, Aug **2013**; [Solar Phys.](#), April **2014**, Volume 289, Issue 4, pp 1279-1312

<http://arxiv.org/pdf/1308.3010v1.pdf>

We continue our study (Grechnev et al. (2013), doi:10.1007/s11207-013-0316-6; Paper I) on the 18 November 2003 geoeffective event. To understand possible impact on geospace of coronal transients observed on that day, we investigated their properties from solar near-surface manifestations in extreme ultraviolet, LASCO white-light images, and dynamic radio spectra. We reconcile near-surface activity with the expansion of coronal mass ejections (CMEs) and determine their orientation relative to the earthward direction. The kinematic measurements, dynamic radio spectra, and

microwave and X-ray light curves all contribute to the overall picture of the complex event and confirm an additional eruption at 08:07-08:20 UT close to the solar disk center presumed in Paper I. Unusual characteristics of the ejection appear to match those expected for a source of the 20 November superstorm but make its detection in LASCO images hopeless. On the other hand, none of the CMEs observed by LASCO seem to be a promising candidate for a source of the superstorm being able to produce, at most, a glancing blow on the Earth's magnetosphere. Our analysis confirms free propagation of shock waves revealed in the event and reconciles their kinematics with "EUV waves" and dynamic radio spectra up to decameters.

A Challenging Solar Eruptive Event of 18 November 2003 and the Causes of the 20 November Geomagnetic Superstorm.

I. Unusual History of an Eruptive Filament

V. V. **Grechnev**, A. M. Uralov, V. A. Slemzin, I. M. Chertok, B. P. Filippov, G. V. Rudenko, M. Temmer
E-print, May **2013**; Solar Phys., (**2014**) 289, Issue 1, 289–318

<http://arxiv.org/pdf/1304.7950v1.pdf>

This is the first of four companion papers, which analyze a complex eruptive event of 18 November 2003 in AR 10501 and the causes of the largest Solar Cycle 23 geomagnetic storm on 20 November 2003. Analysis of a complete data set, not considered before, reveals a chain of eruptions to which hard X-ray and microwave bursts responded. A filament in AR 10501 was not a passive part of a larger flux rope, as usually considered. The filament erupted and gave origin to a CME. The chain of events was as follows: i) an eruption at 07:29 accompanied by a not reported M1.2 class flare associated with the onset of a first southeastern CME1, which is not responsible for the superstorm; ii) a confined eruption at 07:41 (M3.2 flare) that destabilized the filament; iii) the filament acceleration (07:56); iv) the bifurcation of the eruptive filament that transformed into a large cloud; v) an M3.9 flare in AR 10501 associated to this transformation. The transformation of the filament could be due to its interaction with the magnetic field in the neighborhood of a null point, located at a height of about 100 Mm above the complex formed by ARs 10501, 10503, and their environment. The CORONAS-F/SPIRIT telescope observed the cloud in 304 Å as a large Y-shaped darkening, which moved from the bifurcation region to the limb. The masses and kinematics of the cloud and the filament were similar. Remnants of the filament were not observed in the second southwestern CME2, previously regarded as a source of the 20 November superstorm. These facts do not support a simple scenario, in which the interplanetary magnetic cloud is considered as a flux rope formed from a structure initially associated with the pre-eruption filament in AR 10501. Observations suggest a possible additional eruption above the bifurcation region close to solar disk center between 08:07 and 08:17 that could be the source of the superstorm.

Comparative Study of MHD Modeling of the Background Solar Wind

C. **Gressl**, A. M. Veronig, M. Temmer, D. Odstrčil, J. A. Linker, Z. Mikić, P. Riley
Solar Physics, May **2014**, Volume 289, Issue 5, pp 1783-1801

Knowledge about the background solar wind plays a crucial role in the framework of space-weather forecasting. In-situ measurements of the background solar wind are only available for a few points in the heliosphere where spacecraft are located, therefore we have to rely on heliospheric models to derive the distribution of solar-wind parameters in interplanetary space. We test the performance of different solar-wind models, namely Magnetohydrodynamic Algorithm outside a Sphere/ENLIL (MAS/ENLIL), Wang–Sheeley–Arge/ENLIL (WSA/ENLIL), and MAS/MAS, by comparing model results with in-situ measurements from spacecraft located at 1 AU distance to the Sun (ACE, Wind). To exclude the influence of interplanetary coronal mass ejections (ICMEs), we chose **the year 2007** as a time period with low solar activity for our comparison. We found that the general structure of the background solar wind is well reproduced by all models. The best model results were obtained for the parameter solar-wind speed. However, the predicted arrival times of high-speed solar-wind streams have typical uncertainties of the order of about one day. Comparison of model runs with synoptic magnetic maps from different observatories revealed that the choice of the synoptic map significantly affects the model performance.

Recurrent Galactic Cosmic-Ray Flux Modulation in L1 and Geomagnetic Activity during the Declining Phase of the Solar Cycle 24

Catia **Grimani**^{1,2}, Andrea Cesarini², Michele Fabi^{1,2}, Federico Sabbatini³, Daniele Telloni⁴, and Mattia Villani^{1,2}

2020 ApJ 904 64

<https://doi.org/10.3847/1538-4357/abbb90>

<https://arxiv.org/pdf/2012.01152.pdf>

Short-term variations (<1 month) of the galactic cosmic-ray (GCR) flux in the inner heliosphere are mainly associated with the passage of high-speed solar wind streams (HSS) and interplanetary (IP) counterparts of coronal mass ejections (ICMEs). Data gathered with a particle detector flown on board the ESA LISA Pathfinder (LPF) spacecraft, during the declining part of solar cycle 24 (2016 February–2017 July) around the Lagrange point L1, have allowed us to study the characteristics of recurrent cosmic-ray flux modulations above 70 MeV n^{-1} . It is shown that the amplitude and evolution of individual modulations depend in a unique way on both IP plasma parameters and particle flux intensity before HSS and ICME transit. By comparing the LPF data with those gathered contemporaneously with the magnetic spectrometer experiment AMS-02 on board the International Space Station and with those of Earth's polar neutron monitors, the GCR flux modulation was studied at different energies during recurrent short-term variations. It is also aimed to set the near real-time particle observation requirements to disentangle the role of long- and short-term variations of the GCR flux to evaluate the performance of high-sensitivity instruments in space such as the future interferometers for gravitational wave detection. Finally, the association between recurrent GCR flux variation observations in L1 and weak to moderate geomagnetic activity in 2016–2017 is discussed. Short-term recurrent GCR flux variations are good proxies of recurrent geomagnetic activity when the B z component of the IP magnetic field is directed north.

Shock deceleration in interplanetary coronal mass ejections (ICMEs) beyond Mercury's orbit until one AU

J. Space Weather Space Clim. **2018**, 8, A54

<https://www.swsc-journal.org/articles/swsc/pdf/2018/01/swsc180026.pdf>

The CDPP propagation tool is used to propagate interplanetary coronal mass ejections (ICMEs) observed at Mercury by MESSENGER to various targets in the inner solar system (VEX, ACE, STEREO-A and B). The deceleration of ICME shock fronts between the orbit of Mercury and 1 AU is studied on the basis of a large dataset. We focus on the interplanetary medium far from the solar corona, to avoid the region where ICME propagation modifications in velocity and direction are the most drastic. Starting with a catalog of 61 ICMEs recorded by MESSENGER, the propagation tool predicts 36 ICME impacts with targets. ICME in situ signatures are investigated close to predicted encounter times based on velocities estimated at MESSENGER and on the default propagation tool velocity (500 km s⁻¹). ICMEs are observed at the targets in 26 cases and interplanetary shocks (not followed by magnetic ejecta) in two cases. Comparing transit velocities between the Sun and MESSENGER (\bar{v}_{SunMess}) and between MESSENGER and the targets (\bar{v}_{MessTar}), we find an average deceleration of 170 km s⁻¹ (28 cases). Comparing \bar{v}_{MessTar} to the velocities at the targets (v_{Tar}), average ICME deceleration is about 160 km s⁻¹ (13 cases). Our results show that the ICME shock deceleration is significant beyond Mercury's orbit. ICME shock arrival times are predicted with an average accuracy of about six hours with a standard deviation of eleven hours. Focusing on two ICMEs detected first at MESSENGER and later on by two targets illustrates our results and the variability in ICME propagations. The shock velocity of an ICME observed at MESSENGER, then at VEX and finally at STEREO-B decreases all the way. Predicting arrivals of potentially effective ICMEs is an important space weather issue. The CDPP propagation tool, in association with in situ measurements between the Sun and the Earth, can permit to update alert status of such arrivals.

Table 2. Details of the 36 pairs (2011-2014).

Source-dependent properties of two slow solar wind states

Léa **Griton**, Alexis P. Rouillard, Nicolas Poirier, Karine Issautier, Michel Moncuquet, Rui Pinto

ApJ **910** 63 **2021**

<https://arxiv.org/pdf/2102.06568.pdf>

<https://doi.org/10.3847/1538-4357/abe309>

Two states of the slow solar wind are identified from in-situ measurements by Parker Solar Probe (PSP) inside 50 solar radii from the Sun. At such distances the wind measured at PSP has not yet undergone significant transformation related to the expansion and propagation of the wind. We focus in this study on the properties of the quiet solar wind with no magnetic switchbacks. The two states differ by their plasma beta, flux and magnetic pressure. PSP's magnetic connectivity established with Potential Field Source Surface (PFSS) reconstructions, tested against extreme ultraviolet (EUV) and white-light imaging, reveals the two states correspond to a transition from a streamer to an equatorial coronal hole. The expansion factors of magnetic field lines in the streamer are 20 times greater than those rooted near the center of the coronal hole. The very different expansion rates of the magnetic field result in different magnetic pressures

measured by PSP in the two plasma states. Solar wind simulations run along these differing flux tubes reproduce the slower and denser wind measured in the streamer and the more tenuous wind measured in the coronal hole. Plasma heating is more intense at the base of the streamer field lines rooted near the boundary of the equatorial hole than those rooted closer to the center of the hole. This results in a higher wind flux driven inside the streamer than deeper inside the equatorial hole. **March 31, 2019-April 5, 2019**

TWO-PLASMA MODEL FOR LOW CHARGE STATE INTERPLANETARY CORONAL MASS EJECTION OBSERVATIONS

Jacob R. [Gruesbeck](#), Susan T. Lepri, and Thomas H. Zurbuchen

2012 ApJ 760 141

Recent ACE/SWICS observations have revealed that ~5% of all in situ observed interplanetary coronal mass ejections include time periods with very low charge state ions found to be associated with prominence eruptions. It was also shown that these low charge state ions are often observed concurrently with very high charge state ions. But, the physical process leading to these mixed charge states is not known and could be caused by either the mixing of plasmas of different temperatures or by non-local freeze-in effects as discussed by Gruesbeck. We provide a detailed and multi-stage analysis that excludes this latter option. We therefore conclude that time periods of very low charge states are the heliospheric remnants of plasmas born in prominences. We further conclude that the contemporaneously observed low and very high charge states are an indication of mixing of plasmas of different temperatures along magnetic field lines, suggesting that silicon and iron are depleted over carbon and oxygen in the cold, prominence-associated plasma. This represents the first experimental determination of elemental composition of prominence-associated plasma.

CONSTRAINTS ON CORONAL MASS EJECTION EVOLUTION FROM IN SITU OBSERVATIONS OF IONIC CHARGE STATES

Jacob R. [Gruesbeck](#)¹, Susan T. Lepri¹, Thomas H. Zurbuchen¹, and Spiro K. Antiochos²

Astrophysical Journal, 730:103 (9pp), **2011 April**; **File**

We present a novel procedure for deriving the physical properties of coronal mass ejections (CMEs) in the corona. Our methodology uses in situ measurements of ionic charge states of C, O, Si, and Fe in the heliosphere and interprets them in the context of a model for the early evolution of interplanetary CME (ICME) plasma, between 2 and 5R_⊙. We find that the data are best fit by an evolution that consists of an initial heating of the plasma, followed by an expansion that ultimately results in cooling. The heating profile is consistent with a compression of coronal plasma due to flare reconnection jets and an expansion cooling due to the ejection, as expected from the standard CME/flare model. The observed frozen-in ionic charge states reflect this time history and, therefore, provide important constraints for the heating and expansion timescales, as well as the maximum temperature the CME plasma is heated to during its eruption. Furthermore, our analysis places severe limits on the possible density of CME plasma in the corona. We discuss the implications of our results for CME models and for future analysis of ICME plasma composition.

Multiple-Hour-Ahead Forecast of the Dst Index Using a Combination of Long Short-Term Memory Neural Network and Gaussian Process

M. A. [Gruet](#), [M. Chandorkar](#), [A. Sicard](#), [E. Camporeale](#)

Space Weather **2018**

In this study, we present a method that combines a Long Short-Term Memory (LSTM) recurrent neural network with a Gaussian process (GP) model to provide up to 6-hr-ahead probabilistic forecasts of the Dst geomagnetic index. The proposed approach brings together the sequence modeling capabilities of a recurrent neural network with the error bars and confidence bounds provided by a GP. Our model is trained using the hourly OMNI and Global Positioning System (GPS) databases, both of which are publicly available. We first develop a LSTM network to get a single-point prediction of Dst. This model yields great accuracy in forecasting the Dst index from 1 to 6 hr ahead, with a correlation coefficient always higher than 0.873 and a root-mean-square error lower than 9.86. However, even if global metrics show excellent performance, it remains poor in predicting intense storms (Dst < -250 nT) 6 hr in advance. To improve it and to obtain probabilistic forecasts, we combine the LSTM model obtained with a GP and evaluate the hybrid predictor using the receiver operating characteristic curve and the reliability diagram. We conclude that this hybrid methodology provides improvements in the forecast of geomagnetic storms, from 1 to 6 hr ahead.

Detailed composition of iron ions in interplanetary coronal mass ejections based on a multipopulation approach*

Chaoran Gu¹, Verena Heidrich-Meisner¹, Robert F. Wimmer-Schweingruber¹ and Shuo Yao²
A&A 671, A63 (2023)

<https://www.aanda.org/articles/aa/pdf/2023/03/aa45500-22.pdf>

Context. Coronal mass ejections (CMEs) are extremely dynamical, large-scale events in which plasma – but not only the coronal plasma – is ejected into interplanetary space. If a CME is detected in situ by a spacecraft located in the interplanetary medium, it is then called an interplanetary coronal mass ejection (ICME). This solar activity has been studied widely since coronagraphs were first flown into space in the early 1970s.

Aims. Charge states of heavy ions reflect important information about the coronal temperature profile due to the freeze-in effect and it is estimated that iron ions freeze in at heights of ~ 5 solar radii. However, the measured charge-state distribution of iron ions cannot be composed of only one single group of plasma. To identify the different populations of iron charge-state composition of ICMEs and determine their sources, we developed a model that independently uses two, three, and four populations of iron ions to fit the measured charge-state distribution in ICMEs detected by the Advanced Composition Explorer (ACE) at 1 AU.

Methods. Three parameters are used to identify a certain population, namely freeze-in temperature, relative abundance, and kappa value (κ), which together describe the potential non-Maxwellian kappa distributions of coronal electrons. Our method chooses the reduced chi-squared to describe the goodness of fit of the model to the observations. The parameters of our model are optimized with the covariance-matrix-adaptation evolution strategy (CMA-ES).

Results. Two major types of ICMEs are identified according to the existence of hot material, and both, that is, the cool type and the hot type, have two main subtypes. Different populations in those types have their own features related to freeze-in temperature and κ . The electron velocity distribution function usually contains a significant hot tail in typical coronal material and hot material, while the Maxwellian distribution appears more frequently in mid-temperature material. Our model is also suitable for all types of solar wind and the existence of hot populations as well as the change of temperatures of individual populations may indicate boundaries between ICMEs and individual solar wind streams.

Abundances and Charge States of Heavy Ions in ICMEs Highly Related to Speed and Solar Activity

Chaoran Gu¹, Shuo Yao¹, and Lei Dai²

2020 ApJ 900 123

<https://doi.org/10.3847/1538-4357/aba7b8>

This statistical work studies the abundances and the charge states of the carbon, oxygen, and iron ions in 281 interplanetary coronal mass ejections (ICMEs) measured at 1 au by ACE spacecraft from 1998 to 2011. The Gaussian distribution test is applied, and the analysis of variance is used to quantify the similarity between two distributions of ionic charge states and abundances. The correlation coefficient is calculated to reveal the dependence of the abundances and the mean charge of heavy ions on the solar activity. The results show that the mean charge, the abundance, and the speed at 1 au are highly related to the sunspot number (SN). The O⁷⁺/O⁶⁺ shows statistical difference between the high speed and the low speed groups of ICMEs. Different from the cold materials inside ICMEs, the mean charge of carbon ions shows a positive relation to that of oxygen ions. The Mg/O in the studied ICMEs are much higher than that in the solar wind. Three types of charge distribution of C, O, and Fe ions are summarized. The fraction of each of the three types is related to the solar minimum or the solar maximum. The mean charge and the flux of oxygen ions show quasi-linear relations to the SN during solar minimum, and show fluctuations during maximum. The results reveal that the solar activity, which represents the solar magnetic field status by nature, controls the composition of heavy ions in ICMEs.

Forecasting Geoeffective Events from Solar Wind Data and Evaluating the Most Predictive Features through Machine Learning Approaches

Sabrina Guastavino, Katsiaryna Bahamazava, Emma Perracchione, Fabiana Camattari, Gianluca Audone, Daniele Telloni, Roberto Susino, Gianalfredo Nicolini, Silvano Fineschi, Michele Piana, Anna Maria Massone

ApJ 971 94 2024

<https://arxiv.org/pdf/2403.09847.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ad5b57/pdf>

This study addresses the prediction of geomagnetic disturbances by exploiting machine learning techniques. Specifically, the Long-Short Term Memory recurrent neural network, which is particularly suited for application over long time series, is employed in the analysis of in-situ measurements of solar wind plasma and magnetic field acquired over more than one solar cycle, from 2005 to 2019, at the Lagrangian point L1. The problem is approached as a binary classification aiming to predict one hour in advance a decrease in the SYM-H geomagnetic activity index below the threshold of -50 nT, which is generally regarded as indicative of magnetospheric perturbations. The strong class imbalance issue is tackled by using an appropriate loss function tailored to optimize appropriate skill scores in the training phase of the neural network. Beside classical skill scores, value-weighted skill scores are then employed to evaluate predictions, suitable in the study of problems, such as the one faced here, characterized by strong temporal variability. For the first time, the content of magnetic helicity and energy carried by solar transients, associated with their detection and likelihood of geo-effectiveness, were considered as input features of the network architecture. Their predictive capabilities are demonstrated through a correlation-driven feature selection method to rank the most relevant characteristics involved in the neural network prediction model. The optimal performance of the adopted neural network in properly forecasting the onset of geomagnetic storms, which is a crucial point for giving real warnings in an operational setting, is finally showed. **2005 July 24-August 2**

Physics-driven machine learning for the prediction of coronal mass ejections' travel times

<https://iopscience.iop.org/article/10.3847/1538-4357/ace62d/pdf>

Coronal Mass Ejections (CMEs) correspond to dramatic expulsions of plasma and magnetic field from the solar corona into the heliosphere. CMEs are scientifically relevant because they are involved in the physical mechanisms characterizing the active Sun. However, more recently CMEs have attracted attention for their impact on space weather, as they are correlated to geomagnetic storms and may induce the generation of Solar Energetic Particles streams. In this space weather framework, the present paper introduces a physics-driven artificial intelligence (AI) approach to the prediction of CMEs travel time, in which the deterministic drag-based model is exploited to improve the training phase of a cascade of two neural networks fed with both remote sensing and in-situ data. This study shows that the use of physical information in the AI architecture significantly improves both the accuracy and the robustness of the travel time prediction.

Coronal Mass Ejections during Geomagnetic Storms on Earth.

Expansion of magnetic clouds in the outer heliosphere

A.M. **Gulisano**, P. Demoulin, S. Dasso, L. Rodriguez

E-print, April, **2012**; A&A 543, A107 (**2012**)

A large amount of magnetized plasma are frequently ejected from the Sun as Coronal Mass Ejections (CMEs). A part of these ejections are detected in the solar wind as magnetic clouds (MCs) which have flux rope signatures. MCs are typically expanding structures in the inner heliosphere. The aim of this work is to derive the expansion properties of MCs in the outer heliosphere from 1 to 5 AU and to compare them to the ones in the inner heliosphere. We analyze MCs observed by the Ulysses spacecraft using in situ magnetic field and plasma measurements. The MC boundaries are defined in the MC frame after defining the MC axis with a minimum variance method applied only to the flux rope structure. As in the inner heliosphere, a large fraction of the velocity profile within MCs is close to a linear function of time. This implies a self-similar expansion and a MC size that locally follows a power-law of the solar distance with an exponent called zeta. We derive the value of zeta from the in situ velocity data. We analyze separately the non-perturbed MCs (cases presenting a linear velocity profile almost for the full event), and perturbed MCs (cases presenting a strongly distorted velocity profile). We find that non-perturbed MCs expand with a similar non-dimensional expansion rate ($\text{zeta} = 1.05 \pm 0.34$), i.e. slightly faster than the solar distance and than in the inner heliosphere ($\text{zeta} = 0.91 \pm 0.23$). The subset of perturbed MCs expands, as in the inner heliosphere, with a significant lower rate and with a larger dispersion ($\text{zeta} = 0.28 \pm 0.52$) as expected from the temporal evolution found in numerical simulations. This local measure of the expansion is also in agreement with the distribution with distance of MC size, mean magnetic field and plasma

parameters. The MCs in interaction with a strong field region, e.g. another MC, have the most variable expansion rate (ranging from compression to over-expansion).

Global and local expansion of magnetic clouds in the inner heliosphere

A. M. [Gulisano](#), P. Démoulin, S. Dasso, M. E. Ruiz and E. Marsch

A&A 509, A39 (2010)

Context. Observations of magnetic clouds (MCs) are consistent with the presence of flux ropes detected in the solar wind (SW) a few days after their expulsion from the Sun as coronal mass ejections (CMEs).

Aims. Both the in situ observations of plasma velocity profiles and the increase of their size with solar distance show that MCs are typically expanding structures. The aim of this work is to derive the expansion properties of MCs in the inner heliosphere from 0.3 to 1 AU.

Methods. We analyze MCs observed by the two Helios spacecraft using in situ magnetic field and velocity measurements. We split the sample in two subsets: those MCs with a velocity profile that is significantly perturbed from the expected linear profile and those that are not. From the slope of the in situ measured bulk velocity along the Sun-Earth direction, we compute an expansion speed with respect to the cloud center for each of the analyzed MCs.

Results. We analyze how the expansion speed depends on the MC size, the translation velocity, and the heliocentric distance, finding that all MCs in the subset of non-perturbed MCs expand with almost the same non-dimensional expansion rate (ζ). We find departures from this general rule for ζ only for perturbed MCs, and we interpret the departures as the consequence of a local and strong SW perturbation by SW fast streams, affecting the MC even inside its interior, in addition to the direct interaction region between the SW and the MC. We also compute the dependence of the mean total SW pressure on the solar distance and we confirm that the decrease of the total SW pressure with distance is the main origin of the observed MC expansion rate. We found that ζ was 0.91 ± 0.23 for non-perturbed MCs while ζ was 0.48 ± 0.79 for perturbed MCs, the larger spread in the last ones being due to the influence of the solar wind local environment conditions on the expansion.

Ranking ICME's efficiency for geomagnetic and ionospheric storms and risk of false alarms

T.L. [Gulyaeva](#)

Journal of Atmospheric and Solar-Terrestrial Physics Volume 164, November 2017, Pages 39-47

<https://www.sciencedirect.com/science/article/pii/S1364682617300135/pdf?md5=a2eda581d63b2bedcd51945229805b4e&pid=1-s2.0-S1364682617300135-main.pdf>

A statistical analysis is undertaken on ICME's efficiency in producing the geomagnetic and ionospheric storms. The mutually-consistent thresholds for the intense, moderate and weak space weather storms and quiet conditions are introduced with an analytical model based on relations between the equatorial Dst index and geomagnetic indices AE, aa, ap, ap(τ) and the ionospheric $V\sigma$ indices. The ionosphere variability $V\sigma$ index is expressed in terms of the total electron content (TEC) deviation from the -15-day sliding median normalized by the standard deviation for the 15 preceding days. The intensity of global positive ionospheric storm, $V\sigma_p$, and negative storm, $V\sigma_n$, is represented by the relative density of anomalous $\pm V\sigma$ index occurrence derived from the global ionospheric maps GIM-TEC for 1999–2016. An impact of total 421 ICME events for 1999–2016 on the geomagnetic and ionospheric storms expressed by AE, Dst, aa, ap, ap(τ), $V\sigma_p$, $V\sigma_n$ indices and their superposition is analyzed using ICME catalogue by Richardson and Cane (2010) during 24 h after the ICME start time t_0 . Hierarchy of efficiency of ICME \rightarrow storm relation is established. The ICMEs have a higher probability (22–25%) to be followed by the intense ionospheric and auroral electrojet storms at global and high latitudes as compared to the intense storms at middle and low latitudes (18–20%) and to moderate and weak storms at high latitudes (5–17%). At the same time ICMEs are more effective in producing the moderate storms (24–28%) at the middle and low latitudes as compared to the intense and weak storms at these latitudes (13–22%) and to moderate storms at high latitudes (8–17%). The remaining cases when quiet conditions are observed after ICMEs present higher chance for a false alarm. The risk factor for a false alarm can vary from 18% if the superposition of all indices is considered, to 51–64% for individual AE, $V\sigma_p$ and $V\sigma_n$ indices. The analysis indicates that the mutually-consistent thresholds can be successfully applied to the external sources of the geomagnetic and ionospheric storms other than ICME which present challenge for the further investigation.

Modelling the propagation of coronal mass ejections with COCONUT: implementation of the Regularized Biot-Savart Laws flux rope model

[Jinhan Guo](#), [L. Linan](#), [S. Poedts](#), [Y. Guo](#), [A. Lani](#), [B. Schmieder](#), [M. Brchneleva](#), [B. Perri](#), [T. Baratashvili](#), [Y. W. Ni](#), [P. F. Chen](#)

A&A 2023

<https://arxiv.org/pdf/2311.13432.pdf>

Context: Coronal mass ejections (CMEs) are rapid eruptions of magnetized plasma that occur on the Sun, which are known as the main drivers of adverse space weather. Accurately tracking their evolution in the heliosphere in numerical models is of utmost importance for space weather forecasting. Aims: The main objective of this paper is to implement the Regularized Biot-Savart Laws (RBSL) method in a new global corona model COCONUT. This approach has the capability to construct the magnetic flux rope with an axis of arbitrary shape. Methods: We present the implementation process of the RBSL flux rope model in COCONUT, which is superposed onto a realistic solar wind reconstructed from the observed magnetogram around the minimum of solar activity. Based on this, we simulate the propagation of an S-shaped flux rope from the solar surface to a distance of 25 solar radii. Results: Our simulation successfully reproduces the birth process of a CME originating from a sigmoid in a self-consistent way. The model effectively captures various physical processes and retrieves the prominent features of the CMEs in observations. In addition, the simulation results indicate that the magnetic topology of the CME flux rope at around 20 solar radii deviates from a coherent structure, and manifests as a mix of open and closed field lines with diverse footprints. Conclusions: This work demonstrates the potential of the RBSL flux rope model in reproducing CME events that are more consistent with observations. Moreover, our findings strongly suggest that magnetic reconnection during the CME propagation plays a critical role in destroying the coherent characteristic of a CME flux rope. **2007-02-11, 2011-03-08**

Advancing Theory and Modeling Efforts in Heliophysics

2022

<https://arxiv.org/pdf/2209.03611.pdf>

Heliophysics theory and modeling build understanding from fundamental principles to motivate, interpret, and predict observations. Together with observational analysis, they constitute a comprehensive scientific program in heliophysics. As observations and data analysis become increasingly detailed, it is critical that theory and modeling develop more quantitative predictions and iterate with observations. Advanced theory and modeling can inspire and greatly improve the design of new instruments and increase their chance of success. In addition, in order to build physics-based space weather forecast models, it is important to keep developing and testing new theories, and maintaining constant communications with theory and modeling. Maintaining a sustainable effort in theory and modeling is critically important to heliophysics. We recommend that all funding agencies join forces and consider expanding current and creating new theory and modeling programs--especially, 1. NASA should restore the HTMS program to its original support level to meet the critical needs of heliophysics science; 2. a Strategic Research Model program needs to be created to support model development for next-generation basic research codes; 3. new programs must be created for addressing mission-critical theory and modeling needs; and 4. enhanced programs are urgently required for training the next generation of theorists and modelers.

A Global MHD Simulation of Outer Heliosphere Including Anomalous Cosmic-Rays

Xiaocheng **Guo**^{1,2}, Vladimir Florinski³, and Chi Wang^{1,2}

APJ 879:87 (10pp), **2019**

<https://iopscience.iop.org/article/10.3847/1538-4357/ab262b/pdf>

A global MHD-neutrals-cosmic-rays simulation is conducted to investigate the effects of anomalous cosmic-rays (ACRs) on the large-scale structure of the outer heliosphere. In the model, the cosmic-rays are treated as a massless fluid that only contribute their pressure to the dynamics of the system. The diffusion of cosmic-rays in the interstellar medium is assumed to be much faster than inside the heliosphere, where it depends on the strength of the magnetic field. The results show that the influence of the cosmic-rays on the structure of the outer heliosphere depends on momentum and energy transfer from the solar wind plasma to the ACRs, accomplished through diffusive shock acceleration at the termination shock, and the subsequent loss of ACRs across the heliopause and their rapid escape into the interstellar medium. Under favorable conditions characterized by a large fraction of energy conversion and a high enough diffusion coefficient in the solar wind, the ACRs were found to reduce the width of the heliosheath by up to ~18 au.

Consequently, these results indicate that the effect of cosmic-rays is a potential key factor for the global structure of the outer heliosphere in a computer model that could partially explain the timing of the heliopause encounters of the two Voyager probes.

Modeling the Evolution and Propagation of 10 September 2017 CMEs and SEPs Arriving at Mars Constrained by Remote Sensing and In Situ Measurement

Jingnan [Guo](#), [Mateja Dumbović](#), [Robert F. Wimmer-Schweingruber](#), [Manuela Temmer](#), [Henning Lohf](#), [Yuming Wang](#), [Astrid Veronig](#), [Donald M. Hassler](#) ...
Space Weather [Volume16, Issue8](#) August 2018 Pages 1156-1169
<http://sci-hub.tw/10.1029/2018SW001973>

On 10 September 2017, solar energetic particles originating from the active region 12673 produced a ground level enhancement at Earth. The ground level enhancement on the surface of Mars, 160 longitudinally east of Earth, observed by the Radiation Assessment Detector (RAD) was the largest since the landing of the Curiosity rover in August 2012. Based on multipoint coronagraph images and the Graduated Cylindrical Shell model, we identify the initial 3-D kinematics of an extremely fast coronal mass ejection (CME) and its shock front, as well as another two CMEs launched hours earlier with moderate speeds. The three CMEs interacted as they propagated outward into the heliosphere and merged into a complex interplanetary CME (ICME). The arrival of the shock and ICME at Mars caused a very significant Forbush decrease seen by RAD only a few hours later than that at Earth, which was about 0.5 AU closer to the Sun. We investigate the propagation of the three CMEs and the merged ICME together with the shock, using the drag-based model and the WSA-ENLIL plus cone model constrained by the in situ observations. The synergistic study of the ICME and solar energetic particle arrivals at Earth and Mars suggests that to better predict potentially hazardous space weather impacts at Earth and other heliospheric locations for human exploration missions, it is essential to analyze (1) the eruption of the flare and CME at the Sun, (2) the CME kinematics, especially during their interactions, and (3) the spatially and temporally varying heliospheric conditions, such as the evolution and propagation of the stream interaction regions.

GALACTIC COSMIC-RAY INTENSITY MODULATION BY COROTATING INTERACTION REGION STREAM INTERFACES AT 1 au

X. [Guo](#)^{1,2} and V. Florinski

2016 ApJ 826 65

We present a new model that couples galactic cosmic-ray (GCR) propagation with magnetic turbulence transport and the MHD background evolution in the heliosphere. The model is applied to the problem of the formation of corotating interaction regions (CIRs) during the last solar minimum from the period between 2007 and 2009. The numerical model simultaneously calculates the large-scale supersonic solar wind properties and its small-scale turbulent content from 0.3 au to the termination shock. Cosmic rays are then transported through the background, and thus computed, with diffusion coefficients derived from the solar wind turbulent properties, using a stochastic Parker approach. Our results demonstrate that GCR variations depend on the ratio of diffusion coefficients in the fast and slow solar winds. Stream interfaces inside the CIRs always lead to depressions of the GCR intensity. On the other hand, heliospheric current sheet (HCS) crossings do not appreciably affect GCR intensities in the model, which is consistent with the two observations under quiet solar wind conditions. Therefore, variations in diffusion coefficients associated with CIR stream interfaces are more important for GCR propagation than the drift effects of the HCS during a negative solar minimum.

Corotating interaction regions and the 27 day variation of galactic cosmic rays intensity at 1 AU during the cycle 23/24 solar minimum

X. [Guo](#)^{1,*} and V. Florinski

JGR, 119, Issue 4, pages 2411–2429, April 2014

We investigate the formation and evolution of corotating interaction regions (CIRs) in the solar wind and their effects on galactic cosmic rays (GCR) during the recent solar cycle 23/24 solar minimum. The output from a three-dimensional MHD model serves as background for kinetic time-dependent simulations of GCR transport based on the Parker equation. The results show that the CIR forward/reverse shock pairs or compression/rarefaction regions play important roles in the transport of GCR particles and directly control the observed 27 day periodic intensity variations. We find that stream interfaces (SIs) in CIRs and the heliospheric current sheet (HCS) are both closely associated with the GCR depression onset, in agreement with the observations at 1 AU. The HCS is more important when its tilt angle becomes small during the declining phase of the solar minimum, while the passages of SIs control the onset of GCR depressions for larger HCS tilt angles. The mechanism of GCR intensity variation near 1 AU can be explained through an interplay between the effects of particle drift and diffusion. The simulated plasma background and GCR intensity are compared with the observations from spacecraft and a neutron monitor on the ground, to find good qualitative agreement. Evidently, CIRs had a substantial modulational effect on GCR during the recent solar minimum.

Energy transfer during intense geomagnetic storms driven by interplanetary coronal mass ejections and their sheath regions

Guo, Jianpeng; Feng, Xueshang; Emery, Barbara A.; **Zhang, Jie**; Xiang, Changqing; Shen, Fang; Song, Wenbin

J. Geophys. Res., Vol. 116, No. A5, A05106, **2011**, **File**

<http://dx.doi.org/10.1029/2011JA016490>

The interaction of the solar wind and Earth's magnetosphere is complex, and the phenomenology of the interaction is very different for interplanetary coronal mass ejections (ICMEs) compared to their sheath regions. In this paper, a total of 71 intense ($Dst \leq -100$ nT) geomagnetic storm events in 1996–2006, of which 51 are driven by ICMEs and 20 by sheath regions, are examined to demonstrate similarities and differences in the energy transfer. Using superposed epoch analysis, the evolution of solar wind energy input and dissipation is investigated. The solar wind-magnetosphere coupling functions and geomagnetic indices show a more gradual increase and recovery during the ICME-driven storms than they do during the sheath-driven storms. However, the sheath-driven storms have larger peak values. In general, solar wind energy input (the epsilon parameter) and dissipation show similar trends as the coupling functions. The trends of ion precipitation and the ratio of ion precipitation to the total (ion and electron) are quite different for both classes of events. There are more precipitating ions during the peak of sheath-driven storms. However, a quantitative assessment of the relative importance of the different energy dissipation branches shows that the means of input energy and auroral precipitation are significantly different for both classes of events, whereas Joule heating, ring current, and total output energy display no distinguishable differences. The means of electron precipitation are significantly different for both classes of events. However, ion precipitation exhibits no distinguishable differences. The energy efficiency bears no distinguishable difference between these two classes of events. Ionospheric processes account for the vast majority of the energy, with the ring current only being 12%–14% of the total. Moreover, the energy partitioning for both classes of events is similar.

Interplanetary drivers of ionospheric prompt penetration electric fields

Jianpeng **Guo** a,n, XueshangFeng a, PingbingZuo a, JieZhang b, YongWei c, QiugangZong c

Journal of Atmospheric and Solar-Terrestrial Physics 73 (2011) 130–136, **File**

In this paper we discussed the penetration effects of common interplanetary magnetic cloud (MC) structures like sheath region, both sheath and magnetic cloud boundary layer (MCBL), MC body, and shock-running into a preceding MC on the equatorial ionosphere during intense ($SYM-H \leq -100$ nT) geomagnetic storms. Using solar wind data obtained from the ACE and WIND spacecraft, we have identified these four types of MC structures responsible for the electric field penetration events detected by Jicamarca incoherent scatter radar. After elimination of the propagation delay, the observations show that the equatorial electric field (EEF) was changed immediately following the arrival of solar wind disturbance. Moreover, the duration of EEF corresponded well with that of the corresponding MC structure interval. We suggest that identifying the solar wind structures associated with penetration electric field may shed light on the understanding of the penetration processes and further help exploring their effects on the ionospheric plasma.

Statistical properties and geoefficiency of interplanetary coronal mass ejections and their sheaths during intense geomagnetic storms,

Guo, J., X. Feng, J. Zhang, P. Zuo, and C. Xiang

J. Geophys. Res., 115, A09107, doi:10.1029/2009JA015140, (2010), **File**.

In this paper, we examine and compare the statistical properties of interplanetary coronal mass ejections (ICMEs) and their sheath regions in the near-Earth space, mainly focusing on the distributions of various physical parameters and their geoefficiency. The 53 events studied are a subset of events responsible for intense ($Dst \leq -100$ nT) geomagnetic storms during the time period from 1996 to 2005. These events all fall into the single-type category in which each of the geomagnetic storms was caused by a well-isolated single ICME, free of the complexity of the interaction of multiple ICMEs. For both sheaths and ICMEs, we find that the distributions of the magnetic field strength, the solar-wind speed, the density, the proton temperature, the dynamic pressure, the plasma beta, and the Alfvén Mach number are approximately lognormal, while those of the B_z component and the Y component of the electric field are approximately Gaussian. On the average, the magnetic field strengths, the B_z components, the speeds, the densities, the proton temperatures, the dynamic pressures, the plasma betas, and the Mach numbers for the sheaths are 15, 80, 4, 60, 70, 62, 67, and 30% higher than the corresponding values for ICMEs, respectively, whereas the Y component of the electric field for the sheaths is almost 1 s of that for ICMEs. The two structures have almost equal energy transfer efficiency and comparable Newell functions, whereas they show statistically meaningful differences in the dayside reconnection rate, according to the Borovsky function.

High-Speed Solar Wind Streams during 1996 – 2007: Sources, Statistical Distribution, and Plasma/Field Properties

V. **Gupta** · Badruddin

Solar Phys (2010) 264: 165–188, **File**

We present **a catalog of high-speed streams, along with their solar sources for solar cycle 23**. We study their distribution during different years and different phases of solar cycle after classifying them into different groups based on their source(s), duration, and speed. We also study the average plasma/field properties of streams after dividing them into suitable groups on the basis of their source(s), duration and speed. It is expected that the catalog and statistical results presented in this work will further stimulate the space weather and solar-terrestrial studies involving high-speed streams.

We have listed streams of solar cycle 23 (1996 – 2007) satisfying the above criteria

in Table 1 (electronic supplementary material). See [Gupta_Catalogue of high-speed solar wind streams.doc](#)

Identifying the Coronal Source Regions of Solar Wind Streams from Total Solar Eclipse Observations and in situ Measurements Extending Over a Solar Cycle

Shadia R. **Habbal**, [Miloslav Druckmüller](#), [Nathalia Alzate](#), [Adalbert Ding](#), [Judd Johnson](#), [Pavel Starha](#), [Jana Hoderova](#), [Benjamin Boe](#), [Sage Constantinou](#), [Martina Arndt](#)

<https://arxiv.org/pdf/2103.02128.pdf>

<https://iopscience.iop.org/article/10.3847/2041-8213/abe775/pdf>

<https://doi.org/10.3847/2041-8213/abe775>

This Letter capitalizes on a unique set of total solar eclipse observations, acquired between **2006 and 2020**, in white light, Fe XI 789.2 nm ($T_{\text{FeXI}} = 1.2 \pm 0.1$ MK) and Fe XIV 530.3 nm ($T_{\text{FeXIV}} = 1.8 \pm 0.1$ MK) emission, complemented by in situ Fe charge state and proton speed measurements from ACE/SWEPAM-SWICS, to identify the source regions of different solar wind streams. The eclipse observations reveal the ubiquity of open structures, invariably associated with Fe XI emission from Fe10+, hence a constant electron temperature, $T_e = T_{\text{FeXI}}$, in the expanding corona. The in situ Fe charge states are found to cluster around Fe10+, independently of the 300 to 700 km s⁻¹ stream speeds, referred to as the continual solar wind. Fe10+ thus yields the fiducial link between the continual solar wind and its T_{FeXI} sources at the Sun. While the spatial distribution of Fe XIV emission, from Fe13+, associated with streamers, changes throughout the solar cycle, the sporadic appearance of charge states $> \text{Fe11+}$, in situ, exhibits no cycle dependence regardless of speed. These latter streams are conjectured to be released from hot coronal plasmas at temperatures $\geq T_{\text{FeXIV}}$ within the bulge of streamers and from active regions, driven by the dynamic behavior of prominences magnetically linked to them. The discovery of continual streams of slow, intermediate and fast solar wind, characterized by the same T_{FeXI} in the expanding corona, places new constraints on the physical processes shaping the solar wind.

Table 1. Eclipse dates with corresponding observing sites

Forecasting Occurrence and Intensity of Geomagnetic Activity with Pattern-Matching Approaches

C. **Haines**, [M.J. Owens](#), [L. Barnard](#), [M. Lockwood](#), [A. Ruffenach](#), [K. Boykin](#), [R. McGranaghan](#)

Space Weather **Volume19, Issue6** e2020SW002624 **2021**

<https://agupubs.onlinelibrary.wiley.com/doi/10.1029/2020SW002624>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2020SW002624>

<https://doi.org/10.1029/2020SW002624>

Variability in near-Earth solar wind conditions gives rise to space weather which can have adverse effects on space- and ground-based technologies. Enhanced and sustained solar wind coupling with the Earth's magnetosphere can lead to a geomagnetic storm. The resulting effects can interfere with power transmission grids, potentially affecting today's technology-centred society to great cost. It is therefore important to forecast the intensity and duration of geomagnetic storms to improve decision making capabilities of infrastructure operators. The 150-year aaH geomagnetic index gives a substantial history of observations from which empirical predictive schemes can be built. Here we investigate the forecasting of geomagnetic activity with two pattern-matching forecast techniques, using the long aaH record. The

techniques we investigate are an Analogue Ensemble Forecast (AnEn), and a Support Vector Machine (SVM). AnEn produces a probabilistic forecast by explicitly identifying analogues for recent conditions in the historical data. The SVM produces a deterministic forecast through dependencies identified by an interpretable machine learning approach. As a third comparative forecast, we use the 27-day recurrence model, based on the synodic solar rotation period. The methods are analysed using several forecast metrics and compared. All forecasts outperform climatology on the considered metrics and AnEn and SVM outperform 27-day recurrence. A Cost/Loss analysis reveals the potential economic value is maximised using the AnEn, but the SVM is shown as superior by the true skill score. It is likely that the best method for a user will depend on their need for probabilistic information and tolerance of false alarms.

The Variation of Geomagnetic Storm Duration with Intensity

C. [Haines](#), M. J. Owens, L. Barnard, M. Lockwood, A. Ruffenach

[Solar Physics](#) November 2019, 294:154

[sci-hub.se/10.1007/s11207-019-1546-z](https://doi.org/10.1007/s11207-019-1546-z)

Variability in the near-Earth solar wind conditions can adversely affect a number of ground- and space-based technologies. Such space-weather impacts on ground infrastructure are expected to increase primarily with geomagnetic storm intensity, but also storm duration, through time-integrated effects. Forecasting storm duration is also necessary for scheduling the resumption of safe operating of affected infrastructure. It is therefore important to understand the degree to which storm intensity and duration are correlated. The long-running, global geomagnetic disturbance index, *aa*, has recently been recalibrated to account for the geographic distribution of the component stations. We use this *aaHaaH* index to analyse the relationship between geomagnetic storm intensity and storm duration over the past 150 years, further adding to our understanding of the climatology of geomagnetic activity. Defining storms using a peak-above-threshold approach, we find that more intense storms have longer durations, as expected, though the relationship is nonlinear. The distribution of durations for a given intensity is found to be approximately log-normal. On this basis, we provide a method to probabilistically predict storm duration given peak intensity, and test this against the *aaHaaH* dataset. By considering the average profile of storms with a superposed-epoch analysis, we show that activity becomes less recurrent on the 27-day timescale with increasing intensity. This change in the dominant physical driver, and hence average profile, of geomagnetic activity with increasing threshold is likely the reason for the nonlinear behaviour of storm duration. **1870-09-24, 1988-04-04**

The April 2023 SYM-H = -233 nT Geomagnetic Storm: A Classical Event

Rajkumar [Hajra](#), [Bruce Tsatnam Tsurutani](#), [Quanming Lu](#), [Richard B. Horne](#), [Gurbax Singh Lakhina](#), [Xu Yang](#), [Pierre Henri](#), [Aimin Du](#), [Xingliang Gao](#), [Rongsheng Wang](#), [San Lu](#)

JGR 2024

<https://arxiv.org/pdf/2409.08118>

The **23-24 April 2023** double-peak (SYM-H intensities of -179 and -233 nT) intense geomagnetic storm was caused by interplanetary magnetic field southward component B_s associated with an interplanetary fast-forward shock-preceded sheath (B_s of 25 nT), followed by a magnetic cloud (MC) (B_s of 33 nT), respectively. At the center of the MC, the plasma density exhibited an order of magnitude decrease, leading to a sub-Alfvénic solar wind interval for ~2.1 hr. Ionospheric Joule heating accounted for a significant part (~81%) of the magnetospheric energy dissipation during the storm main phase. Equal amount of Joule heating in the dayside and nightside ionosphere is consistent with the observed intense and global-scale DP2 (disturbance polar) currents during the storm main phase. The sub-Alfvénic solar wind is associated with disappearance of substorms, a sharp decrease in Joule heating dissipation, and reduction in electromagnetic ion cyclotron wave amplitude. The shock/sheath compression of the magnetosphere led to relativistic electron flux losses in the outer radiation belt between $L^* = 3.5$ and 5.5. Relativistic electron flux enhancements were detected in the lower $L^* < 3.5$ region during the storm main and recovery phases. Equatorial ionospheric plasma anomaly structures are found to be modulated by the prompt penetration electric fields. Around the anomaly crests, plasma density at ~470 km altitude and altitude-integrated ionospheric total electron content are found to increase by ~60% and ~80%, with ~33% and ~67% increases in their latitudinal extents compared to their quiet-time values, respectively.

Interplanetary Causes and Impacts of the 2024 May Superstorm on the Geosphere: An Overview

Rajkumar [Hajra](#), [Bruce Tsatnam Tsurutani](#), [Gurbax Singh Lakhina](#), [Quanming Lu](#), [Aimin Du](#)

ApJ 2024

<https://arxiv.org/pdf/2408.14799>

The recent superstorm of **2024 May 10-11** is the second largest geomagnetic storm in the space age and the only one that has simultaneous interplanetary data (there were no interplanetary data for the 1989 March storm). The May superstorm was characterized by a sudden impulse (SI+) amplitude of +88 nT, followed by a three-step storm main phase development which had a total duration of ~9 hr. The cause of the first storm main phase with a peak SYM-H intensity of -183 nT was a fast forward interplanetary shock (magnetosonic Mach number $M_{ms} \sim 7.2$) and an interplanetary sheath with southward interplanetary magnetic field component B_s of ~40 nT. The cause of the second storm main phase with a SYM-H intensity of -354 nT was a deepening of the sheath B_s to ~43 nT. A magnetosonic wave ($M_{ms} \sim 0.6$) compressed the sheath to a high magnetic field strength of ~71 nT. Intensified B_s of ~48 nT was the cause of the third and most intense storm main phase with a SYM-H intensity of -518 nT. Three magnetic cloud events with B_s fields of ~25-40 nT occurred in the storm recovery phase, lengthening the recovery to ~2.8 days. At geosynchronous orbit, ~76 keV to ~1.5 MeV electrons exhibited ~1-3 orders of magnitude flux decreases following the shock/sheath impingement onto the magnetosphere. The cosmic ray decreases at Dome C, Antarctica (effective vertical cutoff rigidity <0.01 GV) and Oulu, Finland (rigidity ~0.8 GV) were ~17% and ~11%, respectively relative to quiet time values. Strong ionospheric current flows resulted in extreme geomagnetically induced currents of ~30-40 A in the sub-auroral region. The storm period is characterized by strong polar region field-aligned currents, with ~10 times intensification during the main phase, and equatorward expansion down to ~50 deg geomagnetic (altitude-adjusted) latitude.

Interplanetary Shocks between 0.3 and 1.0 au: Helios 1 and 2 Observations

Rajkumar **Hajra**¹, Bruce T. Tsurutani², Gurbax S. Lakhina³, Quanming Lu^{1,4}, Aimin Du^{5,6}, and Lican Shan^{6,7}

2023 ApJ 951 75

<https://iopscience.iop.org/article/10.3847/1538-4357/acd370/pdf>

The Helios 1 (H1) and Helios 2 (H2) spacecraft measured the solar winds at a distance between ~0.3 and 1.0 au from the Sun. With increasing heliocentric distance (r_h), the plasma speed is found to increase at ~34–40 km s⁻¹ au⁻¹ and the density exhibits a sharper fall (r_h^{-2}) compared to the magnetic field magnitude ($r_h^{-1.5}$) and the temperature ($r_h^{-0.8}$). Using all available solar wind plasma and magnetic field measurements, we identified 68 and 39 fast interplanetary shocks encountered by H1 and H2, respectively. The overwhelming majority (85%) of the shocks are found to be driven by interplanetary coronal mass ejections (ICMEs). While the two spacecraft encountered more than 73 solar wind high-speed streams (HSSs), only ~22% had shocks at the boundaries of corotating interaction regions (CIRs) formed by the HSSs. All of the ICME shocks were found to be fast forward (FF) shocks; only four of the CIR shocks were fast reverse shocks. Among all ICME FF shocks (CIR FF shocks), 60% (75%) are quasi-perpendicular with shock normal angles (θ_{Bn}) $\geq 45^\circ$ relative to the upstream ambient magnetic field, and 40% (25%) are quasi-parallel ($\theta_{Bn} < 45^\circ$). No radial dependences were found in FF shock normal angle and speed. The FF shock Mach number (M_{ms}), magnetic field, and plasma compression ratios are found to increase with increasing r_h at the rates of 0.72, 0.89, and 0.98 au⁻¹, respectively. On average, ICME FF shocks are found to be considerably faster (~20%) and stronger (with ~28% higher M_{ms}) than CIR FF shocks.

Near-Earth High-Speed and Slow Solar Winds: A Statistical Study on Their Characteristics and Geomagnetic Impacts

Rajkumar **Hajra**

Solar Physics volume 298, Article number: 53 (2023)

<https://doi.org/10.1007/s11207-023-02141-6>

Near-Earth solar winds are separated into two groups: slow solar wind (SSW) with plasma speed [V_{sw}] <500 km s⁻¹ and high-speed solar wind (HSW) with V_{sw} >700 km s⁻¹. A comparative study is performed on the plasma and interplanetary magnetic field (IMF) properties of the near-Earth SSW and HSW, using solar wind measurements propagated to Earth's bow shock nose from 1963 through 2022. On average, HSW is characterized by higher alpha-to-proton density ratio [N_a/N_p] (67%), ram pressure [P_{sw}] (95%), proton temperature [T_p] (370%), reconnection electric field [V_B s] (141%), Alfvén speed [V_A] (76%), magnetosonic speed [V_{ms}] (65%), and lower proton density [N_p] (52%) and plasma- β (54%) than SSW. In V_B s, $V = V_{sw}$, B_s is the southward component of IMF. $V_A = B_0 / \mu_0 \rho$, $V_{ms} = \sqrt{V_A^2 + V_S^2}$, where B_0 is the IMF magnitude, μ_0 is the free space permeability, ρ is the solar wind mass density, and V_S is the sound speed. β is defined as the plasma pressure to the magnetic-pressure ratio. The geomagnetic activity is found to be enhanced during HSW, as reflected in higher average auroral electrojet index [AE] (213%) and stronger geomagnetic Dst index (367%) compared to those during SSW. The SSW characteristic parameters N_a/N_p , T_p , B_0 , V_A , and V_{ms} exhibit medium to strong

correlations (correlation coefficients $r=0.51$ to 0.87) with the F10.7 solar flux, while β and Mach numbers exhibit strong anti-correlations ($r=-0.82$ to -0.90) with F10.7. The associations are weaker or insignificant for HSW.

Interplanetary Sheaths and Corotating Interaction Regions: A Comparative Statistical Study on Their Characteristics and Geoeffectiveness

Rajkumar Hajra, Jibin V. Sunny, Megha Babu & Archana Giri Nair

Solar Physics volume 297, Article number: 97 (2022)

<https://doi.org/10.1007/s11207-022-02020-6>

Interplanetary sheaths and corotating interaction regions (CIRs), while having different solar sources, represent turbulent solar-wind plasma and magnetic field that can perturb the Earth's magnetosphere. We explore long-term solar-wind measurements upstream of the Earth during Solar Cycle 24, from January 2008 to December 2019, to compare their solar-cycle variation, characteristic features, and geoeffectiveness. Earth is found to be encountered by ≈ 2.6 times more CIRs (290) than sheaths (110) during this period. The sheath occurrence follows the F10.7 solar radio-flux variation, with a cross-correlation coefficient (ccrcc) of $+0.71$ at zero-year time lag. However, the CIR occurrence is more prominent during the solar cycle descending to minimum phases, reflected in ccrcc values of -0.53 and $+0.50$ at time lags of -2 and $+4$ years, respectively, between the CIR occurrence and the F10.7 solar flux. Both sheath and CIR are characterized by identical average plasma density and interplanetary magnetic-field (IMF) magnitude, and their fluctuations characterized by enhanced variance, and periodic variations of a few minutes to an hour. However, on average, the CIR has $\approx 12\%$ higher plasma speed, $\approx 33\%$ higher temperature, $\approx 20\%$ stronger southward IMF component, $\approx 131\%$ longer duration, and $\approx 158\%$ longer radial extent than the sheath. The intensities of the auroral electrojet index [AE] and the symmetric ring-current index [SYM-H] are, respectively, $\approx 38\%$ and $\approx 55\%$ stronger during the CIR than the sheath, on average. The geoeffectiveness of the CIR is found to be significantly higher than the sheath. Among all CIRs (sheaths), $\approx 25\%$ ($\approx 14\%$) caused moderate storms ($-50 \text{ nT} \geq \text{SYM-H} > -100 \text{ nT}$), and $\approx 5\%$ ($\approx 4\%$) caused intense storms ($\text{SYM-H} \leq -100 \text{ nT}$).

Corotating Interaction Regions during Solar Cycle 24: A Study on Characteristics and Geoeffectiveness

Rajkumar Hajra & Jibin V. Sunny

Solar Physics volume 297, Article number: 30 (2022)

<https://link.springer.com/content/pdf/10.1007/s11207-022-01962-1.pdf>

Corotating interaction regions (CIRs) form in the interaction region between the solar-wind high-speed streams and slow streams, leading to compressed plasma and magnetic fields. Using solar-wind measurements upstream of Earth, we identified 290 CIRs encountered by Earth during January 2008 through December 2019 (Solar Cycle 24). The occurrence rate is the maximum during the solar-cycle descending phase (≈ 33 year $^{-1}$), followed by occurrences during solar minimum (≈ 24 year $^{-1}$), the ascending phase (≈ 22 year $^{-1}$), and solar maximum (≈ 11 year $^{-1}$). At 1 AU, CIRs are found to be large-scale interplanetary structures with an average (median) duration of ≈ 26 hours (≈ 24 hours) and radial extent of ≈ 0.31 AU (≈ 0.27 AU). CIRs are characterized by average (median) plasma density of ≈ 29 cm $^{-3}$ (≈ 26 cm $^{-3}$), ram pressure of ≈ 11 nPa (≈ 9 nPa), temperature of $\approx 5 \times 10^5$ K ($\approx 4 \times 10^5$ K), and magnetic-field magnitude of ≈ 15 nT (≈ 14 nT). The CIR characteristic features exhibit no clear solar-cycle phase dependence. About 30% of the CIRs are found to be geoeffective, causing geomagnetic storms with the peak SYM-H ≤ -50 nT; 25% caused moderate storms ($-50 \text{ nT} \geq \text{SYM-H} > -100 \text{ nT}$), and 5% caused intense storms ($\text{SYM-H} \leq -100 \text{ nT}$). The geoeffectiveness is found to decrease with the decreasing solar flux. CIRs during equinoxes are found to be more geoeffective compared to those during solstices. On average, SYM-H is strongly associated with the CIR plasma characteristic parameters (anti-correlation coefficient $r=-0.65$ to -0.89), while the association is weaker for the AE-index ($r=0.41$ to 0.67). 17 – 18 January 2017, 26 – 27 March 2017

Table 3 Catalog of all CIRs under this study. 2008-2009

Near-Earth Sub-Alfvénic Solar Winds: Interplanetary Origins and Geomagnetic Impacts

Rajkumar Hajra¹ and Bruce T. Tsurutani²

2022 ApJ 926 135

<https://iopscience.iop.org/article/10.3847/1538-4357/ac4471/pdf>

The near-Earth solar wind is in general super-Alfvénic and supermagnetosonic. Using all available near-Earth solar wind measurements between 1973 and 2020, we identified 30 intervals with sub-Alfvénic solar winds. The majority (83%) of the events occurred within interplanetary coronal mass ejection magnetic clouds (MCs)/driver gases. These MC sub-Alfvénic events are characterized by exceptionally low plasma densities (N_{sw}) of ~ 0.04 – 1.20 cm $^{-3}$, low temperatures

(T_{sw}) of $\sim 0.08 \times 10^5$ K to 12.46×10^5 K, enhanced magnetic field intensities (B_0) of ~ 8.3 – 53.9 nT, and speeds (V_{sw}) of ~ 328 – 949 km s $^{-1}$. The resultant high Alfvén wave speeds (VA) ranged from ~ 410 to 1471 km s $^{-1}$. This is consistent with a mechanism of the MC expansions as they propagate radially outward, causing small pockets of sub-Alfvénic wind regions within the MCs. The remainder of the sub-Alfvénic intervals (17%) occurred within the extreme trailing portions of solar wind high-speed streams (HSSs). These HSS sub-Alfvénic winds had low N_{sw} of ~ 0.04 – 0.97 cm $^{-3}$, low T_{sw} of $\sim 0.06 \times 10^5$ K to 0.46×10^5 K, B_0 of ~ 6.3 – 18.2 nT, V_{sw} of ~ 234 – 388 km s $^{-1}$, and a VA range of ~ 364 – 626 km s $^{-1}$. This is consistent with a mechanism of solar wind super-radial expansions in the trailing HSS regions. During sub-Alfvénic solar wind intervals, Earth's bow shock nose exhibited rapid evanescence, and the estimated geocentric magnetopause distance increased by $\sim 33\%$ – 86% . The inner magnetosphere was more or less unaffected by the sub-Alfvénic solar winds. No significant impact was observed in the outer radiation belt relativistic electrons, and no geomagnetic storms or substorms were triggered during the sub-Alfvénic solar wind events. **18–21**

September 2017 Space-Weather Events: A Study on Magnetic Reconnection and Geoeffectiveness

Rajkumar **Hajra**

[Solar Physics](#) volume 296, Article number: 50 (2021)

<https://doi.org/10.1007/s11207-021-01803-7>

<https://link.springer.com/content/pdf/10.1007/s11207-021-01803-7.pdf>

September 2017 was an extremely active space-weather period with multiple events leading to varying impacts on the Earth's magnetosphere. The geoeffectiveness of a space-weather event largely depends on the magnetic reconnection between the southward interplanetary magnetic field and the day-side northward geomagnetic field. In this work, we estimate the reconnection rates during two intense (SYM-H peak $\leq -100 \leq -100$ nT) and two moderate (-50 nT \geq SYM-H $> -100 > -100$ nT) geomagnetic storms, and a high-intensity long-duration continuous auroral electrojet (AE) activity (HILDCAA) event in order to assess the contribution of the reconnection to resultant geomagnetic effects. Strong reconnection rates led to intense geomagnetic storms, while moderate-intensity geomagnetic storms were associated with discrete and weaker reconnection events. Comparatively weak magnetic reconnection continuing for a long interval of time led to the HILDCAA event. On average, a significant correlation was observed between the reconnection rates and geomagnetic-activity indices. However, the relationships are found to be more complex on shorter time-scales, varying from event to event. The importance of a quantitative study of the reconnection process for the prediction of geomagnetic activity is demonstrated. **7 – 8 September 2017, 12 – 13 September 2017, 14 – 17 September 2017, 27 – 28 September 2017**

The Complex Space Weather Events of 2017 September

Rajkumar **Hajra**¹, Bruce T. Tsurutani², and Gurbax S. Lakhina³

2020 ApJ 899 3 File

<https://doi.org/10.3847/1538-4357/aba2c5>

Interplanetary coronal mass ejections (ICMEs), magnetic clouds (MCs), sheaths, corotating interaction regions (CIRs), solar wind high-speed streams (HSSs), fast forward shocks (FSs), reverse waves (RWs), stream interfaces, and heliospheric current sheet crossings detected upstream of the Earth and their geoeffectiveness are studied during 2017 September. The most intense geomagnetic storm (SYM-H peak = -146 nT) starting on September 7 had a three-step main phase. A compound interplanetary structure resulting from an FS encountering and compressing the upstream MC southward interplanetary magnetic fields (IMFs) caused the first two steps of the storm. A magnetospheric supersubstorm (SSS; SML peak = -3712 nT) led to the third and most intense step. An MC portion of an ICME created an intense storm (SYM-H peak = -115 nT) on September 8. A second SSS (SML peak = -2642 nT) occurred during the main phase of this storm. Intense geomagnetically induced currents (GICs) occurred during the SSSs. Two moderate magnetic storms with peak SYM-H indices of -65 and -74 nT occurring on September 13 and 27 were caused by sheath and CIR southward IMFs, respectively. Six FSs and their associated sheaths caused sudden impulses (SI+s) of magnitude ranging from $+11$ to $+56$ nT. The shocks/sheaths led to magnetospheric relativistic electron flux decreases. The RWs caused SI–s and substorm recoveries by reducing southward IMFs. The high-intensity long-duration continuous AE activities (HILDCAAs) caused by the HSSs were related to the increase/acceleration of relativistic electron fluxes.

Interplanetary Shocks Inducing Magnetospheric Supersubstorms (SML < -2500 nT): Unusual Auroral Morphologies and Energy Flow

Rajkumar [Hajra](#)¹ and Bruce T. Tsurutani²

2018 ApJ 858 123

<http://sci-hub.tw/10.3847/1538-4357/aabaed>

We present case studies of two interplanetary shock-induced supersubstorms (SSSs) with extremely high intensities (peak SML -4418 and -2668 nT) and long durations (~ 1.7 and ~ 3.1 hr). The events occurred on **2005 January 21** and **2010 April 5**, respectively. It is shown that these SSSs have a different auroral evolution than a nominal Akasofu-type substorm. The auroras associated with the SSSs did not have the standard midnight onset and following expansion. Instead, at the time of the SML index peak, the midnight sector was generally devoid of intense auroras, while the most intense auroras were located in the pre-midnight and post-midnight magnetic local times. Precursor energy input through magnetic reconnection was insufficient to balance the large ionospheric energy dissipation during the SSSs. It is argued that besides the release of stored magnetotail energy during the SSSs, these were powered by additional direct driving through both dayside magnetic reconnection and solar wind ram energy.

Supersubstorms (SML < -2500 nT): Magnetic Storm and Solar Cycle Dependences[†]

Rajkumar [Hajra](#), Bruce T. Tsurutani, Ezequiel Echer, Walter D. Gonzalez, Jesper W. Gjerloev

JGR 2016

We study extremely intense substorms with SuperMAG AL (SML) peak intensities < -2500 nT (“supersubstorms”/SSSs) for the period from 1981 through 2012. The SSS events were often found to be isolated SML peaks and not statistical fluctuations of the indices. The SSSs occur during all phases of the solar cycle with the highest occurrence (3.8 year⁻¹) in the descending phase. The SSSs exhibited an annual variation with equinoctial maximum altering between spring in solar cycle 22 and fall in solar cycle 23. The occurrence rate and strength of the SSSs did not show any strong relationship with the intensity of the associated geomagnetic storms. All SSS events were associated with strong southward interplanetary magnetic field B_s component. The B_s fields were part of interplanetary magnetic clouds in 46% and of interplanetary sheath fields in 54% of the cases. About 77% of the SSSs were associated with small regions of very high density solar wind plasma parcels or pressure pulses impinging upon the magnetosphere. Comments on how SSS events may cause power outages at Earth are discussed at the end of the paper.

Superposed epoch analyses of HILDCAAs and their interplanetary drivers: Solar cycle and seasonal dependences

Rajkumar [Hajra](#), Ezequiel Echer, Bruce T. Tsurutani, Walter D. Gonzalez

JASTP, Volume 121, Part A, December 2014, Pages 24–31

We study the solar cycle and seasonal dependences of high-intensity, long-duration, continuous AE activity (HILDCAA) events and associated solar wind/interplanetary external drivers for $\sim 3, 1/2$ solar cycle period, from 1975 to 2011. 99 HILDCAAs which had simultaneous solar wind/interplanetary data are considered in the present analyses. The peak occurrence frequency of HILDCAAs was found to be in the descending phase of the solar cycle. These events had the strongest time-integrated AE intensities and were coincident with peak occurrences of high-speed solar wind streams. The event initiations were statistically coincident with high-to-slow speed stream interactions, compressions in the solar wind plasma and interplanetary magnetic field (IMF). The latter were corotating interaction regions (CIRs). The signatures of related CIRs were most prominent for the events occurring during the descending and solar minimum phases of the solar cycles. For these events, the solar wind speed increased by $\sim 41\%$ and $\sim 57\%$ across the CIRs, respectively. There was weak or no stream–stream interaction or CIR structure during the ascending and solar maximum phases. HILDCAAs occurring during spring and fall seasons were found to occur preferentially in negative and positive IMF sector regions (toward and away from the Sun), respectively.

Relativistic electron acceleration during high-intensity, long-duration, continuous AE activity (HILDCAA) events: Solar cycle phase dependences.

Solar wind-magnetosphere energy coupling efficiency and partitioning: HILDCAAs and preceding CIR storms during solar cycle 23

Rajkumar [Hajra](#)^{1,*}, Ezequiel Echer¹, Bruce T. Tsurutani² and Walter D. Gonzalez

JGR, Volume 119, Issue 4, pages 2675–2690, April 2014

A quantitative study on the energetics of the solar wind-magnetosphere-ionosphere system during High-Intensity, Long-Duration, Continuous AE Activity (HILDCAA) events for solar cycle 23 (from 1995 through 2008) is presented. For all

HILDCAAs, the average energy transferred to the magnetospheric/ionospheric system was $\sim 6.3 \times 10^{16}$ J, and the ram kinetic energy of the incident solar wind was $\sim 7.1 \times 10^{18}$ J. For individual HILDCAA events the coupling efficiency, defined as the ratio of the solar wind energy input to the solar wind kinetic energy, varied between 0.3% and 2.8%, with an average value of $\sim 0.9\%$. The solar wind coupling efficiency for corotating interaction region (CIR)-driven storms prior to the HILDCAA events was found to vary from $\sim 1\%$ to 5%, with an average value of $\sim 2\%$. Both of these values are lower than the $> 5\%$ coupling efficiency noted for interplanetary coronal mass ejection (and sheath)-driven magnetic storms. During HILDCAAs, $\sim 67\%$ of the solar wind energy input went into Joule heating, $\sim 22\%$ into auroral precipitation, and $\sim 11\%$ into the ring current energy. The CIR-storm Joule heating ($\sim 49\%$) was noticeably less than that during HILDCAAs, while the ring current energies were comparable for the two. Joule dissipation was higher for HILDCAAs that followed CIR-storms (88%) than for isolated HILDCAAs ($\sim 60\%$). Possible physical interpretations for the statistical results obtained in this paper are discussed.

Electrons in the Young Solar Wind: First Results from the Parker Solar Probe

ApJ 2019

<https://arxiv.org/pdf/1912.02216.pdf>

The Solar Wind Electrons Alphas and Protons experiment on the Parker Solar Probe (PSP) mission measures the three-dimensional electron velocity distribution function. We derive the parameters of the core, halo, and strahl populations utilizing a combination of fitting to model distributions and numerical integration for $\sim 100,000$ electron distributions measured near the Sun on the first two PSP orbits, which reached heliocentric distances as small as ~ 0.17 AU. As expected, the electron core density and temperature increase with decreasing heliocentric distance, while the ratio of electron thermal pressure to magnetic pressure (β_e) decreases. These quantities have radial scaling consistent with previous observations farther from the Sun, with superposed variations associated with different solar wind streams. The density in the strahl also increases; however, the density of the halo plateaus and even decreases at perihelion, leading to a large strahl/halo ratio near the Sun. As at greater heliocentric distances, the core has a sunward drift relative to the proton frame, which balances the current carried by the strahl, satisfying the zero-current condition necessary to maintain quasi-neutrality. Many characteristics of the electron distributions near perihelion have trends with solar wind flow speed, β_e , and/or collisional age. Near the Sun, some trends not clearly seen at 1 AU become apparent, including anti-correlations between wind speed and both electron temperature and heat flux. These trends help us understand the mechanisms that shape the solar wind electron distributions at an early stage of their evolution.

Dependence of the Interplanetary Magnetic Field on Heliocentric Distance at 0.3–1.7 AU: A Six-Spacecraft Study

Cedar [Hanneson](#), [Catherine L. Johnson](#), [Anna Mittelholz](#), [Manar M. Al Asad](#), [Colin Goldblatt](#)

JGR Volume 125, Issue 3 March 2020 e2019JA027139

<https://doi.org/10.1029/2019JA027139>

We use magnetometer data taken simultaneously by MESSENGER, VEX, STEREO and ACE to characterize the variation of the interplanetary magnetic field (IMF) with heliocentric distance, r , for $r > 1$ AU. Power law fits ($\propto r^{-\alpha}$) to the individual IMF components and magnitude indicate that, on average, the IMF is more tightly wound and its strength decreases less rapidly with r than the Parker spiral prediction. During Solar Cycle 24, temporal changes in α were insignificant, but changes in amplitude, B , were correlated with sunspot number, up to sunspot number 84. MAVEN data taken at 1.4–1.7 AU since late 2014 broadly confirm and extend these results in space and time. Our study demonstrates the importance of simultaneous observations from multiple spacecraft to separate heliocentric distance and temporal variations in the IMF and provides a modern benchmark for comparison with data from the Parker Solar Probe Mission.

The Great Storm of May 1921: An Exemplar of a Dangerous Space Weather Event

Mike [Hapgood](#)

Space Weather Volume 17, Issue 7 Pages 950-975 2019

[sci-hub.se/10.1029/2019SW002195](https://doi.org/10.1029/2019SW002195)

We reconstruct the timeline of the extreme space weather event of May 1921, reviewing a wealth of reports from scientific literature, databases, newspaper reports, and reports by historians and astronomers. A series of coronal mass ejections (CMEs) bombarded Earth between 13 and 16 May, as shown by a series of sudden commencements observed across the global network of magnetometers. These CMEs produced three major periods of geomagnetic activity. The first period followed the arrival of two CMEs on 13 May. These may have cleared much density from the inner

heliosphere, enabling a subsequent CME to travel quickly to Earth and cause intense activity. Continuing moderate magnetic activity following the first period may also have preconditioned the magnetosphere so it responded strongly to that later CME. This arrived late on 14 May, driving a short period of very intense activity early on 15 May, including technological impacts indicative of strong geoelectric fields. Another CME arrived early on 16 May, driving intense activity similar to that on 13 May. We show how these impacts fit with scientific observations to give a timeline that can be used in worst-case studies/benchmarks. We also show that some impacts were probably coincidental with the storm, but due to more prosaic faults. This sequence of preconditioning, intense geoelectric fields, and their impacts, plus coincidental faults, makes the 1921 event an excellent basis for building space weather scenarios. Such scenarios are vital scientific input to the development and implementation of policies for mitigation of severe space weather.

The Solar Source of a Magnetic Cloud Using a Velocity Difference Technique

L.K. [Harra](#), · C.H. Mandrini, · S. Dasso, A.M. Gulisano, · K. Steed, · S. Imada

E-print, Nov 2010; Solar Phys. (2011) 268: 213–230, [File](#)

For large eruptions on the Sun, it is often a problem that the **core dimming region** cannot be observed due to the bright emission from the flare itself. However, spectroscopic data can provide the missing information through the measurement of Doppler velocities. In this paper we analyse the well-studied flare and coronal mass ejection that erupted on the Sun on **13 December 2006** and reached the Earth on 14 December 2006. In this example, although the imaging data were saturated at the flare site itself, we could extract information on the core dimming region through velocity measurements, as well as on the remote dimmings. The purpose of this paper is to determine more accurately the magnetic flux of the solar source region, potentially involved in the ejection, through a new technique. The results of its application are compared to the flux in the magnetic cloud observed at 1AU, as a way to check the reliability of this technique. We analysed data from the {it Hinode} EUV Imaging Spectrometer to estimate the Doppler velocity in the active region and its surroundings before and after the event. This allowed us to determine a Doppler velocity 'difference' image. We used the velocity difference image overlaid on a Michelson Doppler Imager magnetogram to identify the regions in which the blue-shifts were more prominent after the event; the magnetic flux in these regions was used as a proxy for the ejected flux and compared to the magnetic cloud flux. This new method provides a more accurate flux determination in the solar source region.

How Does Large Flaring Activity from the Same Active Region Produce Oppositely Directed Magnetic Clouds?

Louise K. [Harra](#) · Nancy U. Crooker · Cristina H. Mandrini · Lidia van Driel-Gesztelyi · Sergio Dasso · Jingxiu Wang · Heather Elliott · Gemma Attrill · Bernard V. Jackson · Mario M. Bisi

Solar Phys, 244: 95–114, **2007**, DOI 10.1007/s11207-007-9002-x

We describe the interplanetary coronal mass ejections (ICMEs) that occurred as a result of a series of solar flares and eruptions from 4 to 8 November 2004. Two ICMEs/magnetic clouds occurring from these events had opposite magnetic orientations. This was despite the fact that the major flares related to these events occurred within the same active region that maintained the same magnetic configuration.

L1 and off Sun-Earth line visible-light imaging of Earth-directed CMEs: An analysis of inconsistent observations

Richard A. [Harrison](#), [Jackie A. Davies](#), [David Barnes](#), [Christian Möstl](#)

Space Weather [Volume21, Issue4](#) e2022SW003358 **2023**

<https://arxiv.org/ftp/arxiv/papers/2304/2304.05264.pdf>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2022SW003358>

The efficacy of coronal mass ejection (CME) observations as a key input to space weather forecasting is explored by comparing on and off Sun-Earth line observations from the ESA/NASA SOHO and NASA STEREO spacecraft. A comparison is made of CME catalogues based on L1 coronagraph imagery and off Sun-Earth line coronagraph and heliospheric imager (HI) observations, for the year 2011. Analysis reveals inconsistencies in the identification of a number of potentially Earth-directed CMEs. The catalogues reflect our ability to identify and characterise CMEs, so any discrepancies can impact our prediction of Earth-directed CMEs. We show that 15 CMEs, which were observed by STEREO, that had estimated directions compatible with Earth-directed events, had no identified halo/partial halo counterpart listed in the L1 coronagraph CME catalogue. In-situ data confirms that for 9 of these there was a consistent

L1 Interplanetary CME (ICME). The number of such "discrepant" events is significant compared to the number of ICMEs recorded at L1 in 2011, stressing the need to address space weather monitoring capabilities, particularly with the inclusion of off Sun-Earth line observation. While the study provides evidence that some halo CMEs are simply not visible in near-Earth coronagraph imagery, there is evidence that some halo CMEs viewed from L1 are compromised by preceding CME remnants or the presence of multiple-CMEs. This underlines (1) the value of multiple vantage point CME observation, and (2) the benefit of off Sun-Earth line platform heliospheric imaging, and coronagraph imaging, for the efficient identification and tracking of Earth-directed events. **2011: 24 Jan, 14 Feb, 25 May, 23 Jun, 03 Jul, 11 Jul, 05 Oct, 26 Oct, 29 Oct, 01 Nov, 29 Nov**

We present a statistical analysis of coronal mass ejections (CMEs) imaged by the Heliospheric Imager (HI) instruments aboard NASA's twin-spacecraft STEREO mission between April 2007 and August 2017 for STEREO-A and between April 2007 and September 2014 for STEREO-B. The analysis exploits a catalogue that was generated within the FP7 HELCATS project. Here, we focus on the observational characteristics of CMEs imaged in the heliosphere by the inner (HI-1) cameras. More specifically, in this paper we present distributions of the basic observational parameters - namely occurrence frequency, central position angle (PA) and PA span - derived from nearly 2000 detections of CMEs in the heliosphere by HI-1 on STEREO-A or STEREO-B from the minimum between Solar Cycles 23 and 24 to the maximum of Cycle 24; STEREO-A analysis includes a further 158 CME detections from the descending phase of Cycle 24, by which time communication with STEREO-B had been lost. We compare heliospheric CME characteristics with properties of CMEs observed at coronal altitudes, and with sunspot number. As expected, heliospheric CME rates correlate with sunspot number, and are not inconsistent with coronal rates once instrumental factors/differences in cataloguing philosophy are considered. As well as being more abundant, heliospheric CMEs, like their coronal counterparts, tend to be wider during solar maximum. Our results confirm previous coronagraph analyses suggesting that CME launch sites don't simply migrate to higher latitudes with increasing solar activity. At solar minimum, CMEs tend to be launched from equatorial latitudes while, at maximum, CMEs appear to be launched over a much wider latitude range; this has implications for understanding the CME/solar source association. Our analysis provides some supporting evidence for the systematic dragging of CMEs to lower latitude as they propagate outwards. **2008-12-13, 2009-09-01, 2010-06-02, 2011-07-03, 2011-12-01, 2013-12-15**

The application of heliospheric imaging to space weather operations: Lessons learned from published studies

Review

Richard A. **Harrison**, Jackie A. Davies, Doug Biesecker, Mark Gibbs

Space Weather Volume 15, Issue 8 August 2017 Pages 985–1003

<http://onlinelibrary.wiley.com/doi/10.1002/2017SW001633/full>

<http://onlinelibrary.wiley.com/doi/10.1002/2017SW001633/epdf>

The field of heliospheric imaging has matured significantly over the last 10 years—corresponding, in particular, to the launch of NASA's STEREO mission and the successful operation of the heliospheric imager (HI) instruments thereon. In parallel, this decade has borne witness to a marked increase in concern over the potentially damaging effects of space weather on space and ground-based technological assets, and the corresponding potential threat to human health, such that it is now under serious consideration at governmental level in many countries worldwide. Hence, in a political climate that recognizes the pressing need for enhanced operational space weather monitoring capabilities most appropriately stationed, it is widely accepted, at the Lagrangian L1 and L5 points, it is timely to assess the value of heliospheric imaging observations in the context of space weather operations. To this end, we review a cross section of the scientific analyses that have exploited heliospheric imagery—particularly from STEREO/HI—and discuss their relevance to operational predictions of, in particular, coronal mass ejection (CME) arrival at Earth and elsewhere. We believe that the potential benefit of heliospheric images to the provision of accurate CME arrival predictions on an operational basis, although as yet not fully realized, is significant and we assert that heliospheric imagery is central to

any credible space weather mission, particularly one located at a vantage point off the Sun-Earth line. **1 August 2010, 15 Feb 2011, 8 March 2012, 5 March 2013, 20-27 May 2017**

AN ANALYSIS OF THE ORIGIN AND PROPAGATION OF THE MULTIPLE CORONAL MASS EJECTIONS OF 2010 AUGUST 1

2012 ApJ 750 45

On **2010 August 1**, the northern solar hemisphere underwent significant activity that involved a complex set of active regions near central meridian with, nearby, two large prominences and other more distant active regions. This activity culminated in the eruption of four major coronal mass ejections (CMEs), effects of which were detected at Earth and other solar system bodies. Recognizing the unprecedented wealth of data from the wide range of spacecraft that were available—providing the potential for us to explore methods for CME identification and tracking, and to assess issues regarding onset and planetary impact—we present a comprehensive analysis of this sequence of CMEs. We show that, for three of the four major CMEs, onset is associated with prominence eruption, while the remaining CME appears to be closely associated with a flare. Using instrumentation on board the Solar Terrestrial Relations Observatory spacecraft, three of the CMEs could be tracked out to elongations beyond 50°; their directions and speeds have been determined by various methods, not least to assess their potential for Earth impact. The analysis techniques that can be applied to the other CME, the first to erupt, are more limited since that CME was obscured by the subsequent, much faster event before it had propagated far from the Sun; we discuss the speculation that these two CMEs interact. The consistency of the results, derived from the wide variety of methods applied to such an extraordinarily complete data set, has allowed us to converge on robust interpretations of the CME onsets and their arrivals at 1 AU.

STEREO SCIENCE RESULTS AT SOLAR MINIMUM

Imaging of the heliosphere is a burgeoning area of research. As a result, it is awash with new results, using novel applications, and is demonstrating great potential for future research in a wide range of topical areas. The STEREO (*Solar TERrestrial Relations Observatory*) Heliospheric Imager (HI) instruments are at the heart of this new development, building on the pioneering observations of the SMEI (Solar Mass Ejection Imager) instrument aboard the *Coriolis* spacecraft. Other earlier heliospheric imaging systems have included ground-based interplanetary scintillation (IPS) facilities and the photometers on the *Helios* spacecraft. With the HI instruments, we now have routine wide-angle imaging of the inner heliosphere, from vantage points outside the Sun-Earth line. HI has been used to investigate the development of coronal mass ejections (CMEs) as they pass through the heliosphere to 1 AU and beyond. Synoptic mapping has also allowed us to see graphic illustrations of the nature of mass outflow as a function of distance from the Sun – in particular, stressing the complexity of the near-Sun solar wind. The instruments have also been used to image co-rotating interaction regions (CIRs), to study the interaction of comets with the solar wind and CMEs, and to witness the impact of CMEs and CIRs on planets. The very nature of this area of research – which brings together aspects of solar physics, space-environment physics, and solar-terrestrial physics – means that the research papers are spread among a wide range of journals from different disciplines. Thus, in this special issue, it is timely and appropriate to provide a review of the results of the first two years of the HI investigations.

Reconstruction of an evolving magnetic flux rope in the solar wind: Decomposing spatial and temporal variations from single-spacecraft data

Hiroshi [Hasegawa](#), Bengt U. Ö. Sonnerup, Qiang Hu and Takuma Nakamura

JGR, Volume 119, Issue 1, pages 97–114, January **2014**

<http://onlinelibrary.wiley.com/doi/10.1002/2013JA019180/pdf>

We present a novel single-spacecraft method for decomposing spatial and temporal variations of physical quantities at points along the path of a spacecraft in space-time. The method is designed for use in the reconstruction of evolving two-dimensional, approximately magnetohydrostatic structures in a space plasma. It is an extension of the one developed by Sonnerup and Hasegawa (2010) and Hasegawa et al. (2010), in which it was assumed that variations in the time series of data, recorded as the structures move past the spacecraft, are all due to spatial effects. In reality, some of the observed variations are usually caused by temporal evolution of the structure during the time it moves past the observing spacecraft; the information in the data about the spatial structure is aliased by temporal effects. The purpose here is to remove this time aliasing from the reconstructed maps of field and plasma properties. Benchmark tests are performed by use of synthetic data taken by a virtual spacecraft as it traverses, at a constant velocity, a magnetic flux rope growing sufficiently slowly (relative to the Alfvén speed) in a two-dimensional magnetohydrodynamic simulation of magnetic reconnection. These tests show that the new method can better recover the space-time behavior of the flux rope than does the original version, in which time-aliasing effects had not been removed. An application of the new method to a solar wind flux rope, observed by the ACE spacecraft, suggests that the cross-sectional shape of the core part of the flux rope was varying. **25–27 March 1998**

Occurrence of Great Magnetic Storms on 6-8 March 1582

Kentaro [Hattori](#), [Hisashi Hayakawa](#), [Yusuke Ebihara](#)

MNRAS Volume 487, Issue 3, Pages 3550–3559 2019

<https://arxiv.org/ftp/arxiv/papers/1905/1905.08017.pdf>

Although knowing the occurrence frequency of severe space weather events is important for a modern society, it is insufficiently known due to the lack of magnetic or sunspot observations, before the Carrington event in 1859 known as one of the largest events during the last two centuries. Here, we show that a severe magnetic storm occurred on 8 March 1582 based on auroral records in East Asia. The equatorward boundary of auroral visibility reached 28.8° magnetic latitude. The equatorward boundary of the auroral oval is estimated to be 33.0° invariant latitude (ILAT), which is comparable to the storms on 25/26 September 1909 (~31.6° ILAT, minimum Dst of -595 nT), 28/29 August 1859 (~36.5° ILAT), and 13/14 March 1989 (~40° ILAT, minimum Dst of -589 nT). Assuming that the equatorward boundary is a proxy for the scale of magnetic storms, we presume that the storm on March 1582 was severe. We also found that the storm on March 1582 lasted, at least, for three days by combining European records. The auroral oval stayed at mid-latitude for the first two days and moved to low-latitude (in East Asia) for the last day. It is plausible that the storm was caused by a series of ICMEs (interplanetary coronal mass ejections). We can reasonably speculate that a first ICME could have cleaned up interplanetary space to make the following ICMEs more geo-effective, as probably occurred in the Carrington and Halloween storms.

The Solar and Geomagnetic Storms in May 2024: A Flash Data Report

2024

<https://arxiv.org/pdf/2407.07665>

In May 2024, the scientific community observed intense solar eruptions that resulted in an extreme geomagnetic storm and auroral extension, highlighting the need to document and quantify these events. This study mainly focuses on their quantification. The source active region (AR 13664) evolved from 113 to 2761 millionths of the solar hemisphere between **4 May and 14 May 2024**. AR 13664's magnetic free energy surpassed 1033 erg on 7 May 2024, triggering 12 X-class flares. Multiple interplanetary coronal mass ejections (ICMEs) came out from this AR, accelerating solar energetic particles toward Earth. At least four ICMEs seemingly piled up to disturb the interplanetary space, according to the satellite data and interplanetary scintillation data. The shock arrival at 17:05 UT on 10 May 2024 significantly compressed the magnetosphere down to ~ 5.04 R_E, and triggered a deep Forbush decrease. GOES satellite data and ground-based neutron monitors confirmed a ground-level enhancement from 2 UT to 10 UT on 11 May 2024. The ICMEs induced extreme geomagnetic storms, peaking at a Dst index of -412 nT at 2 UT on 11 May 2024, marking the sixth-largest storm since 1957. The AE and AL indices showed extreme auroral extensions that located the AE/AL stations into the polar cap. We gathered auroral records at that time and reconstructed the equatorward boundary of the visual auroral oval to 29.8° invariant latitude. We compared naked-eye and camera auroral visibility, providing critical caveats on their difference. We also confirmed global enhancements of storm-enhanced density of the ionosphere.

We review observations of solar activity, geomagnetic variation, and auroral visibility for the extreme geomagnetic storm on **1872 February 4**. The extreme storm (referred to here as the Chapman–Silverman storm) apparently originated from a complex active region of moderate area ($\approx 500 \mu\text{sh}$) that was favorably situated near disk center ($S19^\circ E05^\circ$). There is circumstantial evidence for an eruption from this region at 9–10 UT on 1872 February 3, based on the location, complexity, and evolution of the region, and on reports of prominence activations, which yields a plausible transit time of ≈ 29 hr to Earth. Magnetograms show that the storm began with a sudden commencement at $\approx 14:27$ UT and allow a minimum Dst estimate of ≤ -834 nT. Overhead aurorae were credibly reported at Jacobabad (British India) and Shanghai (China), both at $19^\circ 9'$ in magnetic latitude (MLAT) and $24^\circ 2'$ in invariant latitude (ILAT). Auroral visibility was reported from 13 locations with MLAT below $|20|^\circ$ for the 1872 storm (ranging from $|10^\circ 0'|$ – $|19^\circ 9'|$ MLAT) versus one each for the 1859 storm ($|17^\circ 3'|$ MLAT) and the 1921 storm ($|16^\circ 2'|$ MLAT). The auroral extension and conservative storm intensity indicate a magnetic storm of comparable strength to the extreme storms of 1859 September ($25^\circ 1' \pm 0^\circ 5'$ ILAT and -949 ± 31 nT) and 1921 May ($27^\circ 1'$ ILAT and -907 ± 132 nT), which places the 1872 storm among the three largest magnetic storms yet observed.

The extreme solar and geomagnetic storms on 1940 March 20–25

MNRAS, Volume 517, Issue 2, December 2022, Pages 1709–1723,

<https://doi.org/10.1093/mnras/stab3615>

<https://academic.oup.com/mnras/article-pdf/517/2/1709/46495872/stab3615.pdf>

In late 1940 March, at least five significant solar flares were reported. They likely launched interplanetary coronal mass ejections (ICMEs), and were associated with one of the largest storm sudden commencements (SSCs) since 1868, resulting in space weather hazards that would have significant societal impacts should it occur today. The initial solar activity is associated with a solar proton event. Afterwards, another flare was reported in the eastern solar quadrant (N12 E37–38) at 11:30–12:30 UT on March 23, with significant magnetic crochets (up to $\approx |80|$ nT at Eskdalemuir) during 11:07–11:40 UT. On their basis, we conservatively estimate the required energy flux of the source solar flare as $X35 \pm 1$ in soft X-ray class. The resultant ICMEs caused enormous SSCs (up to >425 nT recorded at Tucson) and allowed us to estimate an extremely inward magnetopause position (estimated magnetopause stand-off position ≈ 3.4 RE). The time series of the resultant geomagnetic storm is reconstructed using a Dst estimate, which peaked at 20 UT on March 24 at ≈ -389 nT. Around the storm main phase, the equatorward boundary of the auroral oval extended $\leq 46.3^\circ$ in invariant latitudes. This sequence also caused a solar proton event and Forbush decrease (≈ 3 per cent). These sequences indicate pile-up of multiple ICMEs, which even achieved a record value of inward magnetopause position. Our analyses of this historical pioneer event bring more insights into possible serious space weather hazards and provide a quantitative basis for future analyses and predictions.

A Review for Japanese auroral records on the three extreme space weather events around the International Geophysical Year (1957 -- 1958)

Hisashi [Hayakawa](#), [Yusuke Ebihara](#), [Hidetoshi Hata](#)

Geoscience Data Journal, 2021

<https://arxiv.org/ftp/arxiv/papers/2112/2112.09432.pdf>

DOI: 10.1002/GDJ3.140

Solar Cycle 19 was probably the greatest solar cycle over the last four centuries and significantly disrupted the solar-terrestrial environments with a number of solar eruptions and resultant geomagnetic storms. At its peak, the International Geophysical Year (IGY: 1957 -- 1958) was organised by international collaborations and benefitted scientific developments, capturing multiple unique extreme space weather events including the third and fourth greatest geomagnetic storms in the space age. In this article, we review and analyse original records of Japanese auroral observations around the IGY. These observations were organised by Masaaki Huruhashi in collaboration with professional observatories and citizen contributors. We have digitised and documented these source documents, which comprise significant auroral displays in March 1957 (minimum Dst = -255 nT), September 1957 (minimum Dst = -427 nT), and February 1958 (minimum Dst = -426 nT). These records allow us to visualise temporal and spatial evolutions

of these auroral displays, reconstruct their equatorward auroral boundaries down to 41.4° , 38.3° , and 33.3° in invariant latitudes, and contextualise their occurrences following contemporary geomagnetic disturbances. Our results have been compared with significant auroral displays during other extreme space weather events. These aurorae generally showed reddish colourations occasionally with yellowish rays. Their colourations are attributed to reddish oxygen emission and its mixture with greenish oxygen emission. Overall, these archival records provide the references for future discussions on the auroral activities during the uniquely intense and extreme space weather events. **2/3 March 1957, 13/14 September 1957, 11/12 February 1958**

Temporal Variations of the Three Geomagnetic Field Components at Colaba Observatory around the Carrington Storm in 1859

Hisashi **Hayakawa**, [Heikki Nevanlinna](#), [Séan P. Blake](#), [Yusuke Ebihara](#), [Ankush T. Bhaskar](#), [Yoshizumi Miyoshi](#)

ApJ **2021**

<https://arxiv.org/pdf/2109.13020>

The Carrington storm in 1859 September has been arguably identified as the greatest geomagnetic storm ever recorded. However, its exact magnitude and chronology remain controversial, while their source data have been derived from the Colaba H magnetometer. Here, we have located the Colaba 1859 yearbook, containing hourly measurements and spot measurements. We have reconstructed the Colaba geomagnetic disturbances in the horizontal component (ΔH), the eastward component (ΔY), and the vertical component (ΔZ) around the time of the Carrington storm. On their basis, we have chronologically revised the ICME transit time as ≤ 17.1 hrs and located the ΔH peak at 06:20 -- 06:25 UT, revealing a magnitude discrepancy between the hourly and spot measurements (-1691 nT vs. -1263 nT). Furthermore, we have newly derived the time series of ΔY and ΔZ , which peaked at $\Delta Y \sim 378$ nT (05:50 UT) and 377 nT (06:25 UT), and $\Delta Z \sim -173$ nT (06:40 UT). We have also computed the hourly averages and removed the solar quiet (Sq) field variations from each geomagnetic component to derive their hourly variations with latitudinal weighting. Our calculations have resulted in the disturbance variations (Dist) with latitudinal weighting of Dist Y ~ 328 nT and Dist Z ~ -36 nT, and three scenarios of Dist H $\sim -918, -979,$ and -949 nT, which also approximate the minimum Dst. These data may suggest preconditioning of the geomagnetic field after the August storm ($\Delta H \leq -570$ nT), which made the September storm even more geoeffective.

The Extreme Space Weather Event in 1941 February/March

2021 ApJ 908 209

<https://arxiv.org/ftp/arxiv/papers/2010/2010.00452.pdf>

<https://doi.org/10.3847/1538-4357/abb772>

Given the infrequency of extreme geomagnetic storms, it is significant to note the concentration of three extreme geomagnetic storms in 1941, whose intensities ranked fourth, twelfth, and fifth within the aa index between 1868–2010. Among them, the geomagnetic storm on 1941 March 1 was so intense that three of the four Dst station magnetograms went off scale. Herein, we reconstruct its time series and measure the storm intensity with an alternative Dst estimate (Dst*). The source solar eruption at 09:29–09:38 GMT on February 28 was located at RGO AR 13814 and its significant intensity is confirmed by large magnetic crochets of 135 nT measured at Abinger. This solar eruption most likely released a fast interplanetary coronal mass ejection with estimated speed 2260 km s^{-1} . After its impact at 03:57–03:59 GMT on March 1, an extreme magnetic storm was recorded worldwide. Comparative analyses on the contemporary magnetograms show the storm peak intensity of minimum $\text{Dst}^* \leq -464$ nT at 16 GMT, comparable to the most and the second most extreme magnetic storms within the standard Dst index since 1957. This storm triggered significant low-latitude aurorae in the East Asian sector and their equatorward boundary has been reconstructed as $38^\circ 5'$ in invariant latitude. This result agrees with British magnetograms, which indicate an auroral oval moving above Abinger at $53^\circ 0'$ in magnetic latitude. The storm amplitude was even more enhanced in equatorial stations and consequently casts caveats on their usage for measurements of the storm intensity in Dst estimates. **February 28-March 1 1941**

The intensity and evolution of the extreme storms in January 1938

<https://doi.org/10.3847/1538-4357/abc427>

Major solar eruptions occasionally direct interplanetary coronal mass ejections (ICMEs) to Earth and cause significant geomagnetic storms and low-latitude aurorae. While single extreme storms are of significant threats to the modern civilization, storms occasionally appear in sequence and, acting synergistically, cause 'perfect storms' at Earth. The stormy interval in January 1938 was one of such cases. Here, we analyze the contemporary records to reveal its time series on their source active regions, solar eruptions, ICMEs, geomagnetic storms, low-latitude aurorae, and cosmic-ray (CR) variations. Geomagnetic records show that three storms occurred successively on **17/18 January** ($D_{cx} \sim -171$ nT) on **21/22 January** ($D_{cx} \sim -328$ nT) and on **25/26 January** ($D_{cx} \sim -336$ nT). The amplitudes of the cosmic-ray variations and sudden storm commencements show the impact of the first ICME as the largest ($\sim 6\%$ decrease in CR and 72 nT in SSC) and the ICME associated with the storms that followed as more moderate ($\sim 3\%$ decrease in CR and 63 nT in SSC; $\sim 2\%$ decrease in CR and 63 nT in SSC). Interestingly, a significant solar proton event occurred on 16/17 January and the Cheltenham ionization chamber showed a possible ground level enhancement. During the first storm, aurorae were less visible at mid-latitudes, whereas during the second and third storms, the equatorward boundaries of the auroral oval were extended down to 40.3° and 40.0° in invariant latitude. This contrast shows that the initial ICME was probably faster, with a higher total magnitude but a smaller southward component.

Intensity and time series of extreme solar-terrestrial storm in 1946 March

Monthly Notices of the Royal Astronomical Society, Volume 497, Issue 4, **2020**, Pages 5507–5517,

<https://doi.org/10.1093/mnras/staa1508>

<https://sci-hub.st/10.1093/mnras/staa1508>

Major solar eruptions occasionally cause magnetic superstorms on the Earth. Despite their serious consequences, the low frequency of their occurrence provides us with only limited cases through modern instrumental observations, and the intensities of historical storms before the coverage of the Dst index have been only sporadically estimated. Herein, we examine a solar-terrestrial storm that occurred in 1946 March and quantitatively evaluate its parameters. During the ascending phase of Solar Cycle 18, two moderate sunspot groups caused a major flare. The $H\alpha$ flaring area was recorded to be ≥ 600 – 1200 millionths of solar hemisphere, suggesting that this was an M- or X-class flare in soft X-ray intensity. Upon this eruption, a rapid interplanetary coronal mass ejection (ICME) with an average speed of ≈ 1590 km s $^{-1}$ was launched. Based on measurements in four known mid-latitude and relatively complete magnetograms, the arrival of this extreme ICME caused a magnetic superstorm, which caused an initial phase with the H-component amplitude of ≥ 80 nT, followed by a main phase whose intensity was reconstructed as ≤ -512 nT using most negative Dst* estimates. Meanwhile, the equatorial boundary of the auroral oval extended down to $\leq 41.0^\circ$ in invariant latitude and formed a corona aurora in Watheroo, Australia. Interestingly, during this magnetic superstorm, larger magnetic disturbances were recorded at dusk and near the dip equator on the dayside. Its cause may be associated with a strong westward equatorial electrojet and field-aligned current, in addition to the contribution from the storm-time ring current.

Candidate Auroral Observations during the Major Solar-Terrestrial Storm in May 1680: Implication for Space Weather Events during the Maunder Minimum

Hisashi [Hayakawa](#), [Kristian Schlegel](#), [Bruno P. Besser](#), [Yusuke Ebihara](#)

ApJ **2020**

<https://arxiv.org/ftp/arxiv/papers/2008/2008.13739.pdf>

The Maunder Minimum (1645-1715) is currently considered the only grand minimum within telescopic sunspot observations since 1610. During this epoch, the Sun was extremely quiet and unusually free from sunspots. However, despite reduced frequency, candidate aurorae were reported in the mid-European sector during this period and have been associated with occurrences of interplanetary coronal mass ejections (ICMEs), whereas some of them have been identified as misinterpretations. Here, we have analysed reports of candidate aurorae on 1 June 1680 with simultaneous observations in mid-Europe, and compared their descriptions with visual accounts of early modern aurorae. Most contemporary sunspot drawings from 22, 24, and 27 May 1680 have shown that this apparent sunspot may have been a source of ICMEs, which caused the reported candidate aurorae. On the other hand, its intensity estimate shows that the magnetic storm during this candidate aurora was probably within the capability of the storms derived from the corotating interaction region (CIR). Therefore, we accommodate both ICMEs and CIRs as their possible origin. This interpretation is probably applicable to the candidate aurorae in the often-cited Hungarian catalogue, on the basis of the reconstructed margin of their equatorward auroral boundary. Moreover, this catalogue itself has clarified that the considerable candidates during the MM were probably misinterpretations. Therefore, frequency of the auroral visibility in Hungary

was probably lower than previously considered and agree more with the generally slow solar wind in the existing reconstructions, whereas sporadic occurrences of sunspots and coronal holes still caused occasional geomagnetic storms.

The Extreme Space Weather Event in 1903 October/November: An Outburst from the Quiet Sun

While the Sun is generally more eruptive during its maximum and declining phases, observational evidence shows certain cases of powerful solar eruptions during the quiet phase of the solar activity. Occurring in the weak Solar Cycle 14 just after its minimum, the extreme space weather event in 1903 October -- November was one of these cases. Here, we reconstruct the time series of geomagnetic activity based on contemporary observational records. With the mid-latitude magnetograms, the 1903 magnetic storm is thought to be caused by a fast coronal mass ejection (~1500 km/s) and is regarded as an intense event with an estimated minimum Dst' of ~-513 nT. The reconstructed time series has been compared with the equatorward extension of auroral oval (~44.1° in invariant latitude) and the time series of telegraphic disturbances. This case study shows that potential threats posed by extreme space weather events exist even during weak solar cycles or near their minima. **Source 30 Nov, 06 UT, Dst ~-513 nT, 31 Nov, 14 UT**

South American auroral reports during the Carrington storm

Hisashi [Hayakawa](#), [José R. Ribeiro](#), [Yusuke Ebihara](#), [Ana P. Correia](#), [Mitsuru Sôma](#)

Earth, Planets and Space, 72, 122, 2020

<https://arxiv.org/ftp/arxiv/papers/2008/2008.13180.pdf>

The importance of the investigation of magnetic superstorms is not limited to academic interest, because these superstorms can cause catastrophic impact on the modern civilisation due to our increasing dependency on technological infrastructure. In this context, the Carrington storm in September 1859 is considered as a benchmark of observational history owing to its magnetic disturbance and equatorial extent of the auroral oval. So far, several recent auroral reports at that time have been published but those reports are mainly derived from the Northern Hemisphere. In this study, we analyse datable auroral reports from South America and its vicinity, assess the auroral extent using philological and astrometric approaches, identify the auroral visibility at - 17.3° magnetic latitude and further poleward and reconstruct the equatorial boundary of the auroral oval to be 25.1° +/- 0.5° in invariant latitude. Interestingly, brighter and more colourful auroral displays were reported in the South American sector than in the Northern Hemisphere. This north-south asymmetry is presumably associated with variations of their magnetic longitude and the weaker magnetic field over South America compared to the magnetic conjugate point and the increased amount of magnetospheric electron precipitation into the upper atmosphere. These results attest that the magnitude of the Carrington storm indicates that its extent falls within the range of other superstorms, such as those that occurred in May 1921 and February 1872, in terms of the equatorial boundary of the auroral oval.

Temporal and Spatial Evolutions of a Large Sunspot Group and Great Auroral Storms around the Carrington Event in 1859

<https://doi.org/10.1029/2019SW002269>

The Carrington event is considered to be one of the most extreme space weather events in observational history within a series of magnetic storms caused by extreme interplanetary coronal mass ejections (ICMEs) from a large and complex active region (AR) emerged on the solar disk. In this article, we study the temporal and spatial evolutions of the source sunspot active region and visual aurorae, and compare this storm with other extreme space weather events on the basis

of their spatial evolution. Sunspot drawings by Schwabe, Secchi, and Carrington describe the position and morphology of the source AR at that time. Visual auroral reports from the Russian Empire, Iberia, Ireland, Oceania, and Japan fill the spatial gap of auroral visibility and revise the time series of auroral visibility in mid to low magnetic latitudes (MLATs). The reconstructed time series is compared with magnetic measurements and shows the correspondence between low to mid latitude aurorae and the phase of magnetic storms. The spatial evolution of the auroral oval is compared with those of other extreme space weather events in 1872, 1909, 1921, and 1989 as well as their storm intensity, and contextualizes the Carrington event, as one of the most extreme space weather events, but likely not unique. **28/29 Aug 1859, 1/2 Sept 1859, 4 Feb 1872, 25 Sept 1909, 14/15 May 1921, 13/14 March 1989**

Long-Lasting Extreme Magnetic Storm Activities in 1770 Found in Historical Documents

ApJL **850** L31 **2017**

<https://arxiv.org/ftp/arxiv/papers/1711/1711.00690.pdf>

Dim red aurora at low magnetic latitudes is a visual and recognized manifestation of geomagnetic storms. The great low-latitude auroral displays seen throughout East Asia on **16-18 September 1770** are considered to manifest one of the greatest storms. Recently found 111 historical documents in East Asia attest that these low-latitude auroral displays were succeeding for almost 9 nights during 10-19 September 1770 in the lowest magnetic latitude areas ($< 30^{\circ}$). This suggests that the duration of the great magnetic storm is much longer than usual. Sunspot drawings from 1770 reveals the fact that sunspots area was twice as large as those observed in another great storm of 1859, which substantiates this unusual storm activities in 1770. These spots likely ejected several huge, sequential magnetic structures in short duration into interplanetary space, resulting in spectacular world-wide aurorae in mid-September 1770. These findings provide new insights about the history, duration, and effects of extreme magnetic storms that may be valuable for those who need to mitigate against extreme events.

Boundary Treatment for the Subsonic/Alfvénic Inner Boundary at $2.5 R_{\odot}$ in a Time-dependent 3D Magnetohydrodynamics Solar Wind Simulation Model

Keiji [Hayashi](#)¹, Chin-Chun Wu², and Kan Liou³

2023 ApJS 268 39

<https://iopscience.iop.org/article/10.3847/1538-4365/acecf7/pdf>

A new magnetohydrodynamics (MHD) simulation model of the global solar corona and solar wind is presented. The model covers the range of heliocentric distance from 2.5 solar radii, so that coronal mass ejections at the earliest phase near the Sun can be treated in the future. This model is constructed by introducing a characteristics-based boundary treatment to an existing heliosphere 3D MHD model. In tailoring a set of characteristic equations for this new model, we assume that the coronal magnetic field is open to interplanetary space and that the solar coronal plasma is flowing outward everywhere at 2.5 solar radii. The characteristic equations for the subsonic/Alfvénic inner boundary surface are satisfied by altering the plasma density and/or temperature to maintain a polytropic relationship. In this article, the details of the characteristics-based boundary treatment for the middle of the corona (named CharM) are provided. The quasi-steady states of the solar wind derived from simulations with various choices of a parameter in the boundary treatments are compared and examined. Although further improvements are needed, we apply the new boundary treatment to simulations for three Carrington rotation periods from the minimum to maximum phase of the solar activity cycle, and show that an optimal choice yields a reasonable quasi-steady state of the transonic/Alfvénic solar wind matching the specified subsonic/Alfvénic plasma speed at $2.5 R_{\odot}$.

Coupling a Global Heliospheric Magnetohydrodynamic Model to a Magnetofrictional Model of the Low Corona

Keiji [Hayashi](#)¹, William P. Abbett², Mark C. M. Cheung³, and George H. Fisher²

2021 ApJS 254 1

<https://doi.org/10.3847/1538-4365/abe9b5>

Recent efforts coupling our Sun-to-Earth magnetohydrodynamics (MHD) model and lower-corona magnetofrictional (MF) model are described. Our Global Heliospheric MHD (GHM) model uses time-dependent three-component magnetic field data from the lower-corona MF model as time-dependent boundary values. The MF model uses data-assimilation techniques to introduce the vector magnetic field data from the Solar Dynamics Observatory/HelioSeismic and Magnetic Imager, hence as a whole this simulation coupling structure is driven with actual observations. The GHM model employs a newly developed interface boundary treatment that is based on the concept of characteristics, and it properly treats the interface boundary sphere set at a height of the sub-Alfvénic lower corona ($1.15 R_{\odot}$ in this work).

The coupled model framework numerically produces twisted nonpotential magnetic features and consequent eruption events in the solar corona in response to the time-dependent boundary values. The combination of our two originally independently developed models presented here is a model framework toward achieving further capabilities of modeling the nonlinear time-dependent nature of magnetic field and plasma, from small-scale solar active regions to large-scale solar wind structures. This work is a part of the Coronal Global Evolutionary Model project for enhancing our understanding of Sun–Earth physics to help improve space weather capabilities.

CME-related Large Decreases in the Differential Phase Delay of Tianwen-1 DOR Signals

Qingbao He¹, Zhichao Wang^{2,3}, Qinghui Liu², Kaijun Liu¹, and Li Guo²

2022 ApJL 940 L45

<https://iopscience.iop.org/article/10.3847/2041-8213/aca2a8/pdf>

Differential phase delay is calculated for the differential one-way range (DOR) signals transmitted by Tianwen-1, the first Chinese Mars spacecraft that entered into the Mars orbit on 2021 February 10. Large decreases in the differential phase delay are identified in the DOR signals received by ground stations on **2021 March 23 and June 18**. The decreases indicate sizable increases of the total electron content (TEC) along the DOR signal path between Tianwen-1 and the ground stations. The TEC increases are estimated to be 85 and 175 TEC units on 2021 March 23 and June 18, respectively. Evidence shows that they are caused by the sheath regions ahead of the coronal mass ejections (CMEs) that traversed the signal path on both days. The results represent the first observations of CME-related structures by the DOR signals and demonstrate the potential of DOR signals in remote sensing the interplanetary plasma structures in the solar wind.

Growth of Outward Propagating Fast-Magnetosonic/Whistler Waves in the Inner Heliosphere Observed by Parker Solar Probe

Jiansen He, Ying Wang, Xingyu Zhu, Die Duan, Daniel Verscharen, Guoqing Zhao

ApJ 2021

<https://arxiv.org/pdf/2109.12768.pdf>

The solar wind in the inner heliosphere has been observed by Parker Solar Probe (PSP) to exhibit abundant wave activities. The cyclotron wave modes in the sense of ions or electrons are among the most crucial wave components. However, their origin and evolution in the inner heliosphere close to the Sun remain mysteries. Specifically, it remains unknown whether it is an emitted signal from the solar atmosphere or an eigenmode growing locally in the heliosphere due to plasma instability. To address and resolve this controversy, we must investigate the key quantity of the energy change rate of the wave mode. We develop a new technique to measure the energy change rate of plasma waves, and apply this technique to the wave electromagnetic fields measured by PSP. We provide the wave Poynting flux in the solar wind frame, identify the wave nature to be the outward propagating fast-magnetosonic/whistler wave mode instead of the sunward propagating waves. We provide the first evidence for growth of the fast-magnetosonic/whistler wave mode in the inner heliosphere based on the derived spectra of the real and imaginary parts of the wave frequencies. The energy change rate rises and stays at a positive level in the same wavenumber range as the bumps of the electromagnetic field power spectral densities, clearly manifesting that the observed fast-magnetosonic/whistler waves are locally growing to a large amplitude. **Nov 4, 2018**

Solar Origin of Compressive Alfvénic Spikes/Kinks as Observed by Parker Solar Probe

Jiansen He¹, Xingyu Zhu¹, Liping Yang², Chuanpeng Hou¹, Die Duan¹, Lei Zhang³, and Ying Wang¹

2021 ApJL 913 L14

<https://doi.org/10.3847/2041-8213/abf83d>

The solar wind is found by the Parker Solar Probe to be abundant with Alfvénic velocity spikes and magnetic field kinks. Temperature enhancement is another remarkable feature associated with the Alfvénic spikes. How the prototype of these coincident phenomena is generated intermittently in the source region is an important and wide-ranging subject. Here we propose a new model introducing guide-field discontinuity into the interchange magnetic reconnection between open funnels and closed loops with different magnetic helicities. The modified interchange reconnection model not only can accelerate jet flows from the newly opening closed loop but also can excite and launch Alfvénic wave pulses along the newly reconnected and post-reconnected open flux tubes. We find that the modeling results can reproduce the following observational features: (1) Alfvén disturbance is pulsive in time and asymmetric in space; (2) Alfvénic pulse is compressive with temperature enhancement and density variation inside the pulse. We point out that three physical processes co-happening with Alfvén wave propagation can be responsible for the temperature enhancement: (a) convection of heated jet flow plasmas (decrease in density), (b) propagation of compressive slow-mode waves (increase in density), and (c) conduction of heat flux (weak change in density). We also suggest that the radial nonlinear evolution of the Alfvénic pulses should be taken into account to explain the formation of magnetic switchback geometry.

Encounter of Parker Solar Probe and a Comet-like Object During Their Perihelia: Model Predictions and Measurements

Jiansen He, Bo Cui, Liping Yang, Chuanpeng Hou, Lei Zhang, Wing-Huen Ip, Yingdong Jia, Chuanfei Dong, Die Duan, Qiugang Zong, Stuart D. Bale, Marc Pulupa, John W. Bonnell, Thierry Dudok de Wit, Keith Goetz, Peter R. Harvey, Robert J. MacDowall, David M. Malaspina

2021 *ApJ* **910** 7

<https://arxiv.org/pdf/2012.00005.pdf>

<https://doi.org/10.3847/1538-4357/abdf4a>

Parker Solar Probe (PSP) aims at exploring the nascent solar wind close to the Sun. Meanwhile, PSP is also expected to encounter small objects like comets and asteroids. In this work, we survey the ephemerides to find a chance of recent encounter, and then model the interaction between released dusty plasmas and solar wind plasmas. On **2019 September 2**, a comet-like object 322P/SOHO just passed its perihelion flying to a heliocentric distance of 0.12 au, and swept by PSP at a relative distance as close as 0.025 au. We present the dynamics of dust particles released from 322P, forming a curved dust tail. Along the PSP path in the simulated inner heliosphere, the states of plasma and magnetic field are sampled and illustrated, with the magnetic field sequences from simulation results being compared directly with the in-situ measurements from PSP. Through comparison, we suggest that 322P might be at a deficient activity level releasing limited dusty plasmas during its way to becoming a "rock comet". We also present images of solar wind streamers as recorded by WISPR, showing an indication of dust bombardment for the images superposed with messy trails. We observe from LASCO coronagraph that 322P was transiting from a dimming region to a relatively bright streamer during its perihelion passage, and simulate to confirm that 322P was flying from relatively faster to slower solar wind streams, modifying local plasma states of the streams.

A Stealth CME Bracketed between Slow and Fast Wind Producing Unexpected Geoeffectiveness

Wen He, Ying D.Liu, Huidong Hu, Rui Wang, Xiaowei Zhao

ApJ **860** 78 **2018**

<https://arxiv.org/pdf/1805.03128.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/aac381/pdf>

We investigate how a weak coronal mass ejection (CME) launched on **2016 October 8** without obvious signatures in the low corona produced a relatively intense geomagnetic storm. Remote sensing observations from SDO, STEREO and SOHO and in situ measurements from WIND are employed to track the CME from the Sun to the Earth. Using a graduated cylindrical shell (GCS) model, we estimate the propagation direction and the morphology of the CME near the Sun. CME kinematics are determined from the wide-angle imaging observations of STEREO A and are used to predict the CME arrival time and speed at the Earth. We compare ENLIL MHD simulation results with in situ measurements to illustrate the background solar wind where the CME was propagating. We also apply a Grad-Shafranov technique to reconstruct the flux rope structure from in situ measurements in order to understand the geoeffectiveness associated with the CME magnetic field structure. Key results are obtained concerning how a weak CME can generate a relatively intense geomagnetic storm: (1) there were coronal holes at low latitudes, which could produce high speed streams (HSSs) to interact with the CME in interplanetary space; (2) the CME was bracketed between a slow wind ahead and a HSS behind, which enhanced the southward magnetic field inside the CME and gave rise to the unexpected geomagnetic storm.

Forbush decreases associated to Stealth Coronal Mass Ejections.

Classification of Enhanced Geoeffectiveness Resulting from High-Speed Solar Wind Streams Compressing Slower Interplanetary Coronal Mass Ejections

Stephan G. Heinemann, Chaitanya Sishla, Simon Good, Maxime Grandin, Jens Pomoell

ApJ **963** L25 **2024**

<https://arxiv.org/pdf/2402.08065.pdf>

<https://iopscience.iop.org/article/10.3847/2041-8213/ad283a/pdf>

High-speed solar wind streams (HSSs) interact with the preceding ambient solar wind to form Stream Interaction Regions (SIRs), which are a primary source of recurrent geomagnetic storms. However, HSSs may also encounter and subsequently interact with Interplanetary Coronal Mass Ejections (ICMEs). In particular, the impact of the interaction between slower ICMEs and faster HSSs, represents an unexplored area that requires further in-depth investigation. This specific interaction can give rise to unexpected geomagnetic storm signatures, diverging from the conventional expectations of individual SIR events sharing similar HSS properties. Our study presents a comprehensive analysis of solar wind data spanning from 1996 to 2020, capturing 23 instances where such encounters led to geomagnetic storms ($SymH < -30$ nT). We determined that interaction events between preceding slower ICMEs and faster HSSs possess the potential to induce substantial storm activity, statistically nearly doubling the geoeffective impact in comparison to SIR storm events. The increase in the amplitude of the SymH index appears to result from heightened dynamic pressure, often coupled with the concurrent amplification of the CMEs rearward $|B|$ and/or B_z components. **4-6 Feb 2011**
Table 2. Summary of ICME - HSS interaction events 1999-2016

A statistical study of the long-term evolution of coronal hole properties as observed by SDO

S. G. **Heinemann**¹, V. Jerčić^{1,2}, M. Temmer¹, S. J. Hofmeister¹, M. Dumbović^{1,3}, S. Vennerstrom⁴, G. Verbanac⁵ and A. M. Veronig^{1,6}
A&A 638, A68 (2020)

<https://www.aanda.org/articles/aa/pdf/2020/06/aa37613-20.pdf>

Context. Understanding the evolution of coronal holes is especially important when studying the high-speed solar wind streams that emanate from them. Slow- and high-speed stream interaction regions may deliver large amounts of energy into the Earth's magnetosphere-ionosphere system, cause geomagnetic storms, and shape interplanetary space.

Aims. By statistically investigating the long-term evolution of well-observed coronal holes we aim to reveal processes that drive the observed changes in the coronal hole parameters. By analyzing 16 long-living coronal holes observed by the Solar Dynamic Observatory, we focus on coronal, morphological, and underlying photospheric magnetic field characteristics, and investigate the evolution of the associated high-speed streams.

Methods. We use the Collection of Analysis Tools for Coronal Holes to extract and analyze coronal holes using 193 Å EUV observations taken by the Atmospheric Imaging Assembly as well as line-of-sight magnetograms observed by the Helioseismic and Magnetic Imager. We derive changes in the coronal hole properties and look for correlations with coronal hole evolution. Further, we analyze the properties of the high-speed stream signatures near 1AU from OMNI data by manually extracting the peak bulk velocity of the solar wind plasma.

Results. We find that the area evolution of coronal holes shows a general trend of growing to a maximum followed by a decay. We did not find any correlation between the area evolution and the evolution of the signed magnetic flux or signed magnetic flux density enclosed in the projected coronal hole area. From this we conclude that the magnetic flux within the extracted coronal hole boundaries is not the main cause for its area evolution. We derive coronal hole area change rates (growth and decay) of $(14.2 \pm 15.0) \times 10^8$ km² per day showing a reasonable anti-correlation ($ccPearson = -0.48$) to the solar activity, approximated by the sunspot number. The change rates of the signed mean magnetic flux density (27.3 ± 32.2 mG day⁻¹) and the signed magnetic flux (30.3 ± 31.5 10¹⁸ Mx day⁻¹) were also found to be dependent on solar activity ($ccPearson = 0.50$ and $ccPearson = 0.69$ respectively) rather than on the individual coronal hole evolutions. Further we find that the relation between coronal hole area and high-speed stream peak velocity is valid for each coronal hole over its evolution, but we see significant variations in the slopes of the regression lines. **May 29, 2013**

CME–HSS Interaction and Characteristics Tracked from Sun to Earth

Stephan G. **Heinemann**, Manuela Temmer, Charles J. Farrugia, Karin Dissauer, Christina Kay, Thomas Wiegmann, Mateja Dumbović, Astrid M. Veronig, Tatiana Podladchikova, Stefan J. Hofmeister, Noé Lugaz, Fernando Carcaboso

Solar Physics September 2019, 294:121

[sci-hub.se/10.1007/s11207-019-1515-6](https://doi.org/10.1007/s11207-019-1515-6)

<https://arxiv.org/pdf/1908.10161.pdf>

In a thorough study, we investigate the origin of a remarkable plasma and magnetic field configuration observed in situ on **June 22, 2011**, near L1, which appears to be a magnetic ejecta (ME) and a shock signature engulfed by a solar wind high-speed stream (HSS). We identify the signatures as an Earth-directed coronal mass ejection (CME), associated with a C7.7 flare on **June 21, 2011**, and its interaction with a HSS, which emanates from a coronal hole (CH) close to the launch site of the CME. The results indicate that the major interaction between the CME and the HSS starts at a

height of $1.3 R_{\odot}$ up to $3 R_{\odot}$. Over that distance range, the CME undergoes a strong north-eastward deflection of at least 30° due to the open magnetic field configuration of the CH. We perform a comprehensive analysis for the CME–HSS event using multi-viewpoint data (from the Solar TERrestrial RELations Observatories, the Solar and Heliospheric Observatory and the Solar Dynamics Observatory), and combined modeling efforts (nonlinear force-free field modeling, Graduated Cylindrical Shell CME modeling, and the Forecasting a CME’s Altered Trajectory – ForeCAT model). We aim at better understanding its early evolution and interaction process as well as its interplanetary propagation and related in situ signatures, and finally the resulting impact on the Earth’s magnetosphere.

Impact of Switchbacks on Turbulent Cascade and Energy Transfer Rate in the Inner Heliosphere

Carlos S. **Hernández**¹, Luca Sorriso-Valvo^{2,3}, Riddhi Bandyopadhyay⁴, Alexandros Chasapis⁵, Christian L. Vásconez¹, Raffaele Marino⁶, and Oreste Pezzi³

2021 ApJL 922 L11

<https://iopscience.iop.org/article/10.3847/2041-8213/ac36d1/pdf>

<https://doi.org/10.3847/2041-8213/ac36d1>

Recent Parker Solar Probe (PSP) observations of inner heliospheric plasma have shown an abundant presence of Alfvénic polarity reversal of the magnetic field, known as "switchbacks." While their origin is still debated, their role in driving the solar wind turbulence has been suggested through analysis of the spectral properties of magnetic fluctuations. Here, we provide a complementary assessment of their role in the turbulent cascade. The validation of the third-order linear scaling of velocity and magnetic fluctuations in intervals characterized by a high occurrence of switchbacks suggests that, irrespective of their local or remote origin, these structures are actively embedded in the turbulent cascade, at least at the radial distances sampled by PSP during its first perihelion. The stronger positive energy transfer rate observed in periods with a predominance of switchbacks indicates that they act as a mechanism injecting additional energy in the turbulence cascade. **3-9 Nov 2018**

SoloHI observations of coronal mass ejections observed by multiple spacecraft*

P. **Hess**¹, R. C. Colaninno¹, A. Vourlidis², R. A. Howard² and G. Stenborg²

A&A 679, A149 (2023)

<https://www.aanda.org/articles/aa/pdf/2023/11/aa46907-23.pdf>

Context. The Solar Orbiter Heliospheric Imager (SoloHI) instrument of the Solar Orbiter mission is a next-generation heliospheric imager. New observations from SoloHI demonstrate the improved spatial and temporal resolution compared to previous observations of the heliosphere and corona. At perihelion, the field of view (FoV) of SoloHI covers the transition between the coronagraph (COR2) and heliospheric imager (HI1) Sun-Earth Connection Coronal and Heliospheric Investigation (SECCHI) suite. In this paper, we focus on an active solar period following the first Solar Orbiter science perihelion that resulted in a number of well-observed large coronal mass ejections (CMEs) in SoloHI data in **March and April 2022**. Specifically, we highlight a series of events produced by AR12795 between **28 March and 2 April** and show overlapping observations with SECCHI/COR2 and HI1 and LASCO/C3.

Aims. We compare the performance of the SoloHI instrument against similar observations from 1 au imagers. We describe CME observations, highlighting the unique structural features captured within the SoloHI FoV. These observations demonstrate that SoloHI will provide new insights into CME morphology and evolution from a unique vantage point.

Methods. To provide a direct and relevant comparison, images from all the telescopes we used in the paper are presented in FoVs common to each and with minimal processing applied. The J-maps we used to highlight outflowing features are also presented to show that the CME kinematics can be tracked through the SoloHI FoV, and also to report how the rest of the Heliophysics Systems Observatory (HSO) can be used to support the SoloHI data.

Results. The high-resolution SoloHI images of these eruptions, taken from ~ 0.3 au, reveal a number of detailed structural CME features, including internal cavities or cores of the CME flux rope(s). They also show the surrounding material and associated sheath region of the compressed upstream solar wind plasma. Many features that could not have been observed by other instruments are highlighted and discussed.

Conclusions. The SoloHI instrument is performing well and has already provided detailed observations of CMEs that can help us understand the details of the internal structure and magnetic field of CMEs. These new observations in combination with synoptic observations from 1 au offer new opportunities for CME propagation from the corona to the heliosphere.

HIGH-RESOLUTION IMAGING OF CORONAL MASS EJECTIONS FROM SOLOHI

<https://arxiv.org/pdf/1912.02255.pdf>

<https://doi.org/10.3847/1538-4365/ab4ff0>

The Wide-field Imager for Solar Probe (WISPR) on board the Parker Solar Probe (PSP) observed a CME on **2018 November 01**, the first day of the initial PSP encounter. The speed of the CME, approximately 200-300 km s⁻¹ in the WISPR field of view, is typical of slow, streamer blowout CMEs. This event was also observed by the LASCO coronagraphs. WISPR and LASCO view remarkably similar structures that enable useful cross-comparison between the two data sets as well as stereoscopic imaging of the CME. Analysis is extended to lower heights by linking the white-light observations to EUV data from AIA, which reveal a structure that erupts more than a full day earlier before the CME finally gathers enough velocity to propagate outward. This EUV feature appears as a brightness enhancement in cooler temperatures such as 171 Å, but as a cavity in nominal coronal temperatures such as 193 Å. By comparing this circular, dark feature in 193 Å to the dark, white-light cavity at the center of the eruption in WISPR and LASCO, it can be seen that this is one coherent structure that exists prior to the eruption in the low corona before entering the heliosphere and likely corresponds to the core of the magnetic flux rope. It is also believed that the relative weakness of the event contributed to the clarity of the flux rope in WISPR, as the CME did not experience impulsive forces or strong interaction with external structures that can lead to more complex structural evolution.

A Study of the Earth-Affecting CMEs of Solar Cycle 24

Phillip [Hess](#), [Jie Zhang](#)

[Solar Physics](#) June 2017, 292:80 [File](#)

Using in situ observations from the Advanced Composition Explorer (ACE), we have identified 70 Earth-affecting interplanetary coronal mass ejections (ICMEs) in Solar Cycle 24. Because of the unprecedented extent of heliospheric observations in Cycle 24 that has been achieved thanks to the Sun Earth Connection Coronal and Heliospheric Investigation (SECCHI) instruments onboard the Solar Terrestrial Relations Observatory (STEREO), we observe these events throughout the heliosphere from the Sun to the Earth, and we can relate these in situ signatures to remote sensing data. This allows us to completely track the event back to the source of the eruption in the low corona. We present a summary of the Earth-affecting CMEs in Solar Cycle 24 and a statistical study of the properties of these events including the source region. We examine the characteristics of CMEs that are more likely to be strongly geoeffective and examine the effect of the flare strength on in situ properties. We find that Earth-affecting CMEs in the first half of Cycle 24 are more likely to come from the northern hemisphere, but after April 2012, this reverses, and these events are more likely to originate in the southern hemisphere, following the observed magnetic asymmetry in the two hemispheres. We also find that as in past solar cycles, CMEs from the western hemisphere are more likely to reach Earth. We find that Cycle 24 lacks in events driving extreme geomagnetic storms compared to past solar cycles.

Table 1 The catalog of Earth-affecting ICME events from 2007 to 2015.

PREDICTING CME EJECTA AND SHEATH FRONT ARRIVAL AT L1 WITH A DATA-CONSTRAINED PHYSICAL MODEL

Phillip [Hess](#) and [Jie Zhang](#)

2015 ApJ 812 144

We present a method for predicting the arrival of a coronal mass ejection (CME) flux rope in situ, as well as the sheath of solar wind plasma accumulated ahead of the driver. For faster CMEs, the front of this sheath will be a shock. The method is based upon geometrical separate measurement of the CME ejecta and sheath. These measurements are used to constrain a drag-based model, improved by including both a height dependence and accurate de-projected velocities. We also constrain the geometry of the model to determine the error introduced as a function of the deviation of the CME nose from the Sun–Earth line. The CME standoff-distance in the heliosphere fit is also calculated, fit, and combined with the ejecta model to determine sheath arrival. Combining these factors allows us to create predictions for both fronts at the L1 point and compare them against observations. We demonstrate an ability to predict the sheath arrival with an average error of under 3.5 hr, with an rms error of about 1.58 hr. For the ejecta the error is less than 1.5 hr, with an rms

error within 0.76 hr. We also discuss the physical implications of our model for CME expansion and density evolution. We show the power of our method with ideal data and demonstrate the practical implications of having a permanent L5 observer with space weather forecasting capabilities, while also discussing the limitations of the method that will have to be addressed in order to create a real-time forecasting tool.

Stereoscopic Study of the Kinematic Evolution of a Coronal Mass Ejection and Its Driven Shock from the Sun to the Earth and the Prediction of Their Arrival Times

Phillip [Hess](#) and Jie Zhang

2014 ApJ 792 49

<http://iopscience.iop.org/article/10.1088/0004-637X/792/1/49/pdf>

We present a detailed study of the complete evolution of a coronal mass ejection (CME). We have tracked the evolution of both the ejecta and its shock, and further fit the evolution of the fronts to a simple but physics-based analytical model. This study focuses on the CME initiated on the Sun on 2012 July 12 and arriving at the Earth on **2012 July 14**. Shock and ejecta fronts were observed by white light images, as well as in situ by the Advanced Composition Explorer satellite. We find that the propagation of the two fronts is not completely dependent upon one another, but can each be modeled in the heliosphere with a drag model that assumes the dominant force of affecting CME evolution to be the aerodynamic drag force of the ambient solar wind. Results indicate that the CME ejecta front undergoes a more rapid deceleration than the shock front within 50 R_{\odot} and therefore the propagation of the two fronts is not completely coupled in the heliosphere. Using the graduated cylindrical shell model, as well as data from time-elongation stack plots and in situ signatures, we show that the drag model can accurately describe the behavior of each front, but is more effective with the ejecta. We also show that without the in situ data, based on measurements out to 80 R_{\odot} combined with the general values for drag model parameters, the arrival of both the shock and ejecta can be predicted within four hours of arrival.

On the Flux-Rope Topology of Ejecta Observed in the Period 1997 – 2006

M. A. [Hidalgo](#), T. Nieves-Chinchilla, J. J. Blanco

Solar Physics, May 2013, Volume 284, Issue 1, pp 151-166

In the following study our aim is to analyse the magnetic flux-rope topology of some events observed in the interplanetary medium related to ejecta. The magnetic field structures associated with interplanetary coronal mass ejections are globally classified in magnetic clouds and ejecta. One of the main questions regarding these phenomena concerns their flux-rope or non-flux-rope magnetic field line configuration. From the experimental measurements the only way to elucidate such a question is analysing the corresponding data by means of a flux-rope physical model. After selecting the ejecta events observed during the period 1997 – 2006, we have analysed them in light of an analytical model with that topology for the magnetic field components, initially developed for magnetic clouds, and with a non-force-free character; then, incorporating the expansion of the magnetic structure during their evolution in the interplanetary medium. Different parameters obtained from the fitting of the model are related to the orientation of the axis of the magnetic flux-rope structure and, additionally, the closest distance approach of the spacecraft to its axis. One of the main conclusions achieved concerns the fact that the axes of most of those structures are close to the Sun–Earth line, which implies that the passage of the spacecraft through the corresponding ejecta event is by its flank. In general, we show a rough procedure for the analysis and classification of ejecta in terms of their magnetic field topology. **Tables.**

A Global Magnetic Topology Model for Magnetic Clouds. III

M. A. [Hidalgo](#)

2014 ApJ 784 67

In two previous papers, we presented a global model for the analysis of magnetic clouds (MCs), where the three components of the magnetic field were fitted to the corresponding Geocentric Solar Ecliptic experimental data, obtaining reliable information, for example, about the orientation of these events in the interplanetary medium. That model, due to its non-force-free character, ($\nabla p \neq 0$), could be extended to determine the plasma behavior. In the present work, we develop that extension, now including the plasma behavior inside the cloud through the analysis of the plasma pressure, and define a fitting procedure where the pressure and the magnetic field components are fitted simultaneously. After deducing the magnetic field topology and the current density components of the model, we calculate the expression of the pressure tensor and, in particular, its trace. In light of the results, we conclude that incorporating the plasma behavior in the analysis of the MCs can give us a better scenario in which to understand the physical mechanisms involved in the evolution of such magnetic structures in the interplanetary medium.

A GLOBAL MAGNETIC TOPOLOGY MODEL FOR MAGNETIC CLOUDS. II.

M. A. [Hidalgo](#)

2013 ApJ 766 125

In the present work, we extensively used our analytical approach to the global magnetic field topology of magnetic clouds (MCs), introduced in a previous paper, in order to show its potential and to study its physical consistency. The model assumes toroidal topology with a non-uniform (variable maximum radius) cross-section along them. Moreover, it has a non-force-free character and also includes the expansion of its cross-section. As is shown, the model allows us, first, to analyze MC magnetic structures—determining their physical parameters—with a variety of magnetic field shapes, and second, to reconstruct their relative orientation in the interplanetary medium from the observations obtained by several spacecraft. Therefore, multipoint spacecraft observations give the opportunity to infer the structure of this large-scale magnetic flux rope structure in the solar wind. For these tasks, we use data from Helios (A and B), STEREO (A and B), and Advanced Composition Explorer. We show that the proposed analytical model can explain quite well the topology of several MCs in the interplanetary medium and is a good starting point for understanding the physical mechanisms under these phenomena.

A GLOBAL MAGNETIC TOPOLOGY MODEL FOR MAGNETIC CLOUDS. I.

M. A. [Hidalgo](#)¹ and T. Nieves-Chinchilla

2012 ApJ 748 109

We present an analytical approach to the global magnetic field topology of magnetic clouds (MCs) that considers them like close magnetic structures with torus geometry and with a non-uniform (variable maximum radius) cross section along them. Following our previous approach to the problem of MCs (Hidalgo 2003, 2011), we establish an intrinsic coordinate system for that topology, and then we analytically solve the Maxwell equations in terms of it. The purpose of the present work is to present this model, which will lead us to understand in a more realistic way the physical mechanisms inside MCs. The model has a non-force-free character and also takes into account the time evolution of the cross sections of the MCs in their movement through the interplanetary medium. In this first paper, we obtain the expressions for the components of the magnetic field and the plasma current density imposing a large mean radius of the torus, and imposing a circular cross section with a variable maximum radius. Eventually, we fit the model to data related to four well-known MCs measurements at 1 AU, (three of them with circular cross sections and without expansion, as it is deduced from the experimental data). We compare the results of this toroidal model with those obtained with our previous cylindrical circular cross section model, also with a non-force-free character.

On the relationship between magnetic clouds and the great geomagnetic storms associated with the period 1995–2006

M.A. [Hidalgo](#) , J.J. Blancoa, F.J. Alvarezb and T. Nieves-Chinchilla

Journal of Atmospheric and Solar-Terrestrial Physics, Volume 73, Issues 11-12, **2011**, Pages 1372-1379

The fact that magnetic clouds are one of the main sources causing geomagnetic storms is a well-established fact. One of the issues is to establish those features of magnetic clouds determinant in the intensity of the Dst corresponding to geomagnetic storms. We examine measurements of geoeffective magnetic clouds during the period 1995–2006 providing geomagnetic storms with Dst indexes lower than -100 nT. These involve 46 geomagnetic storm events. After establishing the different characteristics of the magnetic clouds (plasma velocity, maximum magnetic intensity, etc.) we show some results about the correlations found among them and the storms intensity, finding that maximum magnetic field magnitude is a determinant factor to establish the importance of magnetic clouds in generating geomagnetic storms, having a correlation as good as the electric convective field.

Structured Slow Solar Wind Variability: Streamer-blob Flux Ropes and Torsional Alfvén Waves

A. K. [Higginson](#)¹ and B. J. Lynch

2018 ApJ 859 6

The slow solar wind exhibits strong variability on timescales from minutes to days, likely related to magnetic reconnection processes in the extended solar corona. Higginson et al. presented a numerical magnetohydrodynamic simulation that showed interchange magnetic reconnection is ubiquitous and most likely responsible for releasing much of the slow solar wind, in particular along topological features known as the Separatrix-Web (S-Web). Here, we continue our analysis, focusing on two specific aspects of structured slow solar wind variability. The first type is present in the slow solar wind found near the heliospheric current sheet (HCS), and the second we predict should be present

everywhere S-Web slow solar wind is observed. For the first type, we examine the evolution of three-dimensional magnetic flux ropes formed at the top of the helmet streamer belt by reconnection in the HCS. For the second, we examine the simulated remote and in situ signatures of the large-scale torsional Alfvén wave (TAW), which propagates along an S-Web arc to high latitudes. We describe the similarities and differences between the reconnection-generated flux ropes in the HCS, which resemble the well-known "streamer blob" observations, and the similarly structured TAW. We discuss the implications of our results for the complexity of the HCS and surrounding plasma sheet and the potential for particle acceleration, as well as the interchange reconnection scenarios that may generate TAWs in the solar corona. We discuss predictions from our simulation results for the dynamic slow solar wind in the extended corona and inner heliosphere.

Formation of Heliospheric Arcs of Slow Solar Wind

A. K. [Higginson](#)¹, S. K. Antiochos², C. R. DeVore², P. F. Wyper³, and T. H. Zurbuchen
2017 ApJL 840 L10

A major challenge in solar and heliospheric physics is understanding the origin and nature of the so-called slow solar wind. The Sun's atmosphere is divided into magnetically open regions, known as coronal holes, where the plasma streams out freely and fills the solar system, and closed regions, where the plasma is confined to coronal loops. The boundary between these regions extends outward as the heliospheric current sheet (HCS). Measurements of plasma composition strongly imply that much of the slow wind consists of plasma from the closed corona that escapes onto open field lines, presumably by field-line opening or by interchange reconnection. Both of these processes are expected to release closed-field plasma into the solar wind within and immediately adjacent to the HCS. Mysteriously, however, slow wind with closed-field plasma composition is often observed in situ far from the HCS. We use high-resolution, three-dimensional, magnetohydrodynamic simulations to calculate the dynamics of a coronal hole with a geometry that includes a narrow corridor flanked by closed field and is driven by supergranule-like flows at the coronal-hole boundary. These dynamics produce giant arcs of closed-field plasma that originate at the open-closed boundary in the corona, but extend far from the HCS and span tens of degrees in latitude and longitude at Earth. We conclude that such structures can account for the long-puzzling slow-wind observations.

Influence of Solar Disturbances on Galactic Cosmic Rays in the Solar Wind, Heliosheath, and Local Interstellar Medium: Advanced Composition Explorer, New Horizons, and Voyager Observations

M. E. [Hill](#)¹, R. C. Allen¹, P. Kollmann¹, L. E. Brown¹, R. B. Decker¹, R. L. McNutt Jr.¹, S. M. Krimigis^{1,2}, G. B. Andrews¹, F. Bagenal³, G. Clark¹, +
2020 ApJ 905 69

<https://iopscience.iop.org/article/10.3847/1538-4357/abb408/pdf>

We augment the heliospheric network of galactic cosmic ray (GCR) monitors using 2012–2017 penetrating radiation measurements from the New Horizons (NH) Pluto Energetic Particle Spectrometer Science Investigation (PEPSSI), obtaining intensities of $\gtrsim 75$ MeV particles. The new, predominantly GCR observations provide critical links between the Sun and Voyager 2 and Voyager 1 (V2 and V1), in the heliosheath and local interstellar medium (LISM), respectively. We provide NH, Advanced Composition Explorer (ACE), V2, and V1 GCR observations, using them to track solar cycle variations and short-term Forbush decreases from the Sun to the LISM, and to examine the interaction that results in the surprising, previously reported V1 LISM anisotropy episodes. To investigate these episodes and the hitherto unexplained lagging of associated in situ shock features at V1, propagating disturbances seen at ACE, NH, and V2 were compared to V1. We conclude that the region where LISM magnetic field lines drape around the heliopause is likely critical for communicating solar disturbance signals upstream of the heliosheath to V1. We propose that the anisotropy-causing physical process that suppresses intensities at $\sim 90^\circ$ pitch angles relies on GCRs escaping from a single compression in the draping region, not on GCRs trapped between two compressions. We also show that NH suprathermal and energetic particle data from PEPSSI are consistent with the interpretation that traveling shocks and corotating interaction region (CIR) remnants can be distinguished by the existence or lack of Forbush decreases, respectively, because turbulent magnetic fields at local shocks inhibit GCR transport while older CIR structures reaching the outer heliosphere do not.

Type II solar radio bursts: Modeling and extraction of shock parameters

[Hillan](#), D. S.; Cairns, I. H.; Robinson, P. A.

J. Geophys. Res., Vol. 117, No. A3, A03104, **2012**

<http://dx.doi.org/10.1029/2011JA016754>

This first paper in a two part series summarizes the current theory and the data-driven solar wind model for simulating dynamic spectra of type II radio bursts. It also introduces performance metrics and techniques for extraction of model shock parameters from these dynamic spectra. We use an iterative downhill simplex method which compares two dynamic spectra and quantitatively assesses and improves the agreement using two figures of merit: the first is based on the correlation function and the second is based on a normalized differences over the data set. By maximizing the agreement we are able to extract the input model shock parameters to within 30% or better when using model solar winds of increasing complexity. The effects on the spectra predicted and on the figures of merit from changing the model shock parameters and solar wind model are also investigated. The iterative downhill extraction method is then applied to the type II dynamic spectrum predicted using a realistic model solar wind and a shock model estimated for an observed type II event. The shock parameters are recovered to within 10% of the correct solution.

Drag-based CME modeling with heliospheric images incorporating frontal deformation: ELEvoHI 2.0

<https://doi.org/10.1029/2021SW002836>

The evolution and propagation of coronal mass ejections (CMEs) in interplanetary space is still not well understood. As a consequence, accurate arrival time and arrival speed forecasts are an unsolved problem in space weather research. In this study, we present the ELLipse Evolution model based on HI observations (ELEvoHI) and introduce a deformable front to this model. ELEvoHI relies on heliospheric imagers (HI) observations to obtain the kinematics of a CME. With the newly developed deformable front, the model is able to react to the ambient solar wind conditions during the entire propagation and along the whole front of the CME. To get an estimate of the ambient solar wind conditions, we make use of three different models: Heliospheric Upwind eXtrapolation model (HUX), Heliospheric Upwind eXtrapolation with time dependence model (HUXt), and EUropean Heliospheric FORecasting Information Asset (EUHFORIA). We test the deformable front on a CME first observed in STEREO-A/HI on **February 3, 2010** 14:49 UT. For this case study, the deformable front provides better estimates of the arrival time and arrival speed than the original version of ELEvoHI using an elliptical front. The new implementation enables us to study the parameters influencing the propagation of the CME not only for the apex, but for the entire front. The evolution of the CME front, especially at the flanks, is highly dependent on the ambient solar wind model used. An additional advantage of the new implementation is given by the possibility to provide estimates of the CME mass. **February 6 – 9, 2010**

Why are ELEvoHI CME arrival predictions different if based on STEREO-A or STEREO-B heliospheric imager observations?

<https://arxiv.org/pdf/2102.07478.pdf>

Accurate forecasting of the arrival time and arrival speed of coronal mass ejections (CMEs) is a unsolved problem in space weather research. In this study, a comparison of the predicted arrival times and speeds for each CME based, independently, on the inputs from the two STEREO vantage points is carried out. We perform hindcasts using ELLipse Evolution model based on Heliospheric Imager observations (ELEvoHI) ensemble modelling. An estimate of the ambient solar wind conditions is obtained by the Wang-Sheeley-Arge/Heliospheric Upwind eXtrapolation (WSA/HUX) model combination that serves as input to ELEvoHI. We carefully select 12 CMEs between February 2010 and July 2012 that show clear signatures in both STEREO-A and STEREO-B HI time-elongation maps, that propagate close to the ecliptic plane, and that have corresponding in situ signatures at Earth. We find a mean arrival time difference of 6.5 hrs between predictions from the two different viewpoints, which can reach up to 9.5 hrs for individual CMEs, while the mean arrival speed difference is 63 km s⁻¹. An ambient solar wind with a large speed variance leads to larger differences in the STEREO-A and STEREO-B CME arrival time predictions (cc = 0.92). Additionally, we compare the predicted arrivals, from both spacecraft, to the actual in situ arrivals at Earth and find a mean absolute error of 7.5 ± 9.5 hrs for the arrival time and 87 ± 111 km s⁻¹ for the arrival speed. There is no tendency for one spacecraft to provide more accurate arrival predictions than the other. **2010 May 23-28**

<https://link.springer.com/content/pdf/10.1007%2Fs11207-019-1558-8.pdf>

In order to address the growing need for the more accurate space weather predictions, a new model named EUHFORIA (EUropean Heliospheric FORecasting Information Asset) was recently developed (Pomoell and Poedts, 2018). We present the first results of the solar wind modeling with EUHFORIA and identify possible limitation of its present set up. Using the basic EUHFORIA 1.0.4. model setup with the default input parameters, we modeled background solar wind (no coronal mass ejections) and compared obtained results with ACE, in situ observations. For the need of statistical study we developed a technique of combining daily EUHFORIA runs into continuous time series. Using the combined time series we performed statistical study of the solar wind for years 2008 (low solar activity) and 2012 (high solar activity) with the focus on the in situ speed and density. We find for the low activity phase a better match between model results and observations compared to the considered high activity time interval. The quality of the modeled solar wind parameters is found to be very variable. Therefore, to better understand obtained results we also qualitatively inspected characteristics of coronal holes, sources of the studied fast streams. We discuss how different characteristics of the coronal holes and input parameters to EUHFORIA influence the modeled fast solar wind, and suggest the possibilities for the improvements of the model. 2012 May 7

On the Origin of an F-corona decrease revealed by the Parker Solar Probe

Thiem [Hoang](#), [Alex Lazarian](#), [Hyeseung Lee](#), [Kyungsuk Cho](#), [Pin-Gao Gu](#), [Chi-Hang Ng](#)

ApJ 2020

<https://arxiv.org/pdf/2004.06265.pdf>

The first-year results from the Parker Solar Probe (PSP) reveal a gradual decrease of F-coronal dust from distances of $D=0.166-0.336$ AU (or the inner elongations of $\sim 9.22-18.69 R_{\odot}$) to the Sun, which cannot be explained by the dust sublimation scenario that predicts a dust-free-zone $\leq 4-5 R_{\odot}$. In this paper, we attempt to explain this puzzle using our newly introduced mechanism of dust destruction so-called Radiative Torque Disruption (RATD) mechanism. We demonstrate that RATD rapidly breaks large grains into nanoparticles so that they can be efficiently destroyed by nonthermal sputtering induced by bombardment of energetic protons from slow solar winds. This joint effect extends the dust-free-zone established by thermal sublimation to $R_{dfz} \sim 8 R_{\odot}$, which is called a new dust-free-zone. Beyond this new dust-free-zone, we find that the dust mass decreases gradually from $R \sim 42 R_{\odot}$ toward the Sun due to partial removal of nanodust by nonthermal sputtering. This feature can successfully reproduce the gradual decrease of the F-corona between $19-9 R_{\odot}$ observed by the PSP. Finally, the RATD mechanism can efficiently produce nanoparticles usually observed in the inner solar system.

Application of the Electromotive Force as a Shock Front Indicator in the Inner Heliosphere

Bernhard [Hofer](#)^{1,2} and Philippe-A. Bourdin

2019 ApJ 878 30

[sci-hub.se/10.3847/1538-4357/ab1e48](https://arxiv.org/abs/1908.04488)

The electromotive force (EMF) describes how the evolution and generation of a large-scale magnetic field is influenced by small-scale turbulence. Recent studies of in situ measurements have shown a significant peak in the EMF while a coronal mass ejection (CME) shock front passes by the spacecraft. The goal of this study is to use the EMF as an indicator for the arrival of CME shock fronts. With Helios spacecraft measurements we carry out a statistical study on the EMF during CMEs in the inner heliosphere. We develop an automated shock front detection algorithm using the EMF as the main detection criterion and compare the results to an existing CME database. The properties of the EMF during the recorded events are discussed as a function of the heliocentric distance. Our algorithm reproduces most of the events from Kilpua et al. and finds many additional CME-like events, which proves that the EMF is a good shock front indicator. The largest peaks in the EMF are found from 0 to 50 minutes after the initial shock. We find a power law of -1.54 and -2.18 for two different formulations of the EMF with the heliocentric distance.

How the area of solar coronal holes affects the properties of high-speed solar wind streams near Earth: An analytical model

A&A 659, A190 (2022)

<https://www.aanda.org/articles/aa/pdf/2022/03/aa41919-21.pdf>

<https://doi.org/10.1051/0004-6361/202141919>

Since the 1970s it has been empirically known that the area of solar coronal holes affects the properties of high-speed solar wind streams (HSSs) at Earth. We derive a simple analytical model for the propagation of HSSs from the Sun to Earth and thereby show how the area of coronal holes and the size of their boundary regions affect the HSS velocity, temperature, and density near Earth. We assume that velocity, temperature, and density profiles form across the HSS cross section close to the Sun and that these spatial profiles translate into corresponding temporal profiles in a given radial direction due to the solar rotation. These temporal distributions drive the stream interface to the preceding slow solar wind plasma and disperse with distance from the Sun. The HSS properties at 1 AU are then given by all HSS plasma parcels launched from the Sun that did not run into the stream interface at Earth distance. We show that the velocity plateau region of HSSs as seen at 1 AU, if apparent, originates from the center region of the HSS close to the Sun, whereas the velocity tail at 1 AU originates from the trailing boundary region. Small HSSs can be described to entirely consist of boundary region plasma, which intrinsically results in smaller peak velocities. The peak velocity of HSSs at Earth further depends on the longitudinal width of the HSS close to the Sun. The shorter the longitudinal width of an HSS close to the Sun, the more of its “fastest” HSS plasma parcels from the HSS core and trailing boundary region have impinged upon the stream interface with the preceding slow solar wind, and the smaller is the peak velocity of the HSS at Earth. As the longitudinal width is statistically correlated to the area of coronal holes, this also explains the well-known empirical relationship between coronal hole areas and HSS peak velocities. Further, the temperature and density of HSS plasma parcels at Earth depend on their radial expansion from the Sun to Earth. The radial expansion is determined by the velocity gradient across the HSS boundary region close to the Sun and gives the velocity-temperature and density-temperature relationships at Earth their specific shape. When considering a large number of HSSs, the assumed correlation between the HSS velocities and temperatures close to the Sun degrades only slightly up to 1 AU, but the correlation between the velocities and densities is strongly disrupted up to 1 AU due to the radial expansion. Finally, we show how the number of particles of the piled-up slow solar wind in the stream interaction region depends on the velocities and densities of the HSS and preceding slow solar wind plasma.

On the Dependency between the Peak Velocity of High-speed Solar Wind Streams near Earth and the Area of Their Solar Source Coronal Holes

The relationship between the peak velocities of high-speed solar wind streams near Earth and the areas of their solar source regions, i.e., coronal holes, has been known since the 1970s, but it is still physically not well understood. We perform 3D magnetohydrodynamic (MHD) simulations using the European Heliospheric Forecasting Information Asset (EUHFORIA) code to show that this empirical relationship forms during the propagation phase of high-speed streams from the Sun to Earth. For this purpose, we neglect the acceleration phase of high-speed streams, and project the areas of coronal holes to a sphere at 0.1 au. We then vary only the areas and latitudes of the coronal holes. The velocity, temperature, and density in the cross section of the corresponding high-speed streams at 0.1 au are set to constant, homogeneous values. Finally, we propagate the associated high-speed streams through the inner heliosphere using the EUHFORIA code. The simulated high-speed stream peak velocities at Earth reveal a linear dependence on the area of their source coronal holes. The slopes of the relationship decrease with increasing latitudes of the coronal holes, and the peak velocities saturate at a value of about 730 km s⁻¹, similar to the observations. These findings imply that the empirical relationship between the coronal hole areas and high-speed stream peak velocities does not describe the acceleration phase of high-speed streams, but is a result of the high-speed stream propagation from the Sun to Earth.

The Dependence of the Peak Velocity of High-Speed Solar Wind Streams as Measured in the Ecliptic by ACE and the STEREO satellites on the Area and Co-latitude of Their Solar Source Coronal Holes

Stefan J. [Hofmeister](#), Astrid Veronig, Manuela Temmer, Susanne Vennerstrom, Bernd Heber and Bojan Vršnak

JGR [Volume123, Issue3](#) March 2018 Pages 1738-1753

We study the properties of **115 coronal holes** in the time range from August 2010 to March 2017, the peak velocities of the corresponding high-speed streams as measured in the ecliptic at 1 AU, and the corresponding changes of the Kp index as marker of their geoeffectiveness. We find that the peak velocities of high-speed streams depend strongly on both the areas and the co-latitudes of their solar source coronal holes with regard to the heliospheric latitude of the satellites. Therefore, the co-latitude of their source coronal hole is an important parameter for the prediction of the high-speed stream properties near the Earth. We derive the largest solar wind peak velocities normalized to the coronal hole areas for coronal holes located near the solar equator and that they linearly decrease with increasing latitudes of the coronal holes. For coronal holes located at latitudes $\gtrsim 60^\circ$, they turn statistically to zero, indicating that the associated high-speed streams have a high chance to miss the Earth. Similarly, the Kp index per coronal hole area is highest for the coronal holes located near the solar equator and strongly decreases with increasing latitudes of the coronal holes. We interpret these results as an effect of the three-dimensional propagation of high-speed streams in the heliosphere; that is, high-speed streams arising from coronal holes near the solar equator propagate in direction toward and directly hit the Earth, whereas solar wind streams arising from coronal holes at higher solar latitudes only graze or even miss the Earth.

Toward more reliable long-term indices of geomagnetic activity: Correcting a new inhomogeneity problem in early geomagnetic data

L. [Holappa](#) and K. Mursula

JGR Volume 120, Issue 10 October 2015 Pages 8288–8297

For the time before the space era, our knowledge of the centennial evolution of solar wind (SW) and interplanetary magnetic field (IMF) is based on proxies derived from geomagnetic indices. The reliability of these proxies is dependent on the homogeneity of magnetic field data. In this paper, we study the interhourly (IHV) and interdiurnal (IDV1d) variability indices calculated from the data of two British observatories, Eskdalemuir and Lerwick, and compare them to the corresponding indices of the German Niemeck observatory. We find an excess of about $14 \pm 4\%$ ($5.8 \pm 2\%$) and $27 \pm 10\%$ ($15 \pm 6\%$) in the IHV (IDV1d) in the indices of Eskdalemuir and Lerwick in 1935–1969. The timing of this excess accurately coincides with instrument changes made in these observatories, strongly supporting the interpretation that the excess is indeed caused by instrument related inhomogeneities in the data of Eskdalemuir and Lerwick. We show that the detected excess notably modifies the long-term trend of geomagnetic activity and the centennial evolution of IMF strength and solar wind speed estimated using these indices. We note that the detected inhomogeneity problem may not be limited to the data of the two studied observatories but may be quite common to long series of geomagnetic measurements. These results question the reliability of the present measures of the centennial change in solar wind speed and IMF.

A new method to estimate annual solar wind parameters and contributions of different solar wind structures to geomagnetic activity†

L. [Holappa*](#), K. Mursula and T. Asikainen

JGR, Volume 119, Issue 12, pages 9407–9418, December 2014

<http://onlinelibrary.wiley.com/doi/10.1002/2014JA020599/pdf>

<http://arxiv.org/pdf/1501.03716v1.pdf>

In this paper, we study two sets of local geomagnetic indices from 26 stations using the principal component (PC) and the independent component (IC) analysis methods. We demonstrate that the annually averaged indices can be accurately represented as linear combinations of two first components with weights systematically depending on latitude. We show that the annual contributions of coronal mass ejections (CMEs) and high speed streams (HSSs) to geomagnetic activity are highly correlated with the first and second IC. The first and second ICs are also found to be very highly correlated with the strength of the interplanetary magnetic field (IMF) and the solar wind speed, respectively, because solar wind

speed is the most important parameter driving geomagnetic activity during HSSs while IMF strength dominates during CMEs. These results help in better understanding the long-term driving of geomagnetic activity and in gaining information about the long-term evolution of solar wind parameters and the different solar wind structures.

Signatures of coronal hole substructure in the solar wind: combined Solar Orbiter remote sensing and in situ measurements

A&A 2021

<https://arxiv.org/pdf/2104.14960.pdf>

Context. The Sun's complex corona is the source of the solar wind and interplanetary magnetic field. While the large scale morphology is well understood, the impact of variations in coronal properties on the scale of a few degrees on properties of the interplanetary medium is not known. Solar Orbiter, carrying both remote sensing and in situ instruments into the inner solar system, is intended to make these connections better than ever before. Aims. We combine remote sensing and in situ measurements from Solar Orbiter's first perihelion at 0.5 AU to study the fine scale structure of the solar wind from the equatorward edge of a polar coronal hole with the aim of identifying characteristics of the corona which can explain the in situ variations. Methods. We use in situ measurements of the magnetic field, density and solar wind speed to identify structures on scales of hours at the spacecraft. Using Potential Field Source Surface mapping we estimate the source locations of the measured solar wind as a function of time and use EUVI images to characterise these solar sources. Results. We identify small scale stream interactions in the solar wind with compressed magnetic field and density along with speed variations which are associated with corrugations in the edge of the coronal hole on scales of several degrees, demonstrating that fine scale coronal structure can directly influence solar wind properties and drive variations within individual streams. Conclusions. This early analysis already demonstrates the power of Solar Orbiter's combined remote sensing and in situ payload and shows that with future, closer perihelia it will be possible dramatically to improve our knowledge of the coronal sources of fine scale solar wind structure, which is important both for understanding the phenomena driving the solar wind and predicting its impacts at the Earth and elsewhere. **19-24 June 2020**

Short, large-amplitude speed enhancements in the near-Sun fast solar wind

T S [Horbury](#) [L Matteini](#) [D Stansby](#)

MNRoyal Astronomical Society, Volume 478, Issue 2, 1 August 2018, Pages 1980–1986

<https://doi.org/10.1093/mnras/sty953>

sci-hub.tw/10.1093/mnras/sty953

We report the presence of intermittent, short discrete enhancements in plasma speed in the near-Sun high-speed solar wind. Lasting tens of seconds to minutes in spacecraft measurements at 0.3 au, speeds inside these enhancements can reach 1000 km s⁻¹, corresponding to a kinetic energy up to twice that of the bulk high-speed solar wind. These events, which occur around 5 per cent of the time, are Alfvénic in nature with large magnetic field deflections and are the same temperature as the surrounding plasma, in contrast to the bulk fast wind which has a well-established positive speed–temperature correlation. The origin of these speed enhancements is unclear but they may be signatures of discrete jets associated with transient events in the chromosphere or corona. Such large short velocity changes represent a measurement and analysis challenge for the upcoming Parker Solar Probe and Solar Orbiter missions.

Analysis of Voyager 1 and Voyager 2 in situ CME observations

Skralan [Hosteaux](#), [Luciano Rodriguez](#), [Stefaan Poedts](#)

Advances in Space Research 2022

<https://arxiv.org/pdf/2207.00471.pdf>

This paper studies ICMEs detected by both Voyager spacecraft during propagation from 1 to 10 AU, with observations from 1977 to 1980. ICMEs are detected by using several signatures in the in-situ data, the primary one being the low measured to expected proton temperature ratio. We found 21 events common to both spacecraft and study their internal structure in terms of plasma and magnetic field properties. We find that ICMEs are expanding as they propagate outwards, with decreasing density and magnetic field intensities, in agreement with previous studies. We first carry out a statistical study and then a detailed analysis of each case. Furthermore, we analyse one case in which a shock can be clearly detected by both spacecraft. The methods described here can be interesting for other studies combining data sets from heliospheric missions. Furthermore, they highlight the importance of exploiting useful data from past missions.

Effect of the solar wind density on the evolution of normal and inverse coronal mass ejections

S. Hosteaux, E. Chané, S. Poedts

A&A 632, A89 2019

<https://arxiv.org/pdf/1910.04680.pdf>

We investigate the evolution of both normal and inverse CMEs ejected at different initial velocities, and observe the effect of the background wind density and their magnetic polarity on their evolution up to 1 AU. We performed 2.5D simulations by solving the magnetohydrodynamic equations on a radially stretched grid, employing a block-based adaptive mesh refinement scheme based on a density threshold to achieve high resolution following the evolution of the magnetic clouds and the leading bow shocks. All the simulations discussed in the present paper were performed using the same initial grid and numerical methods. The polarity of the internal magnetic field of the CME has a substantial effect on its propagation velocity and on its deformation and erosion during its evolution towards Earth. We quantified the effects of the polarity of the internal magnetic field of the CMEs and of the density of the background solar wind on the arrival times of the shock front and the magnetic cloud. We determined the positions and propagation velocities of the magnetic clouds and thus also the stand-off distance of the leading shock fronts (i.e. the thickness of the magnetic sheath region) and the deformation and erosion of the magnetic clouds during their evolution from the Sun to the Earth. Inverse CMEs were found to be faster than normal CMEs ejected in the same initial conditions, but with smaller stand-off distances. They also have a higher magnetic cloud length, opening angle, and mass. Synthetic satellite time series showed that the shock magnitude is not affected by the polarity of the CME. However, the density peak of the magnetic cloud is dependent on the polarity and, in case of inverse CMEs, also on the background wind density. The magnitude of the z-component of the magnetic field was not influenced by either the polarity or the wind density.

Connecting Solar Wind Velocity Spikes Measured by Solar Orbiter and Coronal Brightenings Observed by SDO

The Parker Solar Probe's discovery that magnetic switchbacks and velocity spikes in the young solar wind are abundant has prompted intensive research into their origin(s) and formation mechanism(s) in the solar atmosphere. Recent studies, based on in situ measurements and numerical simulations, argue that velocity spikes are produced through interchange magnetic reconnection. Our work studies the relationship between interplanetary velocity spikes and coronal brightenings induced by changes in the photospheric magnetic field. Our analysis focuses on the characteristic periodicities of velocity spikes detected by the Proton Alpha Sensor on the Solar Orbiter during its fifth perihelion pass. Throughout the time period analyzed here, we estimate their origin along the boundary of a coronal hole. Around the boundary region, we identify periodic variations in coronal brightening activity observed by the Atmospheric Imaging Assembly onboard the Solar Dynamics Observatory. The spectral characteristics of the time series of in situ velocity spikes, remote coronal brightenings, and remote photospheric magnetic flux exhibit correspondence in their periodicities. Therefore, we suggest that the localized small-scale magnetic flux within coronal holes fuels a magnetic reconnection process that can be observed as slight brightness augmentations and outward fluctuations or jets. These dynamic elements may act as mediators, bonding magnetic reconnection with the genesis of velocity spikes and magnetic switchbacks. 2022-10-22-23

Nature, Generation, and Dissipation of Alfvénic Kinks/Switchbacks Observed by Parker Solar Probe and WIND

Chuanpeng Hou¹, Xingyu Zhu¹, Rui Zhuo¹, Jiansen He^{3,1}, Daniel Verscharen², and Die Duan¹
2023 ApJ 950 157

<https://iopscience.iop.org/article/10.3847/1538-4357/accf94/pdf>

The discovery of very prominent magnetic kinks/switchbacks in the solar wind within 0.3 au has become a scientific highlight of the Parker Solar Probe (PSP) mission. This discovery points at the promising impact of small-scale solar activity on the inner heliosphere. To address the nature, generation, and dissipation of these kinks, we perform a statistical analysis of the plasma and boundary properties of the kinks using PSP multi-encounter observations and WIND measurements at 1 au. The kinks show strong Alfvénicity and velocity fluctuations of the order of the local Alfvén speed. These findings suggest that the nature of the kinks is consistent with large-amplitude Alfvén pulses, and the steepening of these Alfvén pulses is likely the formation mechanism of these kinks. Based on the angle between the normal direction of the kinks' boundaries and the background magnetic field vector, PSP kinks and WIND kinks can be

divided into two groups: quasi-parallel and quasi-perpendicular kinks. We speculate that quasi-parallel kinks form through the coupling of Alfvén and fast waves as launched from coronal interchange magnetic reconnection. In contrast, quasi-perpendicular kinks may come from the steepening of Alfvén waves launched from both coronal interchange magnetic reconnection and from the more inhomogeneous lower solar atmosphere. We find that the kink velocity perturbation gradually decreases during outward propagation and is much lower than expected from WKB theory, suggesting a progressive dissipation of the kinks. Comparing PSP kinks and WIND kinks, we conjecture that the kinks dissipate through merging with the turbulent energy cascade within 0.25 au.

Overview of the remote sensing observations from PSP solar encounter 10 with perihelion at 13.3 R_{sun}

[Russell A. Howard](#), [Guillermo Stenborg](#), [Angelos Vourlidis](#), [Brendan M. Gallagher](#), [Mark G. Linton](#), [Phillip Hess](#), [Nathan B. Rich](#), [Paulett C. Liewer](#)

ApJ **936** 43 **2022**

<https://arxiv.org/pdf/2207.12175.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac7ff5/pdf>

The closest perihelion pass of Parker Solar Probe (PSP), so far, occurred between **16 and 26 of November 2021** and reached ~13.29 R_{sun} from Sun center. This pass resulted in very unique observations of the solar corona by the Wide-field Instrument for Solar PRobe (WISPR). WISPR observed at least ten CMEs, some of which were so close that the structures appear distorted. All of the CMEs appeared to have a magnetic flux rope (MFR) structure and most were oriented such that the view was along the axis orientation, revealing very complex interiors. Two CMEs had a small MFR develop in the interior, with a bright circular boundary surrounding a very dark interior. Trailing the larger CMEs were substantial outflows of small blobs and flux-rope like structures within striated ribbons, lasting for many hours. When the heliophysics plasma sheet (HPS) was inclined, as it was during the days around perihelion on November 21, 2021, the outflow was over a very wide latitude range. One CME was overtaken by a faster one, with a resultant compression of the rear of the leading CME and an unusual expansion in the trailing CME. The small Thomson Surface creates brightness variations of structures as they pass through the field of view. In addition to this dynamic activity, a brightness band from excess dust along the orbit of asteroid/comet 3200 Phaethon is also seen for several days. **16, 19, 20-21, 22-23, 24-26 Nov 2021**

Measuring an Eruptive Prominence at Large Distances from the Sun. II. Approaching 1 AU

T. A. [Howard](#)

2015 ApJ 806 176

The physical properties of eruptive prominences are unknown at large distances from the Sun. They are rarely, if ever, measured by in situ spacecraft and until recently our ability to measure them beyond the fields of view of solar imagers has been severely limited. The data quality of heliospheric imaging has reached a point where some quantitative measurements of prominences are now possible. I present the first such measurements of a bright prominence continually out to distances of around 1 AU from the Sun. This work follows on from the preparatory work presented in an accompanying paper, which showed that the brightness of a prominence can be safely assumed to arise entirely from Thomson scattering in the STEREO/HI fields of view. Measurements of distance, speed, and mass are provided along with those from its accompanying coronal mass ejection (CME) to demonstrate their geometric, kinematic, and mass relationships. I find that the prominence travels with a slower speed than that of the CME, but its location relative to the CME structure does not conform to the expected location for basic geometric expansion. Further, the mass of the prominence was found to decrease by around an order of magnitude while that of the CME increased by an order of magnitude across the same distance.

Measuring an Eruptive Prominence at Large Distances from the Sun. I. Ionization and Early Evolution

T. A. [Howard](#)

2015 ApJ 806 175

Measurements of H α emission within an eruptive solar prominence are presented, using white light polarization properties as a proxy for the presence of H α in the STEREO COR1 and COR2 coronagraphs. The transition from H α emission to Thomson scattering radiance serves as an indicator of the ionization of the prominence, and I discuss the physical implications regarding the behavior of the neutrals and ions, and also for the measurement of coronal mass ejection properties using the Thomson scattering assumption. I find that the prominence has a high concentration of neutrals at around two solar radii that gradually exhibit ionization characteristics as it moves away from the Sun. The

prominence reaches complete ionization, or at least a state where the Thomson-scattered brightness dominates, by the time it reaches around seven solar radii. This is consistent with predictions inferred from direct H α measurements made from earlier studies in the 1980s and with the predicted ionization rate of neutral hydrogen near solar maximum. These results pave the way for an accompanying paper that reports on measurements of the prominence at large distances from the Sun using the assumptions verified here.

The Solar Mass Ejection Imager and Its Heliospheric Imaging Legacy

Review

Space Science Reviews, **2013**, 180: Issue 1-4, 1–38; **File**

The Solar Mass Ejection Imager (SMEI) was the first of a new class of heliospheric and astronomical white-light imager. A heliospheric imager operates in a fashion similar to coronagraphs, in that it observes solar photospheric white light that has been Thomson scattered by free electrons in the solar wind plasma. Compared with traditional coronagraphs, this imager differs in that it observes at much larger angles from the Sun. This in turn requires a much higher sensitivity and wider dynamic range for the measured intensity. SMEI was launched on the Coriolis spacecraft in January 2003 and was deactivated in September 2011, thus operating almost continuously for nearly nine years. Its primary objective was the observation of interplanetary transients, typically coronal mass ejections (CMEs), and tracking them continuously throughout the inner heliosphere. Towards this goal it was immediately effective, observing and tracking several CMEs in the first month of mission operations, with some 400 detections to follow. Along with this primary science objective, SMEI also contributed to many and varied scientific fields, including studies of corotating interaction regions (CIRs), the high-altitude aurora, zodiacal light, Gegenschein, comet tail disconnections and motions, and variable stars. It was also able to detect and track Earth-orbiting satellites and space debris. Along with its scientific advancements, SMEI also demonstrated a significantly improved accuracy of space weather prediction, thereby establishing the feasibility and usefulness of operational heliospheric imagers. In this paper we review the scientific and operational achievements of SMEI, discuss lessons learned, and present our view of potential next steps in future heliospheric imaging.

WHITE-LIGHT OBSERVATIONS OF SOLAR WIND TRANSIENTS AND COMPARISON WITH AUXILIARY DATA SETS

T. A. **Howard**¹, C. E. DeForest¹, and A. A. Reinard

2012 ApJ 754 102

This paper presents results utilizing a new data processing pipeline for STEREO/SECCHI. The pipeline is used to identify and track 24 large- and small-scale solar wind transients from the Sun out to 1 AU. This comparison was performed during a few weeks around the minimum at the end of Solar Cycle 23 and the start of Cycle 24 (**2008 December to 2009 January**). We use coronagraph data to identify features near the Sun, track them through HI-2A, and identify their signatures with in situ data at the Earth and STEREO-B. We provide measurements and preliminary analysis of the in situ signatures of these features near 1 AU. Along with the demonstration of the utility of heliospheric imagers for tracking even small-scale structures, we identify and discuss an important limitation in using geometric triangulation for determining three-dimensional properties.

INNER HELIOSPHERIC FLUX ROPE EVOLUTION VIA IMAGING OF CORONAL MASS EJECTIONS

T. A. **Howard** and C. E. DeForest

2012 ApJ 746 64, **File**

Understanding the evolution of flux ropes in coronal mass ejections (CMEs) is of importance both to the scientific and technological communities. Scientifically their presence is critical to models describing CME launch and they likely play a role in CME evolution. Technologically they are the major contributor to severe geomagnetic storms. Using a new processing technique on the STEREO/SECCHI heliospheric imaging data, we have tracked a magnetic flux rope observed by the Wind spacecraft in **December 2008** to its origins observed by coronagraphs. We thereby establish that the cavity in the classic three-part coronagraph CME is the feature that becomes the magnetic cloud. This implies that the bright material ahead of the cavity is piled-up coronal or solar wind material. We track the evolution of the cavity en-route and find that its structure transforms from concave inward (curving away from the Sun) to concave outward

(toward the Sun) around 0.065 AU from the Sun. The pileup was tracked and its leading edge remained concave inward throughout its journey. Two other CMEs in **January 2009** are also inspected and a similar cavity is observed in each, suggesting that they too each contained a flux rope. The results presented here are the first direct observation, through continuous tracking, associating a particular flux rope observed in situ with the same flux rope before ejection from the corona. We speculate that detailed heliospheric imagery of CMEs may lead to a means by which flux ropes can be identified remotely in the heliosphere.

Three-dimensional reconstruction of coronal mass ejections using heliospheric imager data

Timothy A. [Howard](#)

Journal of Atmospheric and Solar-Terrestrial Physics, Volume 73, Issue 10, **2011**, Pages 1242-1253, **File**
Innovative techniques have been developed to extract three-dimensional (3-D) information on coronal mass ejections. Some techniques have only been available since the launch of the STEREO spacecraft, where geometry can be applied to white light observations from three different viewpoints. Another technique not necessarily requiring the multiple-viewpoint capabilities of STEREO involves heliospheric imaging. With heliospheric imagers, we may take advantage of the breakdown in geometrical and Thomson scattering linearity and, with careful analysis of the data, extract 3-D parameters from CME images. In this review we discuss the various techniques that are being developed and used to reconstruct the 3-D structure and kinematic evolution of CMEs, with a particular emphasis on the work of the author and colleagues. Following a brief review of multiple-viewpoint coronagraph analysis, we focus on techniques involving heliospheric images, which can be used to achieve the reconstruction with a good degree of accuracy without the need for auxiliary data.

Application of a new phenomenological coronal mass ejection model to space weather forecasting,

[Howard](#), T. A., and S. J. Tappin

Space Weather, 8, S07004, doi:10.1029/2009SW000531 (**2010**), **File**.

Recent work by the authors has produced a new phenomenological model for coronal mass ejections (CMEs). This model, called the Tappin-Howard (TH) Model, takes advantage of the breakdown of geometrical linearity when CMEs are observed by white-light imagers at large distances from the Sun. The model extracts 3-D structure and kinematic information on the CME using heliospheric image data. This can estimate arrival times of the CME at 1 AU and impact likelihood with the Earth. Hence the model can be used for space weather forecasting. We present a preliminary evaluation of this potential with three mock trial forecasts performed using the TH Model. These are already-studied events from 2003, 2004 and 2007 but we performed the trials assuming that they were observed for the first time. The earliest prediction was made 17 hours before impact and predicted arrival times reached differences within one hour for at least one forecast for all three events. The most accurate predicted arrival time was 15 min from the actual, and all three events reach accuracies of the order of 30 min. Arrival speeds were predicted to be very similar to the bulk plasma speed within the CME near 1 AU for each event, with the largest difference around 300 km/s and the least 40 km/s. The model showed great potential and we aspire to fully validate it for integration with existing tools for space weather forecasting.

Interplanetary Coronal Mass Ejections Observed in the Heliosphere:

3. Physical Implications

Timothy A. [Howard](#) · S. James Tappin

Space Sci Rev (**2009**) 147: 89–110; **File**

We conclude the heliospheric image series with this third and final instalment, where we consider the physical implications of our reconstruction of interplanetary coronal mass ejections from heliospheric imagers. In Paper 1 a review of the theoretical framework for the appearance of ICMEs in the heliosphere was presented and in Paper 2 a model was developed that extracted the three-dimensional structure and kinematics of interplanetary coronal mass ejections directly from SMEI images. Here we extend the model to include STEREO Heliospheric Imager data and reproduce the three-dimensional structure and kinematic evolution of a single Earth-directed interplanetary coronal mass ejection that was

observed in November 2007. These measurements were made with each spacecraft independently using leading edge measurements obtained from each instrument. We found that when data from the three instruments was treated as a single collective, we were able to reproduce an estimate of the ICME structure and trajectory. There were some disparities between the modelled ICME and the *in situ* data, and we interpret this as a combination of a slightly more than spherically curved ICME structure and a corotating interaction region brought about by the creation of a coronal hole from the CME eruption. This is the first time evidence for such a structure has been presented and we believe that it is likely that many ICMEs are of this nature.

Part 2: see Tappin (2009)

Interplanetary Coronal Mass Ejections Observed in the Heliosphere:

1. Review of Theory

Timothy A. Howard · S. James Tappin

Space Sci Rev (2009) 147: 31–54; **File**

With the recent advancements in interplanetary coronal mass ejection (ICME) imaging it is necessary to understand how heliospheric images may be interpreted, particularly at large elongation angles. Of crucial importance is how the current methods used for coronal mass ejection measurement in coronagraph images must be changed to account for the large elongations involved in the heliosphere. In this review of theory we build up a picture of ICME appearance and evolution at large elongations in terms of how it would appear to an observer near 1 AU from the Sun. We begin by revisiting the basics of Thomson scattering describing how ICMEs are detected, in this we attempt to clarify a number of common misconceptions. We then build up from a single electron to an integrated line of sight, consider the ICME as a collection of lines of sight and describe how a map of ICME appearance may be developed based on its appearance relative to each line of sight. Finally, we discuss how the topology of the ICME affects its observed geometry and kinematic properties, particularly at large elongations. This review is the first of a three-part series of papers, where a review of theory is presented here and a model is developed and used in subsequent papers.

Interplanetary coronal mass ejections that are undetected by solar coronagraphs,

Howard, T. A., and G. M. Simnett

J. Geophys. Res., 113, A08102, 2008

<http://dx.doi.org/10.1029/2007JA012920>

From February 2003 to September 2005 the Solar Mass Ejection Imager on the Coriolis spacecraft detected 207 interplanetary coronal mass ejections (ICME) in the inner heliosphere. We have examined the data from the Large Angle Spectroscopic Coronagraph (LASCO) on the SOHO spacecraft for evidence of coronal transient activity that might have been the solar progenitor of the Solar Mass Ejection Imager (SMEI) events, taking into account the projected speed of the SMEI event and its position angle in the plane of the sky. We found a significant number of SMEI events where there is either only a weak or unlikely coronal mass ejection (CME) detected by LASCO or no event at all. A discussion of the effects of projection across large distances on the ICME measurements is made, along with a new technique called the Cube-Fit procedure that was designed to model the ICME trajectory more accurately than simple linear fits to elongation-time plots. Of the 207 SMEI events, 189 occurred during periods of full LASCO data coverage. Of these, 32 or 17% were found to have a weak or unlikely LASCO counterpart, and 14 or 7% had no apparent LASCO transient association. Using solar X-ray, EUV and $H\alpha$ data we investigated three main physical possibilities for ICME occurrence with no LASCO counterpart: (1) Corotating interaction regions (CIRs), (2) erupting magnetic structures (EMS), and (3) flare blast waves. We find that only one event may possibly be a CIR and that flare blast waves can be ruled out. *The most likely phenomenon is investigated and discussed, that of EMS. Here, the transient erupts in the same manner as a typical CME, except that they do not have sufficient mass to be detected by LASCO. As the structure moves outward, it accumulates and concentrates solar wind material until it is bright enough to be detected by SMEI.*

ON THE EVOLUTION OF CORONAL MASS EJECTIONS IN THE INTERPLANETARY MEDIUM

T. A. **Howard**, C. D. Fry, J. C. Johnston, and D. F. Webb

The Astrophysical Journal, 667:610-625, **2007**

<https://iopscience.iop.org/article/10.1086/519758/pdf>

Two coronal mass ejections (CMEs) are presented which were tracked through the LASCO field of view (FOV) within 30 R_☉ and later as interplanetary CMEs (ICMEs) through the SMEI FOV from 80 to 150 R_☉. They were also associated with erupting filaments observed by EIT, providing information on trajectory of propagation. This allowed three-dimensional reconstructions of CME/ICME geometry, along with corrected (not sky plane projected) measurements

of distance-time (DT) plots for each event to 0.5 AU. An investigation of morphology was conducted. The results suggest that fine structures of the CMEs are eroded by the solar wind, and curvature becomes more sharply convex outward, suggesting that ICME footpoints remain fixed to the Sun even at 0.5 AU. We also present two models describing the evolution of CMEs/ICMEs at large distances from the Sun (far from the launch mechanism and effects of gravity and solar pressure) and consider two drag models: aerodynamic drag and snowplow. There was little difference between these, and their DT profiles matched well with the SMEI data for event 1. Event 2 showed a net acceleration between the LASCO and SMEI FOVs and we could match the data for this event well by introducing a driving Lorentz force. ICME mass almost doubled as a result of swept-up solar wind material from the snowplow model. Finally, we compared the geometry and kinematics of the ICME with that produced by the HAFv2 model and found that the model reasonably matched the geometry, but overestimated the ICME speed.

Tracking halo coronal mass ejections from 0 -- 1 AU and space weather forecasting using the Solar Mass Ejection Imager (SMEI),

Howard, T. A., D. F. Webb, S. J. Tappin, D. R. Mizuno, and J. C. Johnston

J. Geophys. Res., 111, A04105, doi:10.1029/2005JA011349, (**2006**).

Howard et al. [2006] studied 20 ICMEs observed by SMEI over its first 19 months that were associated with LASCO halo CMEs and shocks observed by ACE at the L1 point. Their study focused on computing distance-time profiles using both the LASCO CME and SMEI ICME data to determine ICME speed, and then to predict its time of arrival at Earth. They used the shock arrival time (AT) at L1 as the indicator for ICME arrival, thus ignoring the shock standoff distance (time) from the ejecta. They then compared the predicted ICME AT with the actual shock ATs at ACE at L1.

Statistical survey of earthbound interplanetary shocks, associated coronal mass ejections and their space weather consequences

Howard, T. A.; Tappin, S. J.

Astronomy and Astrophysics, Volume 440, Issue 1, September II **2005**, pp.373-383; **File**

A comprehensive statistical analysis of events relevant to space weather over the 80 month period from January 1998 to August 2004 is presented. A database has been constructed using data from instruments from the SOHO, ACE, WIND and GOES spacecraft, as well as ground magnetometer data. Parameters investigated include times and epochs of halo and partial halo coronal mass ejections (HCMEs) along with details of the interplanetary shock at L1 (0.99 AU), namely the changes in the interplanetary magnetic field and solar wind density, and shock speed. Transit time to the Earth and average transient speed have also been determined, along with the projected speed and angular width of the HCME at the Sun. An estimate is made of the acceleration of the transients on their passage from the Sun to the Earth, and associated solar flare data are considered. Finally, the geoeffectiveness of the events are analysed using A_p, Dst and sudden commencement data. We found that just over a quarter of the 938 HCMEs observed by LASCO were associated with a forward shock near L1, suggesting that around half of the Earthbound HCMEs are either deflected away from the Sun-Earth line or do not form a shock. Around half of the shocks went on to cause a geomagnetic storm, consistent with a southward B_z IMF occurring 50% of the time. There was a general tendency for HCME and shock speeds to be more varied (with more events at higher speeds) around solar maximum, and most events decelerated in transit to the Earth, implying a speed "equalisation" between the HCME shock and surrounding solar wind, although an assumption of a constant acceleration appears to be invalid. Only around 40% of the shock/storms were associated with an X or M class flare, and there appears to be no relationship between flare intensity and any physical parameter close to the Earth, except in extreme cases. There was a tendency for HCME speed near the Sun to increase with flare intensity. This casts doubt on the validity of using flare data alone as an effective space weather forecaster.

Multi-Hour-Ahead Dst Index Prediction Using Multi-Fidelity Boosted Neural Networks

A. Hu, E. Camporeale, B. Swiger

Space Weather [Volume 21, Issue 4](#) e2022SW003286 2023

<https://doi.org/10.1029/2022SW003286>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2022SW003286>

The Disturbance storm time (Dst) index has been widely used as a proxy for the ring current intensity, and therefore as a measure of geomagnetic activity. It is derived by measurements from four ground magnetometers in the geomagnetic equatorial region. We present a new model for predicting Dst with a lead time between 1 and 6 hr. The model is first developed using a Gated Recurrent Unit (GRU) network that is trained using solar wind parameters. The uncertainty of the Dst model is then estimated by using the Accurate and Reliable Uncertainty Estimate method (Camporeale & Carè, 2021, <https://doi.org/10.1615/int.j.uncertaintyquantification.2021034623>). Finally, a multi-fidelity boosting method is developed in order to enhance the accuracy of the model and reduce its associated uncertainty. It is shown that the developed model can predict Dst 6 hr ahead with a root-mean-square-error of 13.54 nT. This is significantly better than a persistence model or a single GRU model. **20-21 Nov 2003, 07 Nov 2022,**

A Magnetic Flux Rope Configuration Derived by Optimization of Two-Spacecraft In-situ Measurements

Qiang Hu, Wen He, and Yu Chen

Front. Phys. 10: 960315. 2022

doi: 10.3389/fphy.2022.960315

<https://www.frontiersin.org/articles/10.3389/fphy.2022.960315/pdf>

Increasingly one interplanetary coronal mass ejection (ICME) structure can propagate across more than one spacecraft in the solar wind. This usually happens when two or more spacecraft are nearly radially aligned with a relatively small longitudinal separation angle from one another. This provides multi-point measurements of the same structure and enables better characterization and validation of modeling results of the structures embedded in these ICMEs. We report such an event during **October 13-14, 2019** when the Solar TERrestrial RELations Observatory Ahead (STA) spacecraft and the Parker Solar Probe (PSP) crossed one ICME structure at two different locations with nominal separations in both heliocentric distances and the longitudinal angles. We first perform an optimal fitting to the STA in-situ measurements, based on an analytic quasi-three dimensional (3D) model, yielding a minimum reduced $\chi^2 = 0.468$. Then we further apply the optimization approach by combining the magnetic field measurements from both spacecraft along their separate paths across the ICME structure. We find that the output based on the optimization (with the minimum reduced $\chi^2 = 3.15$) of the combined two-spacecraft dataset yields a more consistent result, given the much improved agreement of the model output with PSP data. The result demonstrates a magnetic flux rope configuration with clear 3D spatial variations.

Validation and interpretation of three-dimensional configuration of a magnetic cloud flux rope

Qiang Hu, Chunming Zhu, Wen He, Jiong Qiu, Lan K. Jian, Avijeet Prasad

ApJ 934 50 2022

<https://arxiv.org/pdf/2204.03457>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac7803/pdf>

One "strong" magnetic cloud (MC) with the magnetic field magnitude reaching ~ 40 nT at 1 au during **2012 June 16-17** is examined in association with a pre-existing magnetic flux rope (MFR) identified on the Sun. The MC is characterized by a quasi-three dimensional (3D) flux rope model based on in situ measurements from the Wind spacecraft. The magnetic flux contents and other parameters are quantified. In addition, a correlative study with the corresponding measurements of the same structure crossed by the Venus Express (VEX) spacecraft at a heliocentric distance 0.7 au and with an angular separation $\sim 6^\circ$ in longitude is performed to validate the MC modeling results. The spatial variation between the Wind and VEX magnetic field measurements is attributed to the 3D configuration of the structure as featured by a knotted bundle of flux. The comparison of the magnetic flux contents between the MC and the source region on the Sun indicates that the 3D reconnection process accompanying an M1.9 flare may correspond to the magnetic reconnection between the field lines of the pre-existing MFR rooted in the opposite polarity footpoints. Such a process reduces the amount of the axial magnetic flux in the erupted flux rope, by approximately 50%, in this case.

Probabilistic prediction of Dst storms one-day-ahead using Full-Disk SoHO Images

A. Hu, C. Shneider, A. Tiwari, E. Camporeale

Space Weather e2022SW003064 **Volume20, Issue8 2022**

<https://arxiv.org/pdf/2203.11001.pdf>

<https://doi.org/10.1029/2022SW003064>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2022SW003064>

We present a new model for the probability that the Disturbance storm time (Dst) index exceeds **-100 nT**, with a lead time between 1 and 3 days. Dst provides essential information about the strength of the ring current around the Earth caused by the protons and electrons from the solar wind, and it is routinely used as a proxy for geomagnetic storms. The model is developed using an ensemble of Convolutional Neural Networks (CNNs) that are trained using SoHO images (MDI, EIT and LASCO). The relationship between the SoHO images and the solar wind has been investigated by many researchers, but these studies have not explicitly considered using SoHO images to predict the Dst index.

This work presents a novel methodology to train the individual models and to learn the optimal ensemble weights iteratively, by using a customized class-balanced mean square error (CB-MSE) loss function tied to a least-squares (LS) based ensemble.

The proposed model can predict the probability that $Dst < -100$ nT 24 hours ahead with a True Skill Statistic (TSS) of 0.62 and Matthews Correlation Coefficient (MCC) of 0.37. The weighted TSS and MCC from Guastavino et al. (2021) is 0.68 and 0.47, respectively. An additional validation during non-Earth-directed CME periods is also conducted which yields a good TSS and MCC score.

Configuration of a Magnetic Cloud from Solar Orbiter and Wind Spacecraft In-situ Measurements

Qiang Hu, Wen He, Lingling Zhao, Edward Lu

Frontiers in Physics 9:706056 2021

<https://arxiv.org/pdf/2107.01728.pdf>

<https://www.frontiersin.org/articles/10.3389/fphy.2021.706056/full>

<https://doi.org/10.3389/fphy.2021.706056>

Coronal mass ejections (CMEs) represent one type of the major eruption from the Sun. Their interplanetary counterparts, the interplanetary CMEs (ICMEs), are the direct manifestations of these structures when they propagate into the heliosphere and encounter one or more observing spacecraft. The ICMEs generally exhibit a set of distinctive signatures from the in-situ spacecraft measurements. A particular subset of ICMEs, the so-called Magnetic Clouds (MCs), is more uniquely defined and has been studied for decades, based on in-situ magnetic field and plasma measurements. By utilizing the latest multiple spacecraft measurements and analysis tools, we report a detailed study of the internal magnetic field configuration of an MC event observed by both the Solar Orbiter (SO) and Wind spacecraft in the solar wind near the Sun-Earth line. Both two-dimensional (2D) and three-dimensional (3D) models are applied to reveal the flux rope configurations of the MC. Various geometrical as well as physical parameters are derived and found to be similar within error estimates for the two methods. These results quantitatively characterize the coherent MC flux rope structure crossed by the two spacecraft along different paths. The implication for the radial evolution of this MC event is also discussed. **19 April 2020**

Optimal Fitting of the Freidberg Solution to In Situ Spacecraft Measurements of Magnetic Clouds

Qiang Hu

Solar Physics volume 296, Article number: 101 (2021)

<https://link.springer.com/content/pdf/10.1007/s11207-021-01843-z.pdf>

<https://doi.org/10.1007/s11207-021-01843-z>

We report, in detail, an optimization approach for fitting a three-dimensional (3D) magnetic cloud (MC) model to in situ spacecraft measurements. The model, dubbed the Freidberg solution, encompasses 3D spatial variations in a generally cylindrical geometry, as derived from a linear force-free formulation. The approach involves a least-squares minimization implementation with uncertainty estimates from magnetic field measurements. We present one case study of the MC event on **22 May 2007** to illustrate the method and demonstrate the satisfying result of the minimum reduced $\chi^2 \lesssim 1$, obtained from the Solar and TERrestrial RELations Observatory (STEREO) Behind spacecraft measurements. In addition, since the Advanced Composition Explorer (ACE) spacecraft at Earth crossed the STEREO Behind solution domain with an appropriate separation distance, the result from the optimally fitted Freidberg solution along the ACE

spacecraft path is compared with the actual measurements of magnetic field components. A correlation coefficient of 0.89 is obtained between the two sets of data.

On the quasi-three dimensional configuration of magnetic clouds

Qiang [Hu](#), [Wen He](#), [Jiong Qiu](#), [A. Vourlidas](#), [Chunming Zhu](#)

GRL 2020

<https://arxiv.org/pdf/2010.11889.pdf>

We develop an optimization approach to model the magnetic field configuration of magnetic clouds, based on a linear-force free formulation in three dimensions. Such a solution, dubbed the Freidberg solution, is kin to the axi-symmetric Lundquist solution, but with more general "helical symmetry". The merit of our approach is demonstrated via its application to two case studies of in-situ measured magnetic clouds. Both yield results of reduced $\chi^2 \approx 1$. Case 1 shows a winding flux rope configuration with one major polarity. Case 2 exhibits a double-helix configuration with two flux bundles winding around each other and rooted on regions of mixed polarities. This study demonstrates the three-dimensional complexity of the magnetic cloud structures. **15 July 2012, 14-15 Apr 2013**

Automated Detection of Small-scale Magnetic Flux Ropes in the Solar Wind: First Results from the Wind Spacecraft Measurements

Qiang [Hu](#)¹, Jinlei Zheng², Yu Chen², Jakobus le Roux¹, and Lulu Zhao³

2018 ApJS 239 12

sci-hub.tw/10.3847/1538-4365/aae57d

We have developed a new automated small-scale magnetic flux rope (SSMFR) detection algorithm based on the Grad-Shafranov (GS) reconstruction technique. We have applied this detection algorithm to the Wind spacecraft in situ measurements during 1996–2016, covering two solar cycles, and successfully detected a total number of 74,241 small-scale magnetic flux rope events with duration from 9 to 361 minutes. This large number of small-scale magnetic flux ropes has not been discovered by any other previous studies through this unique approach. We perform statistical analysis of the small-scale magnetic flux rope events based on our newly developed database, and summarize the main findings as follows. (1) The occurrence of small-scale flux ropes has strong solar-cycle dependency with a rate of a few hundred per month on average. (2) The small-scale magnetic flux ropes in the ecliptic plane tend to align along the Parker spiral. (3) In low-speed ($<400 \text{ km s}^{-1}$) solar wind, the flux ropes tend to have lower proton temperature and higher proton number density, while in high-speed ($\geq 400 \text{ km s}^{-1}$) solar wind, they tend to have higher proton temperature and lower proton number density. (4) Both the duration and scale size distributions of the small-scale magnetic flux ropes obey a power law. (5) The waiting time distribution of small-scale magnetic flux ropes can be fitted by an exponential function (for shorter waiting times) and a power-law function (for longer waiting times). (6) The wall-to-wall time distribution obeys double power laws with the break point at 60 minutes (corresponding to the correlation length). (7) The small-scale magnetic flux ropes tend to accumulate near the heliospheric current sheet (HCS). The entire database is available at <http://fluxrope.info> and in machine-readable format in this article.

The Grad-Shafranov Reconstruction of Toroidal Magnetic Flux Ropes: First Applications

Qiang [Hu](#), [M. G. Linton](#), [B. E. Wood](#), [P. Riley](#), [T. Nieves-Chinchilla](#)

Solar Phys. 292:171 2017

<https://arxiv.org/pdf/1707.09454.pdf>

This article completes and extends a recent study of the Grad-Shafranov (GS) reconstruction in toroidal geometry, as applied to a two and a half dimensional configurations in space plasmas with rotational symmetry. A further application to the benchmark study of an analytic solution to the toroidal GS equation with added noise shows deviations in the reconstructed geometry of the flux rope configuration, characterized by the orientation of the rotation axis, the major radius, and the impact parameter. On the other hand, the physical properties of the flux rope, including the axial field strength, and the toroidal and poloidal magnetic flux, agree between the numerical and exact GS solutions. We also present a real event study of a magnetic cloud flux rope from *in situ* spacecraft measurements. The devised procedures for toroidal GS reconstruction are successfully executed. Various geometrical and physical parameters are obtained with associated uncertainty estimates. The overall configuration of the flux rope from the GS reconstruction is compared with the corresponding morphological reconstruction based on white-light images. The results show overall consistency, but also discrepancy in that the inclination angle of the flux rope central axis with respect to the ecliptic plane differs by about 20-30 degrees in the plane of the sky. We also compare the results with the original straight-cylinder GS reconstruction and discuss our findings. **06-07-Jun-2008**

The Grad-Shafranov Reconstruction of Toroidal Magnetic Flux Ropes: Method Development and Benchmark Studies

Qiang **Hu**

Solar Phys. 292:116 2017

<https://www.dropbox.com/sh/wd5btkbldu5xvga/AABHQjCRRUH1NpEprmnKsccOa?dl=0>

<https://arxiv.org/pdf/1706.02732.pdf>

The underlying theory is the GS equation that describes two-dimensional magnetohydrostatic equilibrium as widely applied in fusion plasmas. The geometry is such that the arbitrary cross section of the torus has rotational symmetry about the rotation axis Z , with a major radius r_0 . The magnetic field configuration is thus determined by a scalar flux function Ψ and a functional F that is a single-variable function of Ψ . The algorithm is implemented through a two-step approach: i) a trial-and-error process by minimizing the residue of the functional $F(\Psi)$ to determine an optimal Z axis orientation, and ii) for the chosen Z , a χ^2 minimization process resulting in the range of r_0 . Benchmark studies of known analytic solutions to the toroidal GS equation with noise additions are presented to illustrate the two-step procedures and to demonstrate the performance of the numerical GS solver, separately. For the cases presented, the errors in Z and r_0 are 9° and 22%, respectively, and the relative percent error in the numerical GS solutions is less than 10%. We also make public the computer codes for these implementations and benchmark studies.

Sun-to-Earth Characteristics of the 2012 July 12 Coronal Mass Ejection and Associated Geo-effectiveness

Huidong **Hu**, Ying D. Liu, Rui Wang, [Christian Möstl](#), [Zhongwei Yang](#)

ApJ 829 97 2016

<http://arxiv.org/pdf/1607.06287v1.pdf> File

<https://iopscience.iop.org/article/10.3847/0004-637X/829/2/97/pdf>

We analyze multi-spacecraft observations associated with the 2012 July 12 Coronal Mass Ejection (CME), covering the source region on the Sun from SDO, stereoscopic imaging observations from STEREO, magnetic field characteristics at MESSENGER, and type II radio burst and in situ measurements from Wind. A triangulation method based on STEREO stereoscopic observations is employed to determine the kinematics of the CME, and the outcome is compared with the result derived from the type II radio burst with a solar wind electron density model. A Grad-Shafranov technique is applied to Wind in situ data to reconstruct the flux-rope structure and compare it with the observation of the solar source region, which helps understand the geo-effectiveness associated with the CME structure. Conclusions are as follows: (1) the CME undergoes an impulsive acceleration, a rapid deceleration before reaching MESSENGER, and then a gradual deceleration out to 1 AU, which should be noticed in CME kinematics models; (2) the type II radio burst was probably produced from a high-density interaction region between the CME-driven shock and a nearby streamer or from the shock flank with lower heights, which implies uncertainties in the determination of CME kinematics using solely type II radio bursts; (3) the flux-rope orientation and chirality deduced from in situ reconstruction at Wind agree with those obtained from solar source observations; (4) the prolonged southward magnetic field near the Earth is mainly from the axial component of the largely southward inclined flux rope, which indicates the importance of predicting both the flux-rope orientation and magnetic field components in geomagnetic activity forecasting.

Magnetic field-line lengths inside interplanetary magnetic flux ropes

Qiang **Hu**, Jiong Qiu, Sam Krucker

JGR Special Section: VarSITI, [Volume 120, Issue 7](#) Pages 5266–5283 2015

<http://arxiv.org/pdf/1502.05284v1.pdf>

We report on the detailed and systematic study of field-line twist and length distributions within magnetic flux ropes embedded in Interplanetary Coronal Mass Ejections (ICMEs). The Grad-Shafranov reconstruction method is utilized together with a constant-twist nonlinear force-free (Gold-Hoyle) flux rope model to reveal the close relation between the field-line twist and length in cylindrical flux ropes, based on in-situ Wind spacecraft measurements. We show that the field-line twist distributions within interplanetary flux ropes are inconsistent with the Lundquist model. In particular we utilize the unique measurements of magnetic field-line lengths within selected ICME events as provided by Kahler et al. (2011) based on energetic electron burst observations at 1 AU and the associated type III radio emissions detected by the Wind spacecraft. These direct measurements are compared with our model calculations to help assess the flux-rope interpretation of the embedded magnetic structures. By using the different flux-rope models, we show that the in-situ direct measurements of field-line lengths are consistent with a flux-rope structure with spiral field lines of constant and

low twist, largely different from that of the Lundquist model, especially for relatively large-scale flux ropes. **18 October 1995, 18 September 1997, 30 August 2004**

Structures of Interplanetary Magnetic Flux Ropes and Comparison with Their Solar Sources

Qiang **Hu**, Jiong Qiu, B. Dasgupta, A. Khare, and G. M. Webb

ApJ 793 53, **2014**; **File**

https://dl.dropboxusercontent.com/u/96898685/ms_fr_v4.pdf

<http://arxiv.org/pdf/1408.1470v1.pdf>

During the process of magnetic flux rope ejection, magnetic reconnection is essential to release the flux rope. the question remains: how does the magnetic reconnection change the flux rope structure? In this work, we continue with the original study by Qiu et al. (2007) by using a larger sample of flare-CME-ICME events to compare properties of ICME/MC flux ropes measured at 1 AU and properties of associated solar progenitors including flares, filaments, and CMEs. In particular, the magnetic field-line twist distribution within interplanetary magnetic flux ropes is systematically derived and examined. Our analysis shows that, similar to what was found before, for most of these events, the amount of twisted flux per AU in MCs is comparable with the total reconnection flux on the Sun, and the sign of the MC helicity is consistent with the sign of helicity of the solar source region judged from the geometry of postflare loops.

Remarkably, we find that about one half of the 18 magnetic flux ropes, most of them being associated with erupting filaments, have a nearly uniform and relatively low twist distribution from the axis to the edge, and the majority of the other flux ropes exhibit very high twist near the axis, of up to ≥ 5 turns per AU, which decreases toward the edge. The flux ropes are therefore not linear force free. We also conduct detailed case studies showing the contrast of two events with distinct twist distribution in MCs as well as different flare and dimming characteristics in solar source regions, and discuss how reconnection geometry reflected in flare morphology may be related to the structure of the flux rope formed on the Sun. 03/08/2008, 05/28/2010, 08/04/2010, 03/30/2011, 06/05/2011, 08/05/2011, 09/09/2011, 09/17/2011, **2011 September 13-17**, 10/24/2011

Effect of Electron Pressure on the Grad–Shafranov Reconstruction of Interplanetary Coronal Mass Ejections

Qiang **Hu**, C. J. Farrugia, V. A. Osherovich, C. Möstl, A. Szabo, K. W. Ogilvie, R. P. Lepping

Solar Physics, May **2013**, Volume 284, Issue 1, pp 275-291

We investigate the effect of electron pressure on the Grad–Shafranov (GS) reconstruction of Interplanetary Coronal Mass Ejection (ICME) structures. The GS method uses in situ magnetic field and plasma measurements to solve for a magnetohydrostatic quasi-equilibrium state of space plasmas. For some events, a magnetic flux-rope structure embedded within the ICME can be reconstructed. The electron temperature contributes directly to the calculation of the total plasma pressure, and in ICMEs its contribution often substantially exceeds that of proton temperature. We selected ICME events observed with the Wind spacecraft at 1 AU and applied the GS reconstruction method to each event for cases with and without electron temperature measurements. We sorted them according to the proton plasma β (the ratio of proton plasma pressure to magnetic pressure) and the electron-to-proton temperature ratio. We present case studies of three representative events, show the cross sections of GS reconstructed flux-rope structure, and discuss the electron pressure contribution to key quantities in the numerical reconstruction procedure. We summarize and compare the geometrical and physical parameters derived from the GS reconstruction results for cases with and without electron temperature contribution. We conclude that overall the electron pressure effect on the GS reconstruction results contributes to a 10–20 % discrepancy in some key physical quantities, such as the magnetic flux content of the ICME flux rope observed at 1 AU.

On the magnetic topology of October/November 2003 events

Hu, Q., C. W. Smith, N. F. Ness, and R. M. Skoug

J. Geophys. Res., 110, A09S03, doi:10.1029/2004JA010886, **2005**, **File**.

We examine the topology of several magnetic ejecta events during October–November 2003. The Grad-Shafranov reconstruction results from ACE magnetic and plasma data show magnetic flux rope configurations. Some are large scale, with sizes of tenths of an AU, typical of magnetic clouds. Some are of sizes hundredths of an AU. Their characteristic parameters are reported. Magnetic field data from Wind spacecraft are utilized to compare the prediction from numerical modeling with the actual measurement. Poor to good agreement is achieved. The deviations are discussed, particularly in the context of extremely high-speed solar wind flows.

Ensemble Modeling of Radiation Belt Electron Flux Decay Following a Geomagnetic Storm: Dependence on Key Input Parameters

Man [Hua](#), [Jacob Bortnik](#), [Adam C. Kellerman](#), [Enrico Camporeale](#), [Qianli Ma](#)

Space Weather 2022

<https://doi.org/10.1029/2022SW003051>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2022SW003051>

We perform an ensemble of quasi-linear diffusion simulations of the radiation belt electron flux decay for ~6 days at $L = 3.5$ during the recovery phase of the storm on **7 November 2015**, where plasmaspheric hiss dominantly drives the electron flux decay process. Based on Van Allen Probes measurements, we use percentiles to sample the distributions of the four key input parameters, which are the hiss wave amplitude B_w , hiss wave peak frequency f_m , background magnetic field B_0 and electron density N_e , with 11 points representing that range of each input, leading to 114 (~14,600) ensemble members. By developing a Lookup Table method to rapidly calculate the time-dependent diffusion coefficients, the changing wave environment at every time step is incorporated in our ensemble simulations. The comparison between the ensemble simulations and observation reveals the influence of uncertainties in the input parameters on the simulated electron fluxes. Our results demonstrate that the perturbations in B_w are the primary contributor for discrepancies between modeled and observed electron fluxes, while the simulation errors caused by variations in f_m and N_e are strongly energy-dependent. The simulated electron flux using the wave parameters observed at the 50th percentile agrees with observations, and most of the simulation errors increase with decreasing observational probability density of the parameters, with the largest log accuracy ratio of ~14. Our physics-based ensemble modeling provides the essential information about the robustness of radiation belt simulation and forecast considering the uncertainties in the plasma wave measurement or parameterization.

Solar Wind Driven from GONG Magnetograms in the Last Solar Cycle

Zhenguang [Huang](#)¹, Gábor Tóth¹, Nishtha Sachdeva¹, and Bart van der Holst¹

2024 ApJ 965 1

<https://iopscience.iop.org/article/10.3847/1538-4357/ad32ca/pdf>

In a previous study, Huang et al. used the Alfvén Wave Solar atmosphere Model, one of the widely used solar wind models in the community, driven by ADAPT-GONG magnetograms to simulate the solar wind in the last solar cycle and found that the optimal Poynting flux parameter can be estimated from either the open field area or the average unsigned radial component of the magnetic field in the open field regions. It was also found that the average energy deposition rate (Poynting flux) in the open field regions is approximately constant. In the current study, we expand the previous work by using GONG magnetograms to simulate the solar wind for the same Carrington rotations and determine if the results are similar to the ones obtained with ADAPT-GONG magnetograms. Our results indicate that similar correlations can be obtained from the GONG maps. Moreover, we report that ADAPT-GONG magnetograms can consistently provide better comparisons with 1 au solar wind observations than GONG magnetograms, based on the best simulations selected by the minimum of the average curve distance for the solar wind speed and density.

Interaction between a Coronal Mass Ejection and Comet 67P/Churyumov-Gerasimenko

ApJ 967 43 2024

<https://arxiv.org/pdf/2403.05779.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ad3c42/pdf>

The interaction between a Coronal Mass Ejection (CME) and a comet has been observed several times by in-situ observations from the Rosetta Plasma Consortium (RPC), which is designed to investigate the cometary magnetosphere of comet 67P/Churyumov-Gerasimenko (CG). Goetz et al. (2019) reported a magnetic field of up to 300 nT measured in the inner coma, which is among the largest interplanetary magnetic fields observed in the solar system. They suggested the large magnetic field observations in the inner coma come from magnetic field pile-up regions, which are generated by the interaction between a CME and/or corotating interaction region and the cometary magnetosphere. However, the detailed interaction between a CME and the cometary magnetosphere of comet CG in the inner coma has not been investigated by numerical simulations yet. In this manuscript, we will use a numerical model to simulate the interaction between comet CG and a Halloween class CME and investigate its magnetospheric response to the CME. We find that the plasma structures change significantly during the CME event, and the maximum value of the magnetic field strength is more than 500nT close to the nucleus. Virtual satellites at similar distances as Rosetta show that the magnetic field strength can be as large as 250nT, which is slightly less than what Goetz et al. (2019) reported. **29 Oct 2003**

The Structure and Origin of Switchbacks: Parker Solar Probe Observations

Jia **Huang**¹, J. C. Kasper^{2,3}, L. A. Fisk³, Davin E. Larson¹, Michael D. McManus¹ +++

2023 ApJ 952 33

<https://iopscience.iop.org/article/10.3847/1538-4357/acd17e/pdf>

Switchbacks are rapid magnetic field reversals that last from seconds to hours. Current Parker Solar Probe (PSP) observations pose many open questions in regard to the nature of switchbacks. For example, are they stable as they propagate through the inner heliosphere, and how are they formed? In this work, we aim to investigate the structure and origin of switchbacks. In order to study the stability of switchbacks, we suppose the small-scale current sheets therein are generated by magnetic braiding, and they should work to stabilize the switchbacks. With more than 1000 switchbacks identified with PSP observations in seven encounters, we find many more current sheets inside than outside switchbacks, indicating that these microstructures should work to stabilize the S-shape structures of switchbacks. Additionally, we study the helium variations to trace the switchbacks to their origins. We find both helium-rich and helium-poor populations in switchbacks, implying that the switchbacks could originate from both closed and open magnetic field regions in the Sun. Moreover, we observe that the alpha-proton differential speeds also show complex variations as compared to the local Alfvén speed. The joint distributions of both parameters show that low helium abundance together with low differential speed is the dominant state in switchbacks. The presence of small-scale current sheets in switchbacks along with the helium features are in line with the hypothesis that switchbacks could originate from the Sun via interchange reconnection process. However, other formation mechanisms are not excluded. **27 Apr 2021**

Statistical Study of Ejections in Coronal Hole Regions As Possible Sources of Solar Wind Switchbacks and Small-scale Magnetic Flux Ropes

Nengyi **Huang**^{1,2}, Sophia D'Anna¹, and Haimin Wang^{1,2}

2023 ApJL 946 L17

<https://iopscience.iop.org/article/10.3847/2041-8213/acc0f1/pdf>

The omnipresence of transient fluctuations in the solar wind, such as switchbacks (SBs) and small-scale magnetic flux ropes (SMFRs), have been well observed by the in situ observation of Parker Solar Probe (PSP), yet their sources are not clear. Possible candidates fall into two categories: solar origin and in situ generation in the solar wind. Among the solar-origin scenarios, the small-scale activities (such as ejections and eruptions) in coronal hole (CH) regions, where solar wind originates, are suggested as candidates. Using full-disk extreme ultraviolet images from Atmospheric Imaging Assembly on board the Solar Dynamic Observatory, we identify small-scale ejections in CH regions during PSP Encounters 5, 7, and 8, and study their statistical properties. These ejections belong to two categories: standard jets and blowout jets. With 27,832 ejections identified in 24 days (about 2/3 of them are blowout jets), we updated the expected frequency for PSP to detect their counterparts in the heliospace. The ejections we identified are comparable to the frequency of PSP-detected SMFRs, but they are insufficient to serve as the only producer of SBs or SB patches. Certain smaller events missed by this study, such as jetlets, may fill the gap. **2020-01-23, 2020-06-09-10, 2021-04-29**

Modeling the Solar Wind During Different Phases of the Last Solar Cycle

Zhenguang **Huang**, [Gabor Toth](#), [Nishtha Sachdeva](#), [Lulu Zhao](#), [Bartholomeus van der Holst](#), [Igor](#)

[Sokolov](#), [Ward Manchester](#), [Tamas Gombosi](#)

ApJ **2022**

<https://arxiv.org/pdf/2210.02501.pdf>

We describe our first attempt to systematically simulate the solar wind during different phases of the last solar cycle with the Alfvén Wave Solar atmosphere Model (AWSoM) developed at the University of Michigan. Key to this study is the determination of the optimal values of one of the most important input parameter of the model, the Poynting flux, which prescribes the energy flux passing through the chromospheric boundary of the model in form of Alfvén wave turbulence. It is found that the optimal value of the Poynting flux parameter is correlated with: 1) the open magnetic flux with the linear correlation coefficient of 0.913; 2) the area of the open magnetic field regions with the linear correlation coefficient of 0.946. These highly linear correlations could shed light on understanding how Alfvén wave turbulence accelerates the solar wind during different phases of the solar cycle and estimating the Poynting flux parameter for real-time solar wind predictions with AWSoM.

Comparative Analyses of Plasma Properties and Composition in Two Types of Small-Scale Interplanetary Flux-ropes

Jin [Huang](#), [Yu Liu](#), [Jihong Liu](#), [Yuandeng Shen](#)

ApJL 899 L29 2020

<https://arxiv.org/pdf/2008.02256.pdf>

<https://doi.org/10.3847/2041-8213/abac18>

The origin of small-scale interplanetary magnetic flux-ropes (SIMFRs) and the relationship between SIMFRs and magnetic clouds (MCs) are still controversial. In this study, two populations of SIMFRs were collected, i.e., SIMFRs originating from the Sun (SIMFR-SUN) and those originating from the solar wind (SIMFR-SW). We defined the SIMFR-SUN (SIMFR-SW) as the SIMFRs that include (exclude) the counter-streaming suprathermal electrons and stay away from (close to) the heliospheric current sheet. After fitting with force-free flux-rope model, 52 SIMFR-SUN and 57 SIMFR-SW events observed by Advanced Composition Explorer (ACE) from 1998 February to 2011 August were qualified. Using the approach of relating the measurements to their spatial position within the flux-ropes, a comparative survey of plasma and composition characteristics inside the two populations of SIMFRs is presented. Results show that the two populations of SIMFRs have apparent differences. Compared with SIMFR-SW, SIMFR-SUN are MC-like, featuring lower central proton density, higher V_{rad} , higher low-FIP element abundances, higher and more fluctuate average ion charge-states and the ion charge-state ratios which are related to the heating in low corona. In addition, for the ion charge-state distributions inside SIMFR-SUN, the sunward side is higher than earthward, which might be caused by the flare heating during eruption. Moreover, both SIMFR-SUN and MCs show anti-correlation between plasma beta and He/P trend. These characteristics indicate that SIMFR-SUN and MCs are very likely to have the identical origination. This study supports the two-source origin of SIMFRs, i.e., the solar corona and the solar wind.

Alfvénic Slow Solar Wind Observed in the Inner Heliosphere by Parker Solar Probe

Jia [Huang](#), [J. C. Kasper](#), [M. Stevens](#), [D. Vech](#), [K. G. Klein](#), et al.

ApJS 2020

<https://arxiv.org/pdf/2005.12372>

The slow solar wind is typically characterized as having low Alfvénicity. However, Parker Solar Probe (PSP) observed predominately Alfvénic slow solar wind during several of its initial encounters. From its first encounter observations, about 55.3% of the slow solar wind inside 0.25 au is highly Alfvénic ($|\sigma_C| > 0.7$) at current solar minimum, which is much higher than the fraction of quiet-Sun-associated highly Alfvénic slow wind observed at solar maximum at 1 au. Intervals of slow solar wind with different Alfvénicities seem to show similar plasma characteristics and temperature anisotropy distributions. Some low Alfvénicity slow wind intervals even show high temperature anisotropies, because the slow wind may experience perpendicular heating as fast wind does when close to the Sun. This signature is confirmed by Wind spacecraft measurements as we track PSP observations to 1 au. Further, with nearly 15 years of Wind measurements, we find that the distributions of plasma characteristics, temperature anisotropy and helium abundance ratio (N_{α}/N_p) are similar in slow winds with different Alfvénicities, but the distributions are different from those in the fast solar wind. Highly Alfvénic slow solar wind contains both helium-rich ($N_{\alpha}/N_p \sim 0.045$) and helium-poor ($N_{\alpha}/N_p \sim 0.015$) populations, implying it may originate from multiple source regions. These results suggest that highly Alfvénic slow solar wind shares similar temperature anisotropy and helium abundance properties with regular slow solar winds, and they thus should have multiple origins.

A Statistical Study of the Plasma and Composition Distribution inside Magnetic Clouds: 1998–2011

Jin [Huang](#)^{1,2,3}, [Yu Liu](#)^{1,2,3}, [Hengqiang Feng](#)⁴, [Ake Zhao](#)⁵, [Z. Z. Abidin](#)⁶, [Yuandeng Shen](#)¹, and [Oloketuyi Jacob](#)^{1,3}

2020 ApJ 893 136

[sci-hub.tw/10.3847/1538-4357/ab7a28](https://arxiv.org/abs/2008.02256)

A comprehensive analysis of plasma and composition characteristics inside magnetic clouds (MCs) observed by the Advanced Composition Explorer spacecraft from **1998 February to 2011 August** is presented. The results show that MCs have specific interior structures, and MCs of different speeds show differences in composition and structure. Compared with the slow MCs, fast MCs have enhanced mean charge states of iron, oxygen, silicon, magnesium, , , , and values. For ionic species in fast MCs, a higher atomic number represents a greater enhancement of mean charge state than slow MCs. We also find that both the fast and slow MCs display bimodal structure distribution in the mean iron charge state ($\langle Z \rangle$), which suggests that the existence of flux rope prior to the eruption is common. Furthermore, the , , and ratio distribution inside fast MCs have the feature that the posterior peak is higher than the anterior one. This result agrees with the "standard model" for coronal mass ejection/flares, by which magnetic reconnection occurs beneath the flux rope, thereby ionizing the ions of the posterior part of the flux rope sufficiently by high-energy electron collisions or by direct heating in the reconnection region.

JGR Volume 122, Issue 7 July 2017 Pages 6927–6939

<http://sci-hub.cc/10.1002/2017JA023906>

We present a small flux rope (SFR) with smooth magnetic field rotations entrained by rolling back magnetic field lines around 1 AU. Such SFRs have only been seldom reported in the literature. This SFR was adjacent to a heliospheric plasma sheet (HPS), which is defined as a high plasma beta region in the vicinity of a heliospheric current sheet. Even though the SFR and HPS have different plasma beta, they possess similar plasma signatures (such as temperature, density, and bulk speed), density ratio of alpha particle-to-proton (N_{α}/N_p), and heavy ion ionization states, which imply that they may have a similar origin in the corona. The composition and the configuration of the rolling back magnetic field lines suggested that the SFR originated from the streamer belt through interchange reconnection. The origin processes of the SFR are presented here. Combining the observations of STEREO and ACE, the SFR was shown to have an axis tilted to the ecliptic plane and the radius may vary with different spatial positions. In this study, we suggest that interchange reconnection can play an important role for the origin of, at least, some SFRs and slow solar wind. **26-27 Apr 2007**

A multievent study of the coincidence of heliospheric current sheet and stream interface

Jia **Huang**, Yong C.-M. Liu, Zhaohui Qi, Berndt Klecker, Octav Marghitu, Antoinette B. Galvin, Charles J. Farrugia, Xiaoyu Li

JGR Vol: 121, Pages: 10,768–10,782 2016

Generally, the heliospheric current sheet (HCS) is separated from the stream interface (SI) at about 1 AU. A recent study found an event where the HCS coincides with the SI, and in which the HCS is separated from the true sector boundary (TSB), defined by the switch of suprathermal electron pitch angle distributions. We present a multievent study by using STEREO, ACE, and Wind data during 2007 to 2010 to investigate whether other classes of such coincidence cases exist, as well as their stability. We find coincidence cases related to ideal HCSs, separated TSB and HCS, or heat flux dropouts in the vicinity; therefore, we define them as types I, II, and III. Among the nine coincidence cases, there are seven type I, one type II, and one type III. For each type, a possible schematic origin is presented. We also compared the observations on different spacecraft. Only two out of nine cases are observed by several spacecraft with a large separation, indicating that the coincidence structures are usually unstable. The study also shows that the coincidence cases have a variable connection with pseudostreamers. Interchange reconnection and pseudostreamers could play a role in forming these coincidence cases and lead to different configurations in different situations.

Coincidence of heliospheric current sheet and stream interface: Implications for the origin and evolution of the solar wind

Jia **Huang**, Yong C.-M. Liu, Berndt Klecker, Yao Chen

JGR Volume 121, Issue 1 January 2016 Pages 19–29 2016

In general, the heliospheric current sheet (HCS), which defines the boundary of sunward and antisunward magnetic field, is encased by the slow solar wind. The stream interface (SI) represents the boundary between the solar wind plasmas of different origin and/or characteristics. According to earlier studies using data of low time resolution, the SI and HCS get closer further away from the Sun, and the two structures coincide with each other around 5 AU. In this study, we use STEREO data of a much higher time resolution to reveal an unusual case where the SI and HCS are coincident near 1 AU and separated from the so-called true sector boundary (TSB) at which the suprathermal electrons change their relative propagation directions. Preliminary analysis suggests that the closed loops in pseudostreamers continually have interchange reconnection with the open-field lines that lead them, resulting not only in the coincidence of HCS and SI but also in the separation of the TSB from the HCS/SI. We therefore conclude that the interchange reconnection plays an important role in the evolution of slow solar wind.

Analysis of the Forbush Decreases and Ground-Level Enhancement on September 2017 Using Neutron Spectrometers Operated in Antarctic and Midlatitude Stations

G. [Hubert](#), [M. T. Pазianotto](#) [C. A. Federico](#) [P. Ricaud](#)

JGR [Volume 124, Issue 1](#) January 2019 Pages 661-673

[sci-hub.tw/10.1029/2018JA025834](https://doi.org/10.1029/2018JA025834)

This work investigates solar events occurred in September 2017 characterized by a series of Forbush decreases and a ground level enhancement (GLE). Forbush decreases is a rapid decrease in the observed https://en.wikipedia.org/wiki/Galactic_cosmic_ray intensity following a coronal mass ejection while GLE is induced by a strong solar event for which the flux of high-energy solar particles is sufficient to enhance the radiation level on the ground. These investigations were performed using data recorded by a neutron spectrometer network composed of a Bonner sphere system. Two instruments located at Pic-du-Midi Observatory (+2,885 m above sea level) and at Concordia station (Antarctica, +3,233 m) record simultaneously and continuously the neutron spectra, allowing to consider short-term variations during solar events. The main objective is to analyze neutron spectral properties including their energy distributions and dynamics. This paper presents cosmic ray-induced neutron spectra during active solar event leading to changes in the local cosmic ray spectrum (Forbush decreases and a GLE). Concerning the GLE, analyses show that neutrons in the evaporation domain are particularly amplified during the GLE, while other energetic domains increase uniformly.

An impulsive geomagnetic effect from an early-impulsive flare

Hugh S. [Hudson](#), [Edward. W. Cliver](#), [Lyndsay Fletcher](#), [Declan A. Diver](#), [Peter T. Gallagher](#), [Ying Li](#), [Christopher M.J. Osborne](#), [Craig Stark](#), [Yang Su](#)

MNRAS **2024**

<https://arxiv.org/abs/2407.09233>

The geomagnetic "solar flare effect" (SFE) results from excess ionization in the Earth's ionosphere, famously first detected at the time of the Carrington flare in 1859. This indirect detection of a flare constituted one of the first cases of "multimessenger astronomy," whereby solar ionizing radiation stimulates ionospheric currents. Well-observed SFEs have few-minute time scales and perturbations of >10 nT, with the greatest events reaching above 100 nT. In previously reported cases the SFE time profiles tend to resemble those of solar soft X-ray emission, which ionizes the D-region; there is also a less-well-studied contribution from Lyman-alpha. We report here a specific case, from flare SOL2024-03-10 (M7.4), in which an impulsive SFE deviated from this pattern. This flare contained an "early impulsive" component of exceptionally hard radiation, extending up to gamma-ray energies above 1 MeV, distinctly before the bulk of the flare soft X-ray emission. We can characterize the spectral distribution of this early-impulsive component in detail, thanks to the modern extensive wavelength coverage. A more typical gradual SFE occurred during the flare's main phase. We suggest that events of this type warrant exploration of the solar physics in the "impulse response" limit of very short time scales.

Carrington events.

(2021) *Annu Rev Astron Astrophys* 59:445.

<https://doi.org/10.1146/annurev-astro-112420-023324>

The Carrington event in 1859, a solar flare with an associated geomagnetic storm, has served as a prototype of possible superflare occurrence on the Sun. Recent geophysical (^{14}C signatures in tree rings) and precise time-series photometry [the bolometric total solar irradiance (TSI) for the Sun, and the broadband photometry from *Kepler* and *Transiting Exoplanet Survey Satellite*, for the stars] have broadened our perspective on extreme events and the threats that they pose for Earth and for Earth-like exoplanets. This review assesses the mutual solar and/or stellar lessons learned and the status of our theoretical understanding of the new data, both stellar and solar, as they relate to the physics of the Carrington event. The discussion includes the event's implied coronal mass ejection, its potential "solar cosmic ray" production, and the observed geomagnetic disturbances based on the multimessenger information already available in that era. Taking the Carrington event as an exemplar of the most extreme solar event, and in the context of our rich modern knowledge of solar flare and/or coronal mass ejection events, we discuss the aspects of these processes that might be relevant to activity on solar-type stars, and in particular their superflares.

MHD-Test Particles Simulations of Moderate CME and CIR-Driven Geomagnetic Storms at Solar Minimum

Mary K. [Hudson](#), [Scot R. Elkington](#), [Zhao Li](#), [Maulik Patel](#), [Kevin Pham](#), [Kareem Sorathia](#), [Alex Boyd](#), [Allison Jaynes](#), [Alexis Leali](#)

Space Weather e2021SW002882 2021

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2021SW002882>

<https://doi.org/10.1029/2021SW002882>

As part of the Whole Heliosphere and Planetary Interactions initiative, contrasting drivers of radiation belt electron response at solar minimum have been investigated with MHD-test particle simulations for the **May 13–14, 2019** Coronal Mass Ejection (CME)-shock event and the **August 30–September 3, 2019** high speed solar wind interval. Both solar wind drivers produced moderate geomagnetic storms characterized by a minimum Dst = −65 nT and −52 nT, respectively, with the August - September event accompanied by prolonged substorm activity. The latter, with characteristic features of a Corotating Interaction Region (CIR)-driven storm, produced the hardest relativistic electron spectrum observed by Van Allen Probes during the last two years of the mission, ending in October 2019. MHD simulations were performed using both the Lyon-Fedder-Mobarry global MHD code and recently developed GAMERA model coupled to the Rice Convection Model, run with measured L1 solar wind input for both events studied, and coupled with test particle simulations, including an initial trapped and injected population. Initial electron Phase Space Density (PSD) profiles used measurements from the Relativistic Electron Proton Telescope and MagEIS energetic particle instruments on Van Allen Probes for test particle weighting and updating of the injected population at apogee. Results were compared directly with measurements and found to reproduce magnetopause loss for the CME-shock event and increased PSD for the CIR event. The two classes of events are contrasted for their impact on outer zone relativistic electrons near the end of Solar Cycle 24.

Solar Sector Structure

Review

Hugh S. [Hudson](#), Leif Svalgaard, Iain G. Hannah

[Space Science Reviews](#), December 2014, Volume 186, [Issue 1-4](#), pp 17-34

The interplanetary magnetic field near 1 AU has a characteristic “sector” structure that reflects its polarity relative to the solar direction. Typically we observe large-scale coherence in these directions, with two or four “away” or “towards” sectors per solar rotation, from any platform in deep space and near the ecliptic plane. In a simple picture, this morphology simply reflects the idea that the sources of the interplanetary field lie mainly in or near the Sun, and that the solar-wind flow enforces a radial component in this field. The sector boundaries are sharply defined in the interplanetary field near one AU, but have more complicated sources within the Sun itself. Recent evidence confirms that the origins of this pattern also appear statistically at the level of the photosphere, with signatures found in the highly concentrated fields of sunspots and even solar flares. This complements the associations already known between the interplanetary sectors and large-scale coronal structures (i.e., the streamers). This association with small-scale fields strengthens at the Hale sector boundary, defining the Hale boundary as the one for which the polarity switch matches that of the leading-to-following polarity alternation in the sunspots of a given hemisphere. Surface features that appear 4.5 days prior to the sector crossings observed at 1 AU correlate with this sense of polarity reversal.

Geomagnetic storms over the last solar cycle: A superposed epoch analysis

[Hutchinson](#), J. A.; Wright, D. M.; Milan, S. E.

J. Geophys. Res., Vol. 116, No. A9, A09211, 2011

<http://dx.doi.org/10.1029/2011JA016463>

<https://agupubs.onlinelibrary.wiley.com/doi/pdf/10.1029/2011JA016463>

Presented here is a discussion of the results of a superposed epoch analysis of geomagnetic storms over the last solar cycle. Storms, identified by means of their characteristic SYM-H evolution, are separated by size into weak ($-150 < \text{SYM-H} \leq -80$) nT, moderate ($-300 < \text{SYM-H} \leq -150$) nT, and intense ($\text{SYM-H} \leq -300$) nT categories. Where possible, the corresponding solar wind (SW) onset mechanisms were located by means of 1 min ACE OMNI data. Intense storms were observed to be driven solely by coronal mass ejections (CMEs); moderate storms were dominated by CME onset, while only weak storms were driven by both CMEs and corotating interaction regions (CIRs) at a ratio of ~2:1, respectively. As might be expected, more intense storms resulted from the largest SW enhancements. Individual storm phase durations for different storm sizes were investigated, revealing that the duration of the main phase increases with storm size to a critical point, then decreases for more intense storms, contrary to the findings of a previous study by Yokoyama and Kamide (1997). Various SW-magnetosphere coupling functions were investigated for this data set in an attempt to estimate storm size from SW conditions.

Interplanetary Coronal Mass Ejections During Solar Cycles 23 and 24: Sun–Earth Propagation Characteristics and Consequences at the Near-Earth Region

M. Syed [Ibrahim](#), Bhuwan Joshi, K.-S. Cho, R.-S. Kim, Y.-J. Moon

[Solar Physics](#) May 2019, 294:54 [File](#)

sci-hub.se/10.1007/s11207-019-1443-5

In this article, we present a statistical study probing the relation between interplanetary coronal mass ejections (ICMEs) observed at 1 AU and their corresponding coronal mass ejections at the near-Sun region. The work encompasses the ICME activity that occurred during Solar Cycles 23 and 24 (1996 – 2017) while presenting an overall picture of ICME events during the complete Solar Cycle 24 for the first time. The importance of this study further lies in comparing two subsets of ICMEs, i.e. magnetic clouds (MCs) and ejecta (EJ), to explore how the observed structures of ICMEs at 1 AU could be associated with the properties of CMEs during their launch at the Sun. We find that, although Solar Cycle 24 saw a significant reduction in the number of ICME events compared to the previous cycle, the fraction of MCs was much higher during Cycle 24 than Cycle 23 (60% versus 41%). In general, the ICME transit-time decreases with the increase in the CME initial speed, although a broad range of transit times were observed for a given CME speed. We also find that the high-speed ICMEs ($\geq 500 \text{ km s}^{-1}$) form a distinct group in terms of the deficit in their transit times when compared with low-speed events ($\leq 500 \text{ km s}^{-1}$), which means that high-speed ICMEs acquire a much higher internal energy from the source active regions during the initiation process that effectively overcomes the aerodynamic drag force while they transit in the interplanetary medium. The CME propagation from the Sun to the near-Earth environment shows both an overall positive and negative acceleration (i.e. deceleration), although the acceleration is limited to only low-speed CMEs that are launched with a speed comparable with or less than the mean solar wind speed ($\approx 400\text{--}450 \text{ km s}^{-1}$). Within a given cycle, the similarities of MC and EJ profiles with respect to the CME–ICME speed relation as well as interplanetary acceleration support the hypothesis that all CMEs have a flux rope structure and that the trajectory of the CMEs essentially determines the observed ICME structure at 1 AU. **13 December 2006, 22 June 2015**

Propagation of Coronal Mass Ejections Observed During the Rising Phase of Solar Cycle 24

M. Syed [Ibrahim](#), P. K. Manoharan, A. Shanmugaraju

[Solar Physics](#) September 2017, 292:133 [File](#)

In this study, we investigate the interplanetary consequences and travel time details of 58 coronal mass ejections (CMEs) in the Sun–Earth distance. The CMEs considered are halo and partial halo events of width $>120^\circ$. These CMEs occurred during 2009 – 2013, in the ascending phase of the Solar Cycle 24. Moreover, they are Earth-directed events that originated close to the centre of the solar disk (within about $\pm 30^\circ$ from the Sun’s centre) and propagated approximately along the Sun–Earth line. For each CME, the onset time and the initial speed have been estimated from the white-light images observed by the LASCO coronagraphs onboard the SOHO space mission. These CMEs cover an initial speed range of $\sim 260\text{--}2700 \text{ km s}^{-1}$. For these CMEs, the associated interplanetary shocks (IP shocks) and interplanetary CMEs (ICMEs) at the near-Earth environment have been identified from *in-situ* solar wind measurements available at the OMNI data base. Most of these events have been associated with moderate to intense IP shocks. However, these events have caused only weak to moderate geomagnetic storms in the Earth’s magnetosphere. The relationship of the travel time with the initial speed of the CME has been compared with the observations made in the previous Cycle 23, during 1996 – 2004. In the present study, for a given initial speed of the CME, the travel time and the speed at 1 AU suggest that the CME was most likely not much affected by the drag caused by the slow-speed dominated heliosphere. Additionally, the weak geomagnetic storms and moderate IP shocks associated with the current set of Earth-directed CMEs indicate magnetically weak CME events of Cycle 24. The magnetic energy that is available to propagate CME and cause geomagnetic storm could be significantly low. **15 March 2013.**

Table 1 Observational parameters of 58 CME events (eight interacting CMEs are marked with asterisk symbols).

Transit time of CME/shock associated with four major geo-effective CMEs in solar cycle 24

M. Syed [Ibrahim](#), A. Shanmugaraju, M. Benedict Lawrance

Advances in Space Research, Volume 55, Issue 1, 1 January 2015, Pages 407–415

<http://www.sciencedirect.com/science/article/pii/S0273117714006139>

The kinematics of coronal mass ejection (CME) in the interplanetary medium is very important in the concept of space-weather. Main aim of this paper is to study the propagation of four major geo-effective CMEs and their associated shocks observed in solar cycle 24. The arrival of interplanetary shocks and CMEs of these events near the Earth is seen

from the ACE/wind in situ data available in OMNI data base. The CMEs considered in this study have a wide range of initial speeds 500–1900 km/s in the LASCO field of view, comprising of two slow CMEs ($V \sim 500$ km/s), one fast CME ($V \sim 1800$ km/s) and one moderate speed CME ($V \sim 800$ km/s). The observed transit time of these events are compared with transit time estimated using the empirical shock arrival model (ESA). Especially, we utilize (i) different acceleration – speed equations reported in the literature from the observations made in the last few decades and (ii) various acceleration cessation distances (Ac_d) In addition, we compared the estimated and observed transit time with that from the Drag Based Model (DBM). From the result of this analysis, we demonstrated that each CME behaves in its own way in the interplanetary medium and their propagation is governed by the CME initial speed, interplanetary acceleration and acceleration cessation distances. In the present paper, we found (i) which acceleration equation is better for the transit time calculations (ii) importance of the CME acceleration cessation distances (iii) reducing the transit time error in CME forecasting. Based on these results and on Zhao and Dryer (2014) review (that included physics-based models), the realistic statistics should be based on real-time studies, not on post-mortem case studies.

The effects of solar wind on galactic cosmic ray flux at Earth

G. D. **Ihongo**, C. H.-T. Wang

[Astrophysics and Space Science](#) January 2016, 361:44 **Open Access**

The amount of solar wind produced continuously by the sun is not constant due to changes in solar activity. This unsteady nature of the solar wind seems to be responsible for galactic cosmic ray flux modulation, hence the flux of incoming galactic cosmic rays observed at the top of the Earth's atmosphere varies with the solar wind reflecting the solar activity. The aforementioned reasons have lead to attempts by several researchers to study correlations between galactic cosmic rays and the solar wind. However, most of the correlation studies carried out by authors earlier are based on the analyses of observational data from neutron monitors. In this context, we study the effects of solar wind on galactic cosmic ray flux observed at $r \approx 1$ AU, using a theoretical approach and found that the solar wind causes significant decreases in galactic cosmic ray flux at $r \approx 1$ AU. A short time variation of the calculated flux is also checked and the result is reflected by exposing a negative correlation of the solar wind with the corresponding galactic cosmic ray flux. This means that the higher the solar wind the lower the galactic cosmic rays flux and vice-versa. To obtain a better understanding, the calculated flux and its short time variation at 1 AU are compared to data that shows a good fit to the model making it possible to establish a statistically significant negative correlation of -0.988 ± 0.001 between solar wind variation and galactic cosmic rays flux variation theoretically.

Kinematic Properties of Slow ICMEs and an Interpretation of a Modified Drag Equation for Fast and Moderate ICMEs

T. **Iju**, M. Tokumaru, K. Fujiki

Solar Physics, June 2014, Volume 289, Issue 6, pp 2157-2175

<http://arxiv.org/pdf/1401.1724v1.pdf>

We report kinematic properties of slow interplanetary coronal mass ejections (ICMEs) identified by SOHO/LASCO, interplanetary scintillation, and in situ observations and propose a modified equation for the ICME motion. We identified seven ICMEs between 2010 and 2011 and compared them with 39 events reported in our previous work. We examined 15 fast ($V_{\text{SOHO}} - V_{\text{bg}} > 500$ km s⁻¹), 25 moderate ($0 \text{ km s}^{-1} \leq V_{\text{SOHO}} - V_{\text{bg}} \leq 500$ km s⁻¹), and 6 slow ($V_{\text{SOHO}} - V_{\text{bg}} < 0$ km s⁻¹) ICMEs, where V_{SOHO} and V_{bg} are the initial speed of ICMEs and the speed of the background solar wind. For slow ICMEs, we found the following results: i) They accelerate toward the speed of the background solar wind during their propagation and reach their final speed by 0.34 ± 0.03 AU. ii) The acceleration ends when they reach 479 ± 126 km s⁻¹; this is close to the typical speed of the solar wind during the period of this study. iii) When γ_1 and γ_2 are assumed to be constants, a quadratic equation for the acceleration $a = -\gamma_2 (V - V_{\text{bg}}) |V - V_{\text{bg}}|$ is more appropriate than a linear one $a = -\gamma_1 (V - V_{\text{bg}})$, where V is the propagation speed of ICMEs, while the latter gives a smaller χ^2 value than the former. For the motion of the fast and moderate ICMEs, we found a modified drag equation $a = -2.07 \times 10^{-12} (V - V_{\text{bg}}) |V - V_{\text{bg}}| - 4.84 \times 10^{-6} (V - V_{\text{bg}})$. From the viewpoint of fluid dynamics, we interpret this equation as indicating that ICMEs with $0 \text{ km s}^{-1} \leq V - V_{\text{bg}} \leq 2300$ km s⁻¹ are controlled mainly by the hydrodynamic Stokes drag force, while the aerodynamic drag force is a predominant factor for the propagation of ICME with $V - V_{\text{bg}} > 2300$ km s⁻¹.

Radial Speed Evolution of Interplanetary Coronal Mass Ejections During Solar Cycle 23

T. **Iju**, M. Tokumaru, K. Fujiki

Solar Physics, November 2013, Volume 288, Issue 1, pp 331-353

<http://arxiv.org/pdf/1303.5154v3.pdf>

We report radial-speed evolution of interplanetary coronal mass ejections (ICMEs) detected by the Large Angle and Spectrometric Coronagraph onboard the Solar and Heliospheric Observatory (SOHO/LASCO), interplanetary scintillation (IPS) at 327 MHz, and in-situ observations. We analyze solar-wind disturbance factor (g -value) data derived from IPS observations during 1997–2009 covering nearly the whole period of Solar Cycle 23. By comparing observations from SOHO/LASCO, IPS, and in situ, we identify 39 ICMEs that could be analyzed carefully. Here, we define two speeds [V SOHO and V bg], which are the initial speed of the ICME and the speed of the background solar wind, respectively. Examinations of these speeds yield the following results: i) Fast ICMEs (with V SOHO– V bg > 500 km s $^{-1}$) rapidly decelerate, moderate ICMEs (with 0 km s $^{-1}$ \leq V SOHO– V bg ≤ 500 km s $^{-1}$) show either gradually decelerating or uniform motion, and slow ICMEs (with V SOHO– V bg < 0 km s $^{-1}$) accelerate. The radial speeds converge on the speed of the background solar wind during their outward propagation. We subsequently find; ii) both the acceleration and the deceleration are nearly complete by 0.79 ± 0.04 AU, and those are ended when the ICMEs reach a 480 ± 21 km s $^{-1}$. iii) For ICMEs with $(V$ SOHO– V bg) ≥ 0 km s $^{-1}$, i.e. fast and moderate ICMEs, a linear equation $a = -\gamma_1(V - V_{bg})$ with $\gamma_1 = 6.58 \pm 0.23 \times 10^{-6}$ s $^{-1}$ is more appropriate than a quadratic equation $a = -\gamma_2(V - V_{bg})|V - V_{bg}|$ to describe their kinematics, where γ_1 and γ_2 are coefficients, and a and V are the acceleration and speed of ICMEs, respectively, because the χ^2 for the linear equation satisfies the statistical significance level of 0.05, while the quadratic one does not. These results support the assumption that the radial motion of ICMEs is governed by a drag force due to interaction with the background solar wind. These findings also suggest that ICMEs propagating faster than the background solar wind are controlled mainly by the hydrodynamic Stokes drag.

Table 1. Properties derived from SOHO/LASCO observations and those in the SOHO–IPS region derived from IPS observations for 39 ICMEs during 1997–2009.

Table 2. Properties in the IPS–Earth region derived from IPS observations, detection dates, times, and speeds obtained by in-situ observations at 1 AU, fitting parameters and speeds of the background solar wind for 39 ICMEs during 1997–2009.

Beyond the mini-solar maximum of solar cycle 24: Declining solar magnetic fields and the response of the terrestrial magnetosphere

M. Ingale, P. Janardhan, S. K. Bisoi

JGR **Volume 124, Issue 8** Pages 6363-6383 2019

<https://arxiv.org/pdf/1908.02576.pdf>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2019JA026616>

The present study examines the response of the terrestrial magnetosphere to the long-term steady declining trends observed in solar magnetic fields and solar wind micro-turbulence levels since mid-1990's that has been continuing beyond the mini-solar maximum of cycle 24. A detailed analysis of the response of the terrestrial magnetosphere has been carried out by studying the extent and shape of the Earth's magnetopause and bow shock over the past four solar cycles. We estimate sub-solar stand-off distance of the magnetopause and bow shock, and the shape of the magnetopause using numerical as well as empirical models. The computed magnetopause and bow shock stand-off distances have been found to be increasing steadily since around mid-1990's, consistent with the steady declining trend seen in solar magnetic fields and solar wind micro-turbulence levels. Similarly, we find an expansion in the shape of the magnetopause since 1996. The implications of the increasing trend seen in the magnetopause and bow shock stand-off distances are discussed and a forecast of the shape of the magnetopause in 2020, the minimum of cycle 24, has been made. Importantly, we also find two instances between 1968 and 1991 when the magnetopause stand-off distance dropped to values close to 6.6 earth radii, the geostationary orbit, for duration ranging from 9–11 hours and one event in 2005, post 1995 when the decline in photospheric fields began. Though there have been no such events since 2005, it represents a clear and present danger to our satellite systems.

Recent Voyager Evidence for Rapid Transport of Flare-Generated Disturbances by Polar Coronal Hole Streams

D S Intriligator¹, W D Miller¹, J Intriligator^{1,2}, W Webber³, W Sun⁴, T Detman¹, M Dwyer¹ and C Deehr⁴

Journal of Physics: Conference Series, Volume 900, Number 1 012010 2017

<http://iopscience.iop.org/article/10.1088/1742-6596/900/1/012010/pdf>

Disturbances observed by Voyagers 1 and 2 during the past five years or more may have been transported by plasma emitted from polar coronal holes, thereby having travelled much faster from the Sun to the termination shock than previously recognized. Estimating the average speed to the shock as 750 km/s has produced consistently good

associations between solar flares, or groups of them, and dynamic pressure increases at Voyager 2 and plasma wave events at Voyager 1. Furthermore, magnetograph observations confirm that polar coronal holes were present around the times of the flares to which the events at the Voyagers have been attributed. These calculations also provide revised estimates of the transport of heliospheric current sheet fluctuations. We discuss the possibilities that extrapolations from past observations and simulations based on them may provide insight into currently challenging issues and possible future developments. **Aug. 9, 2011 Sept. 6, 2011, Mar. 10, 2012, Jul. 12, 2012 Jul. 23, 2012, Dec. 14, 2012, Jun. 10, 2014, Dec. 13, 2014 Dec. 17, 2014, Feb. 21, 2015**

Did the July 2012 solar events cause a “tsunami” throughout the heliosphere, heliosheath, and into the interstellar medium?†

Devrie [Intriligator](#)^{1,*}, Wei Sun^{1,2}, Murray Dryer¹, James Intriligator^{1,3}, Charles Deehr², Thomas Detman¹ and William R. Webbe

JGR Volume 120, Issue 10 Volume 120, Issue 10 Oct 2015

The July 2012 major solar events gave rise to manifestations observed at many longitudes/latitudes/radial locations throughout the heliosphere, heliosheath, and into the interstellar medium. For these solar events we present our initial results at 1 AU from our HAFSS (HAF Source Surface) three-dimensional time-dependent kinematic modeling. Our simulations, using WSA maps and solar event observations, start at 2.5 Rs from the center of the Sun. We use both the quiescent background solar conditions and the solar events (e.g., coronal mass ejections (CMEs)) as inputs and propagate outward. We compare HAFSS predictions with in-situ spacecraft measurements and conclude that the July 2012 solar events caused a metaphorical “tsunami” in the plasma and magnetic field throughout the heliosphere/heliosheath/interstellar medium. The simulations show evidence of shocks, interaction regions, and rarefaction regions in the inner heliosphere (1 AU) and shocks, Global Merged Interaction Regions (GMIRs), and rarefaction regions in the heliosheath. The shocks/interaction regions/GMIRs and the rarefaction regions are, respectively, analogous to the “tsunami” “crests” and “troughs”. To provide important insights into 3D processes we simulated 1 AU observations (STEREO A and ACE) and observations at Voyager 2 (V2) and Voyager 1 (V1) far off the ecliptic plane: V2 at ~30° South, 217° longitude, and 102 AU; V1 at 34° North, 174° longitude, and 124 AU. HAFSS successfully predicted observed CME arrival times at 1 AU. Our results for this “tsunami” are the first simulations for these events in the distant V2/V1 radial/latitudinal/longitudinal regions based on 3D time-dependent modeling originating at the Sun.

An Investigation of Properties of the Coronal Holes Producing HSSs InProCH

D. Beşliu [Ionescu](#)^{1, 2} and G. Mariş Muntean¹

SCOSTEP/PRESTO NEWSLETTER Vol. 39, April 2024

https://scostep.org/wp-content/uploads/2024/04/SCOSTEP_PRESTO_Newsletter_Vol39_high_reso.pdf

We have prepared a database that is available online at <http://observer.astro.ro/inproch/>. This database contains coronal holes (CHs) observed during the descending phase of solar cycle 24 (SC24), specifically the period from Apr 2015 to Jul 2017, extended by three months before and after this interval.

FRiED: A NOVEL THREE-DIMENSIONAL MODEL OF CORONAL MASS EJECTIONS

A. [Isavnin](#)

2016 ApJ 833 267

<http://sci-hub.cc/10.3847/1538-4357/833/2/267>

We present a novel three-dimensional (3D) model of coronal mass ejections (CMEs) that unifies all key evolutionary aspects of CMEs and encapsulates their 3D magnetic field configuration. This fully analytic model is capable of reproducing the global geometrical shape of a CME with all major deformations taken into account, i.e., deflection, rotation, expansion, “pancaking,” front flattening, and rotational skew. Encapsulation of 3D magnetic structure allows the model to reproduce in-situ measurements of magnetic field for trajectories of spacecraft-CME encounters of any degree of complexity. As such, the model can be used single-handedly for the consistent analysis of both remote and in-situ observations of CMEs at any heliocentric distance. We demonstrate the latter by successfully applying the model for the analysis of two CMEs. **2010 December 12, 2011 October 1**

Three-Dimensional Evolution of Flux-Rope CMEs and Its Relation to the Local Orientation of the Heliospheric Current Sheet

A. [Isavnin](#), A. Vourlidas, E. K. J. Kilpua

Solar Phys., 2014, File

Flux ropes ejected from the Sun may change their geometrical orientation during their evolution, which directly affects their geoeffectiveness. Therefore, it is crucial to understand how solar flux ropes evolve in the heliosphere to improve our space-weather forecasting tools. We present a follow-up study of the concepts described by Isavnin, Vourlidas, and Kilpua (Solar Phys. 284, 203, 2013). We analyze 14 coronal mass ejections (CMEs), with clear flux-rope signatures, observed during the decay of Solar Cycle 23 and rise of Solar Cycle 24. First, we estimate initial orientations of the flux ropes at the origin using extreme-ultraviolet observations of post-eruption arcades and/or eruptive prominences. Then we reconstruct multi-viewpoint coronagraph observations of the CMEs from ≈ 2 to $30 R_{\odot}$ with a three-dimensional geometric representation of a flux rope to determine their geometrical parameters. Finally, we propagate the flux ropes from $\approx 30 R_{\odot}$ to 1 AU through MHD-simulated background solar wind while using in-situ measurements at 1 AU of the associated magnetic cloud as a constraint for the propagation technique. This methodology allows us to estimate the flux-rope orientation all the way from the Sun to 1 AU. We find that while the flux-ropes' deflection occurs predominantly below $30 R_{\odot}$, a significant amount of deflection and rotation happens between $30 R_{\odot}$ and 1 AU. We compare the flux-rope orientation to the local orientation of the heliospheric current sheet (HCS). We find that slow flux ropes tend to align with the streams of slow solar wind in the inner heliosphere. During the solar-cycle minimum the slow solar-wind channel as well as the HCS usually occupy the area in the vicinity of the solar equatorial plane, which in the past led researchers to the hypothesis that flux ropes align with the HCS. Our results show that exceptions from this rule are explained by interaction with the Parker-spiraled background magnetic field, which dominates over the magnetic interaction with the HCS in the inner heliosphere at least during solar-minimum conditions.

Three-Dimensional Evolution of Erupted Flux Ropes from the Sun ($2 - 20 R_{\odot}$) to 1 AU

A. [Isavnin](#), A. Vourlidas, E. K. J. Kilpua

Solar Physics

May **2013**, Volume 284, Issue 1, pp 203-215; **File**

Studying the evolution of magnetic clouds entrained in coronal mass ejections using in-situ data is a difficult task, since only a limited number of observational points is available at large heliocentric distances. Remote sensing observations can, however, provide important information for events close to the Sun. In this work we estimate the flux rope orientation first in the close vicinity of the Sun ($2 - 20 R_{\odot}$) using forward modeling of STEREO/SECCHI and SOHO/LASCO coronagraph images of coronal mass ejections and then in situ using Grad-Shafranov reconstruction of the magnetic cloud. Thus, we are able to measure changes in the orientation of the erupted flux ropes as they propagate from the Sun to 1 AU. We present both techniques and use them to study 15 magnetic clouds observed during the minimum following Solar Cycle 23 and the rise of Solar Cycle 24. This is the first multievent study to compare the three-dimensional parameters of CMEs from imaging and in-situ reconstructions. The results of our analysis confirm earlier studies showing that the flux ropes tend to deflect towards the solar equatorial plane. We also find evidence of rotation on their travel from the Sun to 1 AU. In contrast to past studies, our method allows one to deduce the evolution of the three-dimensional orientation of individual flux ropes rather than on a statistical basis.

Grad-Shafranov Reconstruction of Magnetic Clouds: Overview and Improvements

A. [Isavnin](#), E. K. J. Kilpua and H. E. J. Koskinen

Solar Physics, Volume 273, Number 1, 205-219, **2011**,

The Grad-Shafranov reconstruction is a method of estimating the orientation (invariant axis) and cross section of magnetic flux ropes using the data from a single spacecraft. It can be applied to various magnetic structures such as magnetic clouds (MCs) and flux ropes embedded in the magnetopause and in the solar wind. We develop a number of improvements of this technique and show some examples of the reconstruction procedure of interplanetary coronal mass ejections (ICMEs) observed at 1 AU by the STEREO, Wind, and ACE spacecraft during the minimum following Solar Cycle 23. The analysis is conducted not only for ideal localized ICME events but also for non-trivial cases of magnetic clouds in fast solar wind. The Grad-Shafranov reconstruction gives reasonable results for the sample events, although it possesses certain limitations, which need to be taken into account during the interpretation of the model results.

Suzaku detection of enigmatic geocoronal solar wind charge exchange event associated with coronal mass ejection

[Daiki Ishi](#), [Kumi Ishikawa](#), [Masaki Numazawa](#), [Yoshizumi Miyoshi](#), [Naoki Terada](#), [Kazuhiisa Mitsuda](#), [Takaya Ohashi](#), [Yuichiro Ezoe](#)

PASJ 2019

<https://arxiv.org/pdf/1902.07652.pdf>

Suzaku detected an enhancement of soft X-ray background associated with solar eruptions on **2013 April 14-15**. The solar eruptions were accompanied by an M6.5 solar flare and a coronal mass ejection with magnetic flux ropes. The enhanced soft X-ray background showed a slight variation in half a day and then a clear one in a few hours. The former spectrum was composed of oxygen emission lines, while the later one was characterized by a series of emission lines from highly ionized carbon to silicon. The soft X-ray enhancement originated from geocoronal solar wind charge exchange. However, there appeared to be no significant time correlation with the solar wind proton flux measured by the ACE and WIND satellites. From other solar wind signatures, we considered that an interplanetary shock associated with the coronal mass ejection and a turbulent sheath immediately behind the shock compressed the ambient solar wind ions and then resulted in the soft X-ray enhancement. Furthermore, the enriched emission lines were presumed to be due to an unusual set of ion abundances and ionization states within the coronal mass ejection. We found a better time correlation with the solar wind alpha flux rather than the solar wind proton flux. Our results suggest that the solar wind proton flux is not always a good indicator of geocoronal solar wind charge exchange, especially associated with coronal mass ejections. Instead, the solar wind alpha flux should be investigated when such a soft X-ray enhancement is detected in astronomical observations.

Intense geomagnetic storm during Maunder minimum possibly by a quiescent filament eruption

[Hiroaki Isobe](#), [Yusuke Ebihara](#), [Akito D. Kawamura](#), [Harufumi Tamazawa](#), [Hisashi Hayakawa](#)

ApJ 887 7 2019

<https://arxiv.org/pdf/1903.08466.pdf>

<https://doi.org/10.3847/1538-4357/ab107e>

<https://sci-hub.st/10.3847/1538-4357/ab107e>

The sun occasionally undergoes the so-called grand minima, in which its magnetic activity, measured by the number of sunspots, is suppressed for decades. The most prominent grand minima, since the beginning of telescopic observations of sunspots, is the Maunder minimum (1645-1715), when the sunspots became rather scarce. The mechanism underlying the grand minima remains poorly understood as there is little observational information of the solar magnetic field at that time. In this study, we examine the records of one candidate aurora display in China and Japan during the Maunder minimum. The presence of auroras in such mid magnetic latitudes indicates the occurrence of great geomagnetic storms that are usually produced by strong solar flares. However, the records of contemporary sunspot observations from Europe suggest that, at least for the likely aurora event, there was no large sunspot that could produce a strong flare. Through simple theoretical arguments, we show that this geomagnetic storm could have been generated by an eruption giant quiescent filament, or a series of such events. **March 2, 1653**

Solar-terrestrial storm of November 18 20, 2003. 1. Near-Earth disturbances in the solar wind

[Ivanov](#), K. G.; [Romashets](#), E. P.; [Kharshiladze](#), A. F.

Geomagnetism and Aeronomy, Volume 46, Issue 3, pp.275-293, 2006, File

Geomagnetizm i Aeronomiya, 2006, Vol. 46, No. 3, pp. 291–309.

The structure, configuration, dynamics, and solar sources of the near-Earth MHD disturbance of the solar wind on November 20, 2003, is considered. The disturbances of October 24 and November 22 after flares from the same AR 10484 (10501) are compared. The velocity field in the leading part of the sporadic disturbance is for the first time studied in the coordinate system stationary relative to the bow shock. A possible scenario of the physical processes in the course of this solar-terrestrial storm is discussed in comparison with the previously developed scenario for the storm of July 15, 2000. It has been indicated that (1) the near-Earth disturbance was observed at the sector boundary (HCS) and in its vicinities and (2) the disturbance MHD structure included: the complicated bow shock, wide boundary layer with reconnecting fields at a transition from the shock to the magnetic cloud, magnetic cloud with a magnetic cavity including packed substance of an active filament, and return shock layer (supposedly). It has been found out that the shock front configuration and the velocity field are reproduced at an identical position of AR and HCS relative to the Earth on November 20 and 24. It has been indicated that the maximal magnetic induction in the cloud satisfied the condition $B_m = (8\pi n l m p)^{1/2} (D - NV1)$, i.e., depended on the dynamic impact on the cloud during all three storms [Ivanov et al., 1974]. When the disturbance was related to solar sources, the attention has been paid to the parallelism of the axes of symmetry of the active filament, transient coronal hole, coronal mass ejection, zero line of the open coronal

field (HCS), and the axis of the near-Earth magnetic cloud: the regularity previously established in the scenario of the storm of July 15, 2000 [Ivanov et al., 2005]. It has been indicated that the extremely large B_m value in the cloud of October 20 was caused by a strong suppression of the series of postflare shocks reflected from the heliospheric streamer.

Interplanetary hydromagnetic clouds as flare-generated spheromaks

Ivanov, K.G., Kharshiladze, A.F.:

1985, Sol. Phys. 98, 379, **File**.

Solar flare-generated interplanetary clouds are proposed to be treated as oblate spheromaks (oblamaks) with predominantly force-free magnetic field. The solution found for a force-free field equation in spheroidal coordinates makes it possible to describe the spheromak magnetic fields by a series of spheroidal wave functions. Comparison between theoretical and experimental results is shown in the case of the hydromagnetic cloud from the November 22, 1977 flare (STIP Interval IV).

Magnetohydrodynamic simulation of coronal mass ejections using interplanetary scintillation data observed from radio sites ISEE and LOFAR

Kazumasa **Iwai**, [Richard A. Fallows](#), [Mario M. Bisi](#), [Daikou Shiota](#), [Bernard V. Jackson](#), [Munetoshi Tokumaru](#), [Ken'ichi Fujiki](#)

Advances in Space Research **2022**

<https://arxiv.org/ftp/arxiv/papers/2209/2209.12486.pdf>

Interplanetary scintillation (IPS) is a useful tool for detecting coronal mass ejections (CMEs) throughout interplanetary space. Global magnetohydrodynamic (MHD) simulations of the heliosphere, which are usually used to predict the arrival and geo-effectiveness of CMEs, can be improved using IPS data. In this study, we demonstrate an MHD simulation that includes IPS data from multiple stations to improve CME modelling. The CMEs, which occurred on 09-10 September 2017, were observed over the period 10-12 September 2017 using the Low-Frequency Array (LOFAR) and IPS array of the Institute for Space-Earth Environmental Research (ISEE), Nagoya University, as they tracked through the inner heliosphere. We simulated CME propagation using a global MHD simulation, SUSANOO-CME, in which CMEs were modeled as spheromaks, and the IPS data were synthesised from the simulation results. The MHD simulation suggests that the CMEs merged in interplanetary space, forming complicated IPS g-level distributions in the sky map. We found that the MHD simulation that best fits both LOFAR and ISEE data provided a better reconstruction of the CMEs and a better forecast of their arrival at Earth than from measurements when these simulations were fit from the ISEE site alone. More IPS data observed from multiple stations at different local times in this study can help reconstruct the global structure of the CME, thus improving and evaluating the CME modelling. **9-12 Sep 2017**

Development of a coronal mass ejection arrival time forecasting system using interplanetary scintillation observations

<https://arxiv.org/ftp/arxiv/papers/2012/2012.12635.pdf>

[sci-hub.se/10.1186/s40623-019-1019-5](https://doi.org/10.1186/s40623-019-1019-5)

Coronal mass ejections (CMEs) cause disturbances in the environment of the Earth when they arrive at the Earth. However, the prediction of the arrival of CMEs still remains a challenge. We have developed an interplanetary scintillation (IPS) estimation system based on a global magnetohydrodynamic (MHD) simulation of the inner heliosphere to predict the arrival time of CMEs. In this system, the initial speed of a CME is roughly derived from white light coronagraph observations. Then, the propagation of the CME is calculated by a global MHD simulation. The IPS response is estimated by the three-dimensional density distribution of the inner heliosphere derived from the MHD simulation. The simulated IPS response is compared with the actual IPS observations made by the Institute for Space-Earth Environmental Research, Nagoya University, and shows good agreement with that observed. We demonstrated how the simulation system works using a halo CME event generated by a X9.3 flare observed on **September 6, 2017**. We find that the CME simulation that best estimates the IPS observation can more accurately predict the time of arrival of the CME at the Earth. These results suggest that the accuracy of the CME arrival time can be improved if our current MHD simulations include IPS data.

Table 1. CME characteristics investigated in this study and their observed and forecasted arrival times.

Forecasting Heliospheric CME Solar-Wind Parameters Using the UCSD Time-Dependent Tomography and ISEE Interplanetary Scintillation Data: The 10 March 2022 CME

Bernard V. Jackson, Munetoshi Tokumaru, Kazumasa Iwai, Matthew T. Bracamontes, +++
Solar Physics volume 298, Article number: 74 (2023)

<https://link.springer.com/content/pdf/10.1007/s11207-023-02169-8.pdf>

Remotely sensed interplanetary scintillation (IPS) data from the Institute for Space-Earth Environmental Research (ISEE), Japan, allows a determination of solar-wind parameters throughout the inner heliosphere. We show the 3D analysis technique developed for these data sets that forecast plasma velocity, density, and component magnetic fields at Earth, as well at the other inner heliospheric planets and spacecraft. One excellent coronal mass ejection (CME) example that occurred on the **10 March 2022** was viewed not only in the ISEE IPS analyses, but also by the spacecraft near Earth that measured the CME arrival at one AU. Solar Orbiter, that was nearly aligned along the Earth radial at 0.45 AU, also measured the CME in plasma density, velocity, and magnetic field. BepiColombo at 0.42 AU was also aligned with the STEREO A spacecraft, and viewed this CME. The instruments used here from BepiColombo include: 1) the European-Space-Agency Mercury-Planetary-Orbiter magnetic field measurements; 2) the Japan Aerospace Exploration Agency Mio spacecraft Solar Particle Monitor that viewed the CME Forbush decrease, and the Mercury Plasma Experiment/Mercury Electron Analyzer instruments that measured particles and solar-wind density from below the spacecraft protective sunshield covering. This article summarizes the analysis using ISEE, Japan real-time data for these forecasts: it provides a synopsis of the results and confirmation of the CME event morphology after its arrival, and discusses how future IPS analyses can augment these results.

Iterative Tomography: A Key to Providing Time- dependent 3-D Reconstructions of the Inner Heliosphere and the Unification of Space Weather Forecasting Techniques

Bernard Jackson^{1*}, Andrew Buffington¹, Lucas Cotal¹, Dusan Odstrcil², Mario M. Bisi³, Richard Fallows⁴ and Munetoshi Tokumaru

<https://www.frontiersin.org/articles/10.3389/fspas.2020.568429/full>

Over several decades UCSD has developed and continually updated a time dependent iterative three-dimensional (3-D) reconstruction technique to provide global heliospheric parameters – density, velocity, and component magnetic fields. For expediency, this has used a kinematic model as a kernel to provide a fit to either interplanetary scintillation (IPS) or Thomson-scattering observations. This technique has been used in near real time over this period, employing Institute for Space-Earth Environmental Research (ISEE), Japan IPS data to predict the propagation of these parameters throughout the inner heliosphere.

We have extended the 3-D reconstruction analysis to include other IPS Stations around the Globe in a Worldwide Interplanetary Scintillation Stations (WIPSS) Network. In addition, we also plan to resurrect the Solar Mass Ejection Imager (SMEI) Thomson-scattering analysis as a basis for 3-D analysis to be used by the latest NASA Small Explorer heliospheric imagers of the Polarimeter to Unify the Corona and Heliosphere (PUNCH) mission, the All Sky Heliospheric Imager (ASHI), and other modern wide-field imagers. Better data require improved Heliospheric modeling that incorporates non-radial transport of heliospheric flows, and shock processes. Looking ahead to this, we have constructed an interface between the 3-D reconstruction tomography and 3-D MHD models, and currently include the ENLIL model as a kernel in the reconstructions to provide this fit. In short, we are now poised to provide all of these innovations in a next step: to include them for planned ground-based and spacecraft instruments, all to be combined into a truly global 3-D heliospheric system which utilizes these aspects in their data and modeling.

A DAILY DETERMINATION OF BZ USING THE RUSSELL-MCPHERRON EFFECT TO FORECAST GEOMAGNETIC ACTIVITY

B.V. Jackson, H.-S. Yu, A. Buffington, P.P. Hick, M. Tokumaru, K. Fujiki, J. Kim, J. Yun

Space Weather Volume17, Issue4 Pages 639-652 2019

[sci-hub.se/10.1029/2018SW002098](https://doi.org/10.1029/2018SW002098)

Since the middle of the last decade, UCSD has incorporated magnetic field data in its Institute for Space-Earth Environmental Research interplanetary scintillation tomographic analysis. These data are extrapolated upward from the solar surface using the Current Sheet Source Surface model (Zhao & Hoeksema, 1995, <https://doi.org/10.1029/94JA02266>) to provide predictions of the interplanetary field in RTN coordinates. Over the years this technique has become ever more sophisticated, and allows different types of magnetogram data (SOLIS, Global Oscillation Network Group, etc.,) to be incorporated in the field extrapolations. At Earth, these fields can be displayed in a variety of ways, including Geocentric Solar Magnetospheric (GSM) Bx, By, and Bz coordinates.

Displayed daily, the Current Sheet Source Surface model-derived GSM Bz shows a significant positive correlation with the low-resolution (few day variation) in situ measurements of the Bz field. The nano-Tesla variations of Bz maximize in spring and fall as Russell and McPherron (1973, <https://doi.org/10.1029/JA078i001p00092>) have shown. More significantly, we find that the daily variations are correlated with geomagnetic Kp and Dst index variations, and that a decrease from positive to negative Bz has a high correlation with minor-to-moderate geomagnetic storm activity, as defined by NOAA Space Weather Prediction Center planetary Kp values. Here we provide an 11-year study of the predicted Bz field, from the extrapolation of the Global Oscillation Network Group-magnetograms. We provide a skill-score analysis of the technique's geomagnetic storm prediction capability, which allows forecasts of moderate enhanced geomagnetic storm activity. UCSD and the Korean Space Weather Center currently operate a website that predicts this low-resolution GSM Bz field component variation several days in advance. **2007/04/21; 2017/03/01**

A Determination of the North–South Heliospheric Magnetic Field Component from Inner Corona Closed-loop Propagation

B. V. **Jackson**¹, P. P. Hick¹, A. Buffington¹, H.-S. Yu¹, M. M. Bisi², M. Tokumaru³, and X. Zhao
2015 ApJ 803 L1

A component of the magnetic field measured in situ near the Earth in the solar wind is present from north–south fields from the low solar corona. Using the Current-sheet Source Surface model, these fields can be extrapolated upward from near the solar surface to 1 AU. Global velocities inferred from a combination of interplanetary scintillation observations matched to in situ velocities and densities provide the extrapolation to 1 AU assuming mass and mass flux conservation. The north–south field component is compared with the same ACE in situ magnetic field component—the Normal (Radial Tangential Normal) Bn coordinate—for three years throughout the solar minimum of the current solar cycle. We find a significant positive correlation throughout this period between this method of determining the Bn field compared with in situ measurements. Given this result from a study during the latest solar minimum, this indicates that a small fraction of the low-coronal Bn component flux regularly escapes from closed field regions. The prospects for Space Weather, where the knowledge of a Bz field at Earth is important for its geomagnetic field effects, is also now enhanced. This is because the Bn field provides the major portion of the Geocentric Solar Magnetospheric Bz field coordinate that couples most closely to the Earth's geomagnetic field.

The UCSD kinematic IPS solar wind boundary and its use in the ENLIL 3-D MHD prediction model

B. V. **Jackson**^{1,*}, D. Odstrcil^{2,3}, H.-S. Yu¹, P. P. Hick¹, A. Buffington¹, J. C. Mejia-Ambriz^{1,4}, J. Kim⁵, S. Hong⁵, Y. Kim⁵, J. Han⁵ and M. Tokumaru
Space Weather [Volume 13, Issue 2](#), pages 104–115, February **2015**

The University of California, San Diego interplanetary scintillation (IPS) time-dependent kinematic 3-D reconstruction technique has been used and expanded upon for over a decade to provide predictions of heliospheric solar wind parameters. These parameters include global reconstructions of velocity, density, and (through potential field modeling and extrapolation upward from the solar surface) radial and tangential interplanetary magnetic fields. Time-dependent results can be extracted at any solar distance within the reconstructed volume and are now being exploited as inner boundary values to drive the ENLIL 3-D MHD model in near real time. The advantage of this coupled system is that it uses the more complete physics of 3-D MHD modeling to provide an automatic prediction of coronal mass ejections and solar wind stream structures several days prior to their arrival at Earth without employing coronagraph observations. Here we explore, with several examples, the current differences between the IPS real-time kinematic analyses and those from the ENLIL 3-D MHD modeling using IPS-derived real-time boundaries. Future possibilities for this system include incorporating many different worldwide IPS stations as input to the remote sensing analysis using ENLIL as a kernel in the iterative 3-D reconstructions.

- Tomographic inner-boundaries are used to drive ENLIL in real-time
- CMEs, shocks, and other interplanetary structures are predicted
- Several comparisons and a successful prediction are shown

2011-09-02, 2014 Apr 18-20

Inclusion of Real-Time In-Situ Measurements into the UCSD Time-Dependent Tomography and Its Use as a Forecast Algorithm

B. V. **Jackson**, J. M. Clover, P. P. Hick, A. Buffington, M. M. Bisi and M. Tokumaru
Solar Physics, July **2013**, Volume 285, Issue 1-2, pp 151-165

The University of California, San Diego (UCSD) three-dimensional (3D) time-dependent tomography program, used for over a decade to reconstruct and forecast coronal mass ejections (CMEs), does so from observations of interplanetary scintillation (IPS) taken using the Solar-Terrestrial Environment Laboratory (STELab) radio arrays in Japan. An earlier article (Jackson et al. in *Solar Phys.* 265, 245, 2010) demonstrated how in-situ velocity measurements from the Advanced Composition Explorer (ACE) space-borne instrumentation can be used in addition to remote-sensing data to constrain a time-dependent tomographic velocity solution. Here we extend this in-situ inclusion to density measurements, and show how this constrains the tomographic density solution. Supplementing remote-sensing observations with in-situ measurements provides additional information to construct an iterated solar-wind parameter that is propagated outward from near the solar surface past the measurement location, and throughout the volume. As in the case of velocity when this is done, the largest changes within the volume are close to the radial directions around Earth that incorporate the in-situ measurements; the inclusion significantly reduces the uncertainty in extending these measurements to global 3D reconstructions that are distant in time and space from the spacecraft. At Earth, this analysis provides a finely tuned real-time result up to the latest time for which in-situ measurements are available, and enables more-accurate extension of these results near Earth to those remotely sensed. We show examples of this new algorithm using real-time STELab IPS data that were used in our forecasts throughout Carrington rotations 2010 through 2016, and we provide one metric prescription that we have used to determine the forecasting accuracy one, two, and three days in advance of the time data become available to analyze from STELab. We show that the accuracy is considerably better than assuming persistence of the same signal over one to two days in advance of when the data are available.

Forecasting transient heliospheric solar wind parameters at the location of the inner planets

B.V. **Jackson**, P.P. Hick, A. Buffington, J.M. Clover and M. Tokumaru

Advances in Geosciences: Solar and Terrestrial Science 30, 93–115, November **2012**

Remotely-sensed interplanetary scintillation (IPS) from the solar-terrestrial environment laboratory (STELab) system, and Thomson-scattering observations from the U.S. Air Force/NASA Solar Mass Ejection Imager (SMEI) allow the determination of solar wind parameters at the locations of the inner planets. We show a 3D analysis technique developed to provide daily-cadence transient solar wind forecasts of velocity and density at Earth and the inner planets. These now include in-situ measurements near Earth available in real time. Where in-situ measurements are available these real-time analyses are compared with the predicted values. Using the global velocity measurements available from IPS analysis and daily updated magnetograms from the National Solar Observatory, we are also able to project outward solar-surface magnetic fields in order to provide reasonable global in-situ magnetic-field component trends from one day to the next. This paper summarizes the analysis available and current progress in using the STELab, Japan real-time data for validating these forecasts. A discussion is also provided as to how we can derive more meaningful future information from these remotely-sensed heliospheric measurements.

The 3D analysis of the heliosphere using interplanetary scintillation and Thomson-scattering observations

B.V. **Jackson**

Adv. in Geosciences, Volume 30: Planetary Science (PS) and Solar & Terrestrial Science (ST), 69-91, **2012**

Both interplanetary scintillation (IPS) and Thomson-scattering observations from the U.S. Air Force/NASA Solar Mass Ejection Imager (SMEI) allow a determination of velocity and density in the inner heliosphere and its forecast from remote-sensing heliospheric observations. Recent solar missions, such as Hinode, STEREO, and SDO, and resultant modeling analysis using these data enhance our ability to measure detailed aspects of specific solar events, including their outflow and three-dimensional structure. Current success in this 3D heliospheric endeavor includes the analysis of heliospheric structures that are also measured in situ: interplanetary Coronal Mass Ejections (CMEs), shocks, solar co-rotating structures, and the energy transport provided by solar wind plasma throughout the heliosphere. This report highlights a portion of the work on this multi-faceted topic.

Solar Mass Ejection Imager (SMEI) 3-D reconstruction of density enhancements behind interplanetary shocks: In-situ comparison near Earth and at STEREO

B.V. **Jackson**, , M.S. Hamiltona, P.P. Hicka, b, A. Buffingtona, M.M. Bisia, c, J.M. Clovera, M. Tokumaru and K. Fujiki

Journal of Atmospheric and Solar-Terrestrial Physics, Volume 73, Issues 11-12, **2011**, Pages 1317-1329

SMEI and IPS remotely observe increased brightness and velocity enhancements behind interplanetary shocks that are also seen in situ. We use the UCSD time-dependent 3-D reconstruction technique to map these enhancements, and compare them with measurements at the SOHO, Wind, ACE, and STEREO spacecraft. The analyses of these shocks from hour-averaged in-situ data show that the enhanced density column associated with the shock response varies considerably between different instruments, even for in-situ instruments located at L1 near Earth. The relatively-low-resolution SMEI 3-D reconstructions generally show density enhancements, and within errors, the column excesses match those observed in situ. In these SMEI 3-D reconstructions from remotely-sensed data, the shock density enhancements appear not as continuous broad fronts, but as segmented structures. This may provide part of the explanation for the observed discrepancies between the various in-situ measurements at Earth and STEREO, but not between individual instruments near L1.

Three-dimensional reconstruction of heliospheric structure using iterative tomography: A review

B.V. Jackson, P.P. Hick, A. Buffington, M.M. Bisi, J.M. Clover, M. Tokumaru, M. Kojima, K. Fujiki
Journal of Atmospheric and Solar-Terrestrial Physics, Volume 73, Issue 10, 2011, Pages 1214-1227
Current perspective and in-situ analyses using data from NASA's twin Solar Terrestrial Relations Observatory (STEREO) spacecraft have focused studies on ways to provide three-dimensional (3-D) reconstructions of coronal and heliospheric structure. Data from STEREO are preceded by and contemporaneous with many other types of data and analysis techniques; most of the latter have provided 3-D information by relying on remote-sensing information beyond those of the near corona (outside 10 RS). These include combinations of past data from the Helios spacecraft and the Solwind coronagraphs and, continuing from the past to the present, from observations of interplanetary scintillation (IPS) and the Solar Mass Ejection Imager (SMEI) instrument. In this article we review past and ongoing analyses that have led to a current great wealth of 3-D information. When properly utilized, these analyses can provide not only shapes of CME/ICMEs but also a characterization of any solar wind structure or global outflow.

Research highlights

► Helios spacecraft photometer data began heliospheric Thomson-scattering analyses. ► SMEI Thomson-scattering data now allows a 3-D analysis of the heliosphere. ► UCSD and Japanese tomography of heliospheric data sets provides their 3-D structure. ► These techniques allow 3-D reconstruction of transient and co-rotating structure.

SMEI 3D RECONSTRUCTION OF A CORONAL MASS EJECTION INTERACTING WITH A COROTATING SOLAR WIND DENSITY ENHANCEMENT: THE 2008 APRIL 26 CME

B. V. Jackson¹, A. Buffington¹, P. P. Hick^{1,2}, J. M. Clover¹, M. M. Bisi^{1,3}, and D. F. Webb⁴
Astrophysical Journal, 724:829–834, 2010

The Solar Mass Ejection Imager (SMEI) has recorded the brightness responses of hundreds of interplanetary coronal mass ejections (CMEs) in the interplanetary medium. Using a three-dimensional (3D) reconstruction technique that derives its perspective views from outward-flowing solar wind, analysis of SMEI data has revealed the shapes, extents, and masses of CMEs. Here, for the first time, and using SMEI data, we report on the 3D reconstruction of a CME that intersects a corotating region marked by a curved density enhancement in the ecliptic. Both the CME and the corotating region are reconstructed and demonstrate that the CME disrupts the otherwise regular density pattern of the corotating material. Most of the dense CME material passes north of the ecliptic and east of the Sun–Earth line: thus, in situ measurements in the ecliptic near Earth and at the *Solar-Terrestrial Relations Observatory Behind* spacecraft show the CME as a minor density increase in the solar wind. The mass of the dense portion of the CME is consistent with that measured by the Large Angle Spectrometric Coronagraph on board the *Solar and Heliospheric Observatory* spacecraft, and is comparable to the masses of many other three-dimensionally reconstructed solar wind features at 1 AU observed in SMEI 3D reconstructions.

SMEI direct, 3-D-reconstruction sky maps, and volumetric analyses, and their comparison with SOHO and STEREO observations

B. V. Jackson, P. P. Hick, A. Buffington, M. M. Bisi, and J. M. Clover
Ann. Geophys., 27, 4097–4104, 2009; File

In this paper we present the results of the analysis of the late January 2007 Coronal Mass Ejection (CME) events recorded by the Solar Mass Ejection Imager (SMEI), the Solar Terrestrial Relations Observatory (STEREO), and the Solar and Heliospheric Observatory (SOHO) spacecraft. This period occurs when the two STEREO spacecraft views

are from close to Earth, and thus the views from both SMEI and the STEREO outer Heliospheric Imagers (HI-2s) coincide. Three-dimensional (3-D) analyses derived from SMEI data show many CMEs that have also been studied by others using short-term image subtractions (image-differencing techniques). During this interval we map several CME structures that are observed in both SMEI and the STEREO-A HI instruments. SMEI brightness analyses provided by short-term image subtractions ("difference images") and, alternatively, subtractions of a mean-brightness fit over a long-time duration, both show the extents of the CMEs travelling outward above the East limb that erupted from the Sun on **24 and 25 January 2007**. The SMEI 3-D-reconstructions not only enhance distinct features within the CME events, but also reconcile difference-imaging results with those where a long-term base has been removed. In the January 2007 example the structure as mapped by CME difference images traces the sharp intensity gradients at the front of the CMEs; generally brighter ejected material follows behind the location of the CME front, but shows poorly in these because of its larger angular extent. Using the long-duration background removal enables SMEI's 3-D analysis to determine a mass for this CME sequence North of the ecliptic.

Solar Mass Ejection Imager 3-D reconstruction of the 27–28 May 2003 coronal mass ejection sequence,

Jackson, B. V., M. M. Bisi, P. P. Hick, A. Buffington, J. M. Clover, and W. Sun, *J. Geophys. Res.*, 113, A00A15, doi:10.1029/2008JA013224, (2008).

<http://www.agu.org/pubs/crossref/2008/2008JA013224.shtml>

The Solar Mass Ejection Imager (SMEI) has recorded the inner-heliospheric response in white-light Thomson scattering for many hundreds of interplanetary coronal mass ejections (ICMEs). Some of these have been observed by the Solar and Heliospheric Observatory (SOHO) Large-Angle Spectroscopic Coronagraph (LASCO) instruments and also in situ by near-Earth spacecraft. This article presents a low-resolution three-dimensional (3-D) reconstruction of the 27–28 May 2003 halo CME event sequence observed by LASCO and later using SMEI observations; this sequence was also observed by all in situ monitors near Earth. The reconstruction derives its perspective views from outward flowing solar wind. Analysis results reveal the shape, extent, and mass of this ICME sequence as it reaches the vicinity of Earth. The extended shape has considerable detail that is compared with LASCO images and masses for this event. The 3-D reconstructed density, derived from the remote-sensed Thomson scattered brightness, is also compared with the Advanced Composition Explorer (ACE) and Wind spacecraft in situ plasma measurements. These agree well in peak and integrated total value for this ICME event sequence when an appropriately enhanced (~20%) electron number density is assumed to account for elements heavier than hydrogen in the ionized plasma.

SMEI observations in the STEREO era,

Jackson, B. V., P. P. Hick, A. Buffington, M. M. Bisi, and E. A. Jensen *Proc. SPIE Int. Soc. Opt. Eng.*, 6689, 66890G, 1 -14, doi:10.1117/12.734870, **2007, File**.

White-light Thomson scattering observations from the Solar Mass Ejection Imager (SMEI) have recorded the inner heliospheric response to many CMEs. Some of these are also observed from the LASCO instrumentation and, most recently, the STEREO spacecraft. Here, we detail several CME events in SMEI observations that have also been observed by the LASCO instrumentation and STEREO spacecrafts. We show how SMEI is able to measure CME events from their first observations as close as 20° from the solar disk until they fade away in the SMEI 180° field of view. We employ a 3D reconstruction technique that provides perspective views as observed from Earth, from outward-flowing solar wind. This is accomplished by iteratively fitting the parameters of a kinematic solar wind density model to the SMEI white-light observations and, where possible, including interplanetary scintillation (IPS) velocity data. This 3D modeling technique enables separating the true heliospheric response in SMEI from background noise, and reconstructing the 3D heliospheric structure as a function of time. These reconstructions allow both separation of CME structure from other nearby heliospheric features and a determination of CME mass. Comparisons with LASCO and STEREO images for individual CMEs or portions of them allow a detailed view of changes to the CME shape and mass as they propagate outward.

2003.05.28-29, 2003.10.28-30

Comparison of the extent and mass of CME events in the interplanetary medium using IPS and SMEI Thomson scattering observations

B. V. **JACKSON***†, P. P. **HICK**†, A. **BUFFINGTON**†, M. M. **BISI**†, M. **KOJIMA**‡,

and M. TOKUMARU[‡]

Astronomical and Astrophysical Transactions, Vol. 26, No. 6, December **2007**, 477–487, **File**
The Solar-Terrestrial Environment Laboratory (STELab), Japan, interplanetary scintillation (IPS) *g*-level and velocity measurements can be used to give the extent of CME disturbances in the interplanetary medium arising from the scattering of the radio waves from distant point-like natural sources through the intervening medium. In addition, white-light Thomson-scattering observations from the Solar Mass Ejection Imager (SMEI) have recorded the inner heliospheric response to several hundred CMEs. The work described here compares and details the difference in three-dimensional (3D) reconstructions for these two data sets for the well-observed **28 October 2003** halo CME seen in LASCO; this passed Earth on 29 October in the SMEI data at the same elongations as IPS *g*-level observations. The SMEI data analysis employs a 3D tomographic reconstruction technique that obtains perspective views from outward-flowing solar wind as observed from Earth, iteratively fitting a kinematic solar wind density model, and when available, including IPS velocity data. This technique improves the separation of the heliospheric response in SMEI from other sources of background noise, and also provides the 3D structure of the CME and its mass. The analysis shows and tracks outward the northward portion of a loop structure of this halo CME. We determine an excess mass for this structure of 6.74×10^{16} g and a total mass of 8.34×10^{16} g in the SMEI analysis, and these are comparable to values obtained using IPS *g*-level data and a 3D reconstruction technique developed for these data and applied to this event. We also extend further the application for these analyses.

Analysis of Solar Wind Events Using Interplanetary Scintillation Remote Sensing 3D Reconstructions and Their Comparison at Mars

B.V. **Jackson** · J.A. Boyer · P.P. Hick · A. Buffington · M.M. Bisi · D.H. Crider
Solar Phys (**2007**) 241: 385–396

Interplanetary Scintillation (IPS) allows observation of the inner heliospheric response to corotating solar structures and coronal mass ejections (CMEs) in scintillation level and velocity. With colleagues at STELab, Nagoya University, Japan, we have developed near-real-time access of STELab IPS data for use in space-weather forecasting. We use a 3D reconstruction technique that produces perspective views from solar corotating plasma and outward-flowing solar wind as observed from Earth by iteratively fitting a kinematic solar wind model to IPS observations. This 3D modeling technique permits reconstruction of the density and velocity structure of CMEs and other interplanetary transients at a relatively coarse resolution: a solar rotational cadence and 10° latitudinal and longitudinal resolution for the corotational model and a one-day cadence and 20° latitudinal and longitudinal heliographic resolution for the time-dependent model. This technique is used to determine solar-wind pressure (“ram” pressure) at Mars. Results are compared with rampressure observations derived from *Mars Global Surveyor* magnetometer data (Crider *et al.*, **2003**, *J. Geophys. Res.* **108**(A12), 1461) for the years 1999 through 2004. We identified 47 independent *in situ* pressure-pulse events above 3.5 nPa in the *Mars Global Surveyor* data in this time period where sufficient IPS data were available. We detail the large pressure pulse observed at Mars in association with a CME that erupted from the Sun on 27 May 2003, which was a halo CME as viewed from Earth. We also detail the response of a series of West-limb CME events and compare their response observed at Mars about 160° west of the Sun – Earth line by the *Mars Global Surveyor* with the response derived from the IPS 3D reconstructions.

Preliminary three-dimensional analysis of the heliospheric response to the 28 October 2003 CME using SMEI white-light observations,

B. V. **Jackson**, A. Buffington, P. P. Hick, X. Wang, D. Webb

JOURNAL OF GEOPHYSICAL RESEARCH, VOL. 111, A04S91, doi:10.1029/2004JA010942, **2006**, **File**.

The Solar Mass Ejection Imager (SMEI) has recorded the inner heliospheric response in white-light Thomson scattering to the 28 October 2003 coronal mass ejection (CME). This preliminary report shows the evolution of this particular event in SMEI observations, as we track it from a first measurement at approximately 20° elongation (angular distance) from the solar disk until it fades in the antisolar hemisphere in the SMEI 180° field of view. The large angle and

spectrometric coronagraph (LASCO) images show a CME and an underlying bright ejection of coronal material that is associated with an erupting prominence. Both of these are seen by SMEI in the interplanetary medium. We employ a three-dimensional (3-D) reconstruction technique that derives its perspective views from outward flowing solar wind to reveal the shape and extent of the CME. This is accomplished by iteratively fitting the parameters of a kinematic solar wind density model to both SMEI white-light observations and Solar-Terrestrial Environment Laboratory (STELab), interplanetary scintillation (IPS) velocity data. This modeling technique separates the true heliospheric signal in SMEI observations from background noise and reconstructs the 3-D heliospheric structure as a function of time. These reconstructions allow separation of the 28 October CME from other nearby heliospheric structure and a determination of its mass. The present results are the first utilizing this type of 3-D reconstruction with the SMEI data. We determine an excess-over-ambient mass for the southward moving ejecta associated with the prominence material of 7.1×10^{16} g and a total mass of 8.9×10^{16} g. Preliminary SMEI white-light calibration indicates that the total mass of this CME including possible associated nearby structures may have been as much as $\sim 2.0 \times 10^{17}$ g spread over much of the earthward facing hemisphere.

The Solar Mass Ejection Imager (SMEI): The mission,

Jackson, B. V., A. Buffington, P. P. Hick, R. C. Altrrock, S. Figueroa, P. E. Holladay, J. C. Johnston, S. W. Kahler, J. B. Mozer and S. Price, et al. (2004), *Sol. Phys.*, 225, 177-- 207

We have launched into near-Earth orbit a solar mass-ejection imager (SMEI) that is capable of measuring sunlight Thomson-scattered from heliospheric electrons from elongations to as close as 18 to greater than 90 from the Sun. SMEI is designed to observe time-varying heliospheric brightness of objects such as coronal mass ejections, co-rotating structures and shock waves. The instrument evolved from the heliospheric imaging capability demonstrated by the zodiacal light photometers of the Helios spacecraft. A near-Earth imager can provide up to three days warning of the arrival of a mass ejection from the Sun. In combination with other imaging instruments in deep space, or alone by making some simple assumptions about the outward flow of the solar wind, SMEI can provide a three-dimensional reconstruction of the surrounding heliospheric density structures.

Models for coronal mass ejections Review

Carla **Jacobsa**, b and Stefaan Poedtsa

Journal of Atmospheric and Solar-Terrestrial Physics, Volume 73, Issue 10, **2011**, Pages 1148-1155

Coronal mass ejections (CMEs) play a key role in space weather. The mathematical modelling of these violent solar phenomena can contribute to a better understanding of their origin and evolution and as such improve space weather predictions. We **review** the state-of-the-art in CME simulations, including a brief overview of current models for the background solar wind as it has been shown that the background solar wind affects the onset and initial evolution of CMEs quite substantially. We mainly focus on the attempt to retrieve the initiation and propagation of CMEs in the framework of computational magnetofluid dynamics (CMFD). Advanced numerical techniques and large computer resources are indispensable when attempting to reconstruct an event from Sun to Earth. Especially the simulations developed in dedicated event studies yield very realistic results, comparable with the observations. However, there are still a lot of free parameters in these models and ad hoc source terms are often added to the equations, mimicking the physics that is not really understood yet in detail.

Research highlights

► New insights in the origin and dynamics of coronal mass ejections. ► New developments in the numerical modelling of CMEs. ► State-of-the-art solar wind models. ► New pieces of the space weather puzzle.

The Internal Structure of Coronal Mass Ejections: Are all Regular Magnetic Clouds Flux Ropes?

C. **Jacobs**, I. I. Roussev, N. Lugaz, and S. Poedts

ApJL, 695, L171-L175, **2009**; doi: [10.1088/0004-637X/695/2/L171](https://doi.org/10.1088/0004-637X/695/2/L171)

In this Letter, we investigate the internal structure of a coronal mass ejection (CME) and its dynamics by invoking a realistic initiation mechanism in a quadrupolar magnetic setting. The study comprises a compressible three-dimensional magnetohydrodynamics simulation. We use an idealized model of the solar corona, into which we superimpose a

quadrupolar magnetic source region. By applying shearing motions resembling flux emergence at the solar boundary, the initial equilibrium field is energized and it eventually erupts, yielding a fast CME. The simulated CME shows the typical characteristics of a magnetic cloud (MC) as it propagates away from the Sun and interacts with a bimodal solar wind. However, no distinct flux rope structure is present in the associated interplanetary ejection. In our model, a series of reconnection events between the eruptive magnetic field and the ambient field results in the creation of significant writhe in the CME's magnetic field, yielding the observed rotation of the magnetic field vector, characteristic of an MC. We demonstrate that the magnetic field lines of the CME may suffer discontinuous changes in their mapping on the solar surface, with footpoints subject to meandering over the course of the eruption due to magnetic reconnection. We argue that CMEs with internal magnetic structure such as that described here should also be considered while attempting to explain in situ observations of regular MCs at L1 and elsewhere in the heliosphere.

Turbulence dynamics and flow speeds in the inner solar corona: Results from radio-sounding experiments by the Akatsuki spacecraft

Richa N. [Jain](#), [R. K. Choudhary](#), [Anil Bhardwaj](#), [T. Imamura](#), [Anshuman Sharma](#), [Umang M. Parikh](#)

MNRAS **2023**

<https://arxiv.org/pdf/2308.12596.pdf>

The solar inner corona is a region that plays a critical role in energizing the solar wind and propelling it to supersonic and supra-Alfvenic velocities. Despite its importance, this region remains poorly understood because of being least explored due to observational limitations. The coronal radio sounding technique in this context becomes useful as it helps in providing information in parts of this least explored region. To shed light on the dynamics of the solar wind in the inner corona, we conducted a study using data obtained from coronal radio-sounding experiments carried out by the Akatsuki spacecraft during the 2021 Venus-solar conjunction event. By analyzing X-band radio signals recorded at two ground stations (IDSN in Bangalore and UDSC in Japan), we investigated plasma turbulence characteristics and estimated flow speed measurements based on isotropic quasi-static turbulence models. Our analysis revealed that the speed of the solar wind in the inner corona (at heliocentric distances from 5 to 13 solar radii), ranging from 220-550 km/sec, was higher than the expected average flow speeds in this region. By integrating our radio-sounding results with EUV images of the solar disk, we gained a unique perspective on the properties and energization of high-velocity plasma streams originating from coronal holes. We tracked the evolution of fast solar wind streams emanating from an extended coronal hole as they propagated to increasing heliocentric distances. Our study provides unique insights into the least-explored inner coronal region by corroborating radio sounding results with EUV observations of the corona. **14 Mar-2 Apr 2021**

Sensitivity of Model Estimates of CME Propagation and Arrival Time to Inner Boundary Conditions

Space Weather [Volume21, Issue4](#) e2022SW003289 **2023**

<https://doi.org/10.1029/2022SW003289>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2022SW003289>

Accurately forecasting the arrival of coronal mass ejections (CMEs) at Earth is important to enabling mitigation of the associated space weather risks to society. This is only possible with accurate modeling of the event. To do so, we must understand the propagation of a CME through the heliosphere and quantify the performance of models through comparison with spacecraft observations. For the **12 December 2008** Earth-directed CME event, we compute ensembles using the HUXt solar wind model to analyze CME distortion with a structured solar wind and explore hindcast arrival time error (ATE). By highlighting the impact CME shape has on Root-Mean-Square-Error (RMSE) values, we show that time-elongation profiles of fronts captured by the Heliospheric Imager (HI) instruments onboard NASA's STEREO mission match those of the modeled CME nose and flank and can therefore be used to infer details of the longitudinal extent of the CME. We then show that accounting for CME distortion is important to enable accurate estimates of the CME arrival at Earth. This can be achieved by either using observations of multiple features in HI data to infer CME evolution or mapping the solar wind back to a lower inner boundary to allow CMEs to be distorted close to the Sun. For the event studied we show that these approaches resulted in reduced RMSEs of 0.73° and 0.64° with an ATE of 1 hour and 3 hours respectively.

Comparison of ICME arrival times and solar wind parameters based on the WSA-ENLIL model with three cone types and observations†

Soojeong **Jang**, Y.-J. Moon*, Jae-Ok Lee and Hyeonock Na
JGR, Volume 119, Issue 9, pages 7120–7127, **2014**

We have made a comparison between CME-associated shock propagations based on the WSA-ENLIL model using three cone types and in-situ observations. For this we use 28 full-halo CMEs, whose cone parameters are determined and their corresponding interplanetary shocks were observed at the Earth, from 2001 to 2002. We consider three different cone types (an asymmetric cone model, an ice-cream cone model, and an elliptical cone model) to determine 3-D CME cone parameters (radial velocity, angular width and source location), which are the input values of the WSA-ENLIL model. The mean absolute error (MAE) of the CME-associated shock travel times for the WSA-ENLIL model using the ice-cream cone model is 9.9 hours, which is about 1 hour smaller than those of the other models. We compare the peak values and profiles of solar wind parameters (speed and density) with in-situ observations. We find that the root mean square (RMS) errors of solar wind peak speed and density for the ice-cream and asymmetric cone model are about 190 km/s and 24 /cm³, respectively. We estimate the cross correlations between the models and observations within the time lag of ± 2 days from the shock travel time. The correlation coefficients between the solar wind speeds from the WSA-ENLIL model using three cone types and in-situ observations are approximately 0.7, which is larger than those of solar wind density (~ 0.6). Our preliminary investigations show that the ice-cream cone model seems to be better than the other cone models in terms of the input parameters of the WSA-ENLIL model. **7 Sept 2002**

The two-step Forbush decrease: a tale of two substructures modulating galactic cosmic rays within coronal mass ejections

Miho **Janvier**, [Pascal Démoulin](#), [Jingnan Guo](#), [Sergio Dasso](#), [Florian Regnault](#), [Sofia Topsis-Moutesidou](#), [Christian Gutierrez](#), [Barbara Perri](#)

<https://doi.org/10.3847/1538-4357/ac2b9b>

Interplanetary Coronal Mass Ejections (ICMEs) are known to modify the structure of the solar wind as well as interact with the space environment of planetary systems. Their large magnetic structures have been shown to interact with galactic cosmic rays, leading to the Forbush decrease (FD) phenomenon. We revisit in the present article the 17 years of Advanced Composition Explorer spacecraft ICME detection along with two neutron monitors (McMurdo and Oulu) with a superposed epoch analysis to further analyze the role of the magnetic ejecta in driving FDs. We investigate in the following the role of the sheath and the magnetic ejecta in driving FDs, and we further show that for ICMEs without a sheath, a magnetic ejecta only is able to drive significant FDs of comparable intensities. Furthermore, a comparison of samples with and without a sheath with similar speed profiles enable us to show that the magnetic field intensity, rather than its fluctuations, is the main driver for the FD. Finally, the recovery phase of the FD for isolated magnetic ejecta shows an anisotropy in the level of the GCRs. We relate this finding at 1 au to the gradient of the GCR flux found at different heliospheric distances from several interplanetary missions.

Generic Magnetic Field Intensity Profiles of Interplanetary Coronal Mass Ejections at Mercury, Venus, and Earth From Superposed Epoch Analyses

[sci-hub.tw/10.1029/2018JA025949](https://doi.org/10.1029/2018JA025949)

<https://arxiv.org/pdf/1901.09921.pdf>

We study interplanetary coronal mass ejections (ICMEs) measured by probes at different heliocentric distances (0.3–1 AU) to investigate the propagation of ICMEs in the inner heliosphere and determine how the generic features of ICMEs change with heliospheric distance. Using data from the Mercury Surface, Space ENvironment, GEochemistry, and Ranging (MESSENGER), Venus Express and ACE spacecraft, we analyze with the superposed epoch technique the profiles of ICME substructures, namely, the sheath and the magnetic ejecta. We determine that the median magnetic field magnitude in the sheath correlates well with ICME speeds at 1 AU, and we use this proxy to order the ICMEs at all spacecraft. We then investigate the typical ICME profiles for three categories equivalent to slow, intermediate, and fast ICMEs. Contrary to fast ICMEs, slow ICMEs have a weaker solar wind field at the front and a more symmetric magnetic field profile. We find the asymmetry to be less pronounced at Earth than at Mercury, indicating a relaxation taking place as ICMEs propagate. We also find that the magnetic field intensities in the wake region of the ICMEs do not go back to the pre-ICME solar wind intensities, suggesting that the effects of ICMEs on the ambient solar wind last longer than the duration of the transient event. Such results provide an indication of physical processes that need to be

reproduced by numerical simulations of ICME propagation. The samples studied here will be greatly improved by future missions dedicated to the exploration of the inner heliosphere, such as Parker Solar Probe and Solar Orbiter.

Comparing generic models for interplanetary shocks and magnetic clouds axis configurations at 1 AU

Miho **Janvier**, Sergio Dasso, Pascal Demoulin, Jimmy Masias-Meza, Noe Lugaz

JGR Volume 120, Issue 5 Pages i - vi, pages 3328–3349 2015

<http://arxiv.org/pdf/1503.06128v1.pdf>

Interplanetary Coronal Mass Ejections are the manifestation of solar transient eruptions, which can significantly modify the plasma and magnetic conditions in the heliosphere. They are often preceded by a shock, and a magnetic flux rope is detected in situ in a third to half of them. The main aim of this study is to obtain the best quantitative shape for the flux rope axis and for the shock surface from in situ data obtained during spacecraft crossings of these structures. We first compare the orientation of the flux ropes axes and shock normals obtained from independent data analyses of the same events, observed in situ at 1AU from the Sun. Then, we carry out an original statistical analysis of axes/shock normals by deriving the statistical distributions of their orientations. We fit the observed distributions using the distributions derived from several synthetic models describing these shapes. We show that the distributions of axis/shock orientations are very sensitive to their respective shape. One classical model, used to analyze interplanetary imager data, is incompatible with the in situ data. Two other models are introduced, for which the results for axis and shock normals lead to very similar shapes; the fact that the data for MCs and shocks are independent strengthen this result. The model which best fit all the data sets has an ellipsoidal shape with similar aspect ratio values for all the data sets. These derived shapes for the flux rope axis and shock surface have several potential applications. First, these shapes can be used to construct a consistent ICME model. Second, these generic shapes can be used to develop a quantitative model to analyze imager data, as well as constraining the output of numerical simulations of ICMEs. Finally, they will have implications for space weather forecasting, in particular for forecasting the time arrival of ICMEs at the Earth.

In Situ Properties of Small and Large Flux Ropes in the Solar Wind

M. **Janvier**, P. Demoulin, S. Dasso

JGR, Volume 119, Issue 9, pages 7088–7107, 2014

<http://arxiv.org/pdf/1408.5520v1.pdf> ; File

Two populations of twisted magnetic field tubes, or flux ropes (hereafter, FRs), are detected by in situ measurements in the solar wind. While small FRs are crossed by the observing spacecraft within few hours, with a radius typically less than 0.1AU, larger FRs, or magnetic clouds (hereafter, MCs), have durations of about half a day.

The main aim of this study is to compare the properties of both populations of FRs observed by the Wind spacecraft at 1 AU.

To do so, we use standard correlation techniques for the FR parameters, as well as histograms and more refined statistical methods. Although several properties seem at first different for small FRs and MCs, we show that they are actually governed by the same propagation physics. For example, we observe no in situ signatures of expansion for small FRs, contrary to MCs. We demonstrate that this result is in fact expected: small FRs expand similarly to MCs, as a consequence of a total pressure balance with the surrounding medium, but the expansion signature is well hidden by velocity fluctuations.

Next, we find that the FR radius, velocity and magnetic field strength are all positively correlated, with correlation factors than can reach a value >0.5 . This result indicates a remnant trace of the FR ejection process from the corona. We also find a larger FR radius at the apex than at the legs (up to three times larger at the apex), for FR observed at 1 AU.

Finally, assuming that the detected FRs have a large-scale configuration in the heliosphere, we derived the mean axis shape from the probability distribution of the axis orientation. We therefore interpret the small FR and MC properties in a common framework of FRs interacting with the solar wind, and we disentangle the physics present behind their common and different features.

Mean shape of interplanetary shocks deduced from in situ observations and its relation with interplanetary CMEs

M. **Janvier**, P. Démoulin and S. Dasso

A&A 565, A99 (2014)

Context. Shocks are frequently detected by spacecraft in the interplanetary space. However, the in situ data of a shock do not provide direct information on its overall properties even when a following interplanetary coronal mass ejection (ICME) is detected.

Aims. The main aim of this study is to constrain the general shape of ICME shocks with a statistical study of shock orientations.

Methods. We first associated a set of shocks detected near Earth over 10 years with a sample of ICMEs over the same period. We then analyzed the correlations between shock and ICME parameters and studied the statistical distributions of the local shock normal orientation. Supposing that shocks are uniformly detected all over their surface projected on the 1 AU sphere, we compared the shock normal distribution with synthetic distributions derived from an analytical shock shape model. Inversely, we derived a direct method to compute the typical general shape of ICME shocks by integrating observed distributions of the shock normal.

Results. We found very similar properties between shocks with and without an in situ detected ICME, so that most of the shocks detected at 1 AU are ICME-driven even when no ICME is detected. The statistical orientation of shock normals is compatible with a mean shape having a rotation symmetry around the Sun-apex line. The analytically modeled shape captures the main characteristics of the observed shock normal distribution. Next, by directly integrating the observed distribution, we derived the mean shock shape, which is found to be comparable for shocks with and without a detected ICME and weakly affected by the limited statistics of the observed distribution. We finally found a close correspondence between this statistical result and the leading edge of the ICME sheath that is observed with STEREO imagers.

Conclusions. We have derived a mean shock shape that only depends on one free parameter. This mean shape can be used in various contexts, such as studies for high-energy particles or space weather forecasts.

New approach to unveil the shape of interplanetary structures

M. **Janvier**, P. Demoulin, S. Dasso

How local in situ data can still reveal the mean shape of interplanetary structures

Are There Different Populations of Flux Ropes in the Solar Wind?

M. **Janvier**, P. Demoulin, S. Dasso

E-print, Feb 2014, Solar Physics July 2014, Volume 289, Issue 7, pp 2633-2652

<http://arxiv.org/pdf/1401.6812v1.pdf>

Flux ropes are twisted magnetic structures, which can be detected by in situ measurements in the solar wind. However, different properties of detected flux ropes suggest different types of flux-rope population. As such, are there different populations of flux ropes? The answer is positive, and is the result of the analysis of four lists of flux ropes, including magnetic clouds (MCs), observed at 1 AU. The in situ data for the four lists have been fitted with the same cylindrical force-free field model, which provides an estimation of the local flux-rope parameters such as its radius and orientation. Since the flux-rope distributions have a large dynamic range, we go beyond a simple histogram analysis by developing a partition technique that uniformly distributes the statistical fluctuations over the radius range. By doing so, we find that small flux ropes with radius $R < 0.1$ AU have a steep power-law distribution in contrast to the larger flux ropes (identified as MCs), which have a Gaussian-like distribution. Next, from four CME catalogs, we estimate the expected flux-rope frequency per year at 1 AU. We find that the predicted numbers are similar to the frequencies of MCs observed in situ. However, we also find that small flux ropes are at least ten times too abundant to correspond to CMEs, even to narrow ones. Investigating the different possible scenarios for the origin of those small flux ropes, we conclude that these twisted structures can be formed by blowout jets in the low corona or in coronal streamers.

Global axis shape of magnetic clouds deduced from the distribution of their local axis orientation

Janvier M., Demoulin P., Dasso S.

E-print, May 2013, A&A 556, A50 (2013)

Context. Coronal mass ejections (CMEs) are routinely tracked with imagers in the interplanetary space, while magnetic clouds (MCs) properties are measured locally by spacecraft. However, both imager and in situ data do not provide any direct estimation of the general flux rope properties.

Aims. The main aim of this study is to constrain the global shape of the flux rope axis from local measurements and to compare the results from in-situ data with imager observations.

Methods. We performed a statistical analysis of the set of MCs observed by WIND spacecraft over 15 years in the vicinity of Earth. We analyzed the correlation between different MC parameters and studied the statistical distributions of the angles defining the local axis orientation. With the hypothesis of having a sample of MCs with a uniform distribution of spacecraft crossing along their axis, we show that a mean axis shape can be derived from the distribution of the axis orientation. As a complement, while heliospheric imagers do not typically observe MCs but only their sheath region, we analyze one event where the flux rope axis can be estimated from the STEREO imagers.

Results. From the analysis of a set of theoretical models, we show that the distribution of the local axis orientation is strongly affected by the overall axis shape. Next, we derive the mean axis shape from the integration of the observed orientation distribution. This shape is robust because it is mostly determined from the overall shape of the distribution. Moreover, we find no dependence on the flux rope inclination on the ecliptic. Finally, the derived shape is fully consistent with the one derived from heliospheric imager observations of the June 2008 event.

Conclusions. We have derived a mean shape of MC axis that only depends on one free parameter, the angular separation of the legs (as viewed from the Sun). This mean shape can be used in various contexts, such as studies of high-energy particles or space weather forecasts. **2008-06-03**

Direct Measurements of Synchrotron-emitting Electrons at Near-Sun Shocks

<https://iopscience.iop.org/article/10.3847/2041-8213/ad8eb8/pdf>

In this study, we present the first-ever direct measurements of synchrotron-emitting heliospheric traveling shocks, intercepted by the Parker Solar Probe (PSP) during its close encounters. Given that much of our understanding of powerful astrophysical shocks is derived from synchrotron radiation, these observations by PSP provide an unprecedented opportunity to explore how shocks accelerate relativistic electrons and the conditions under which they emit radiation. The probe's unparalleled capabilities to measure both electromagnetic fields and energetic particles with high precision in the near-Sun environment has allowed us to directly correlate the distribution of relativistic electrons with the resulting photon emissions. Our findings reveal that strong quasi-parallel shocks emit radiation at significantly higher intensities than quasi-perpendicular shocks due to the efficient acceleration of ultrarelativistic electrons. These experimental results are consistent with theory and recent observations of supernova remnant shocks and advance our understanding of shock physics across diverse space environments. **2022 September 5, 2023 March 13**

Acceleration of electrons and ions by an "almost" astrophysical shock in the heliosphere

Immanuel Christopher **Jebaraj**, [Oleksiy Agapitov](#), [Vladimir Krasnoselskikh](#), [Laura Vuorinen](#), [Michael Gedalin](#), +++

ApJ **2024**

<https://arxiv.org/pdf/2405.07074>

Collisionless shock waves, ubiquitous in the universe, are crucial for particle acceleration in various astrophysical systems. Currently, the heliosphere is the only natural environment available for their in situ study. In this work, we showcase the collective acceleration of electrons and ions by one of the fastest in situ shocks ever recorded, observed by the pioneering Parker Solar Probe at only 34.5 million kilometers from the Sun. Our analysis of this unprecedented, near-parallel shock shows electron acceleration up to 6 MeV amidst intense multi-scale electromagnetic wave emissions. We also present evidence of a variable shock structure capable of injecting and accelerating ions from the solar wind to high energies through a self-consistent process. The exceptional capability of the probe's instruments to measure electromagnetic fields in a shock traveling at 1% the speed of light has enabled us, for the first time, to confirm that the structure of a strong heliospheric shock aligns with theoretical models of strong shocks observed in astrophysical environments. This alignment offers viable avenues for understanding astrophysical shock processes and the acceleration of charged particles. **13 Mar 2023**

The Faraday Effect Tracker of Coronal and Heliospheric Structures (FETCH) Instrument

Elizabeth **Jensen**, Nat Gopalswamy, Lynn Wilson III, Lan Jian, Shing Fung, +++

Front. Astron. Space Sci., 10:1064069. **2023**

<https://www.frontiersin.org/articles/10.3389/fspas.2023.1064069/pdf>

There continue to be open questions regarding the solar wind and coronal mass ejections (CMEs). For example: how do magnetic fields within CMEs and corotating/stream interaction regions (CIRs/SIRs) evolve in the inner heliosphere? What is the radially distributed magnetic profile of shock-driving CMEs? What is the internal magnetic structure of CMEs that cause magnetic storms? It is clear that these questions involve the magnetic configurations of solar wind and transient interplanetary plasma structures, for which we have limited knowledge. In order to better understand the origin of the magnetic field variability in steady-state structures and transient events, it is necessary to probe the magnetic field in Earth-directed structures/disturbances. This is the goal of the Multiview Observatory for Solar Terrestrial Science (MOST) mission ([Gopalswamy et al., 2022](#)). For MOST to answer the aforementioned questions, we propose the instrument concept of the Faraday Effect Tracker of Coronal and Heliospheric structures (FETCH), a simultaneous quad-line-of-sight polarization radio remote-sensing instrument. With FETCH, spacecraft radio beams passing through the Sun–Earth line offer the possibility of obtaining information of plasma conditions via analysis of radio propagation effects such as Faraday rotation and wave dispersion, which provide information of the magnetic field and total electron content (TEC). This is the goal of the FETCH instrument, one of ten instruments proposed to be hosted on the MOST mission. The MOST mission will provide an unprecedented opportunity to achieve NASA’s heliophysics science goal to “explore and characterize the physical processes in the space environment from the Sun” ([Gopalswamy et al., 2022](#)).

Novel Magnetic Field and Electron Density Measurements of CMEs (within AU) with the Proposed Multiview Observatory for Solar Terrestrial Science (MOST) Mission

Jensen, P. E., C. S. P., Elizabeth ; [Manchester, Ward](#) ; [Fung, Shing](#) ; [Gopalswamy, Nat](#) et al.

AGU Fall Meeting 2021, held in New Orleans, LA, 13-17 December 2021, id. SH33A-08. **2021**

The Multiview Observatory for Solar Terrestrial Science (MOST) mission concept will be the most advanced solar observatory to date (Gopalswamy et al, SH0001, 2021). Comprising four spacecraft, two located in the L4 and ahead of L4 position and two located in the L5 and behind of the L5 position, the four lines-of-sight (LOSs) form the basis for the unique Faraday Effect Tracker of Coronal and Heliospheric Structures (FETCH) instrument (Wexler et al, SH0019, 2021). We report on our modeling into the expected Faraday rotation (FR) caused by an Earth-directed CME crossing the MOST/FETCH radio-sensing paths using a heliospheric 3-D MHD model to obtain the necessary LOS data on electron density and magnetic field components (see example image). Specifically, we utilized simulation data of the 2005 May 13 CME (Manchester IV et al., 2014, Plasma Phys. Control. Fusion), which erupted from the north-south polarity inversion line of AR 10759 at 16:03 UT, reaching speeds around 2000 km/s in the corona. The trajectory of the CME at an acute angle to the Earth-Sun line crosses each FETCH LOS at a different time. Two LOSs are at different viewing angles with little overlap between the CME sheath and magnetic flux rope core. A blind test fitting of the Faraday rotation functions (Figures 6 and 7 in Jensen et al., 2010, Sol. Phys.) to the simulated FETCH observations reproduced the orientation of the CME for its handedness as well as its associated complementary degenerate solution. In conclusion, one of the four LOSs will be more sensitive to observing CME flux rope structure of Earthward CMEs, depending on their trajectory. We find that two of the four LOSs enable analyzing CME evolution, whereas the other two LOSs enable analyzing the average magnetic field vector in the corresponding high density regions dominating the measurements at that time. For example, the average sheath magnetic field vector can be partially measured in the plane of the ecliptic due to the angular differences between 2 LOSs. We discuss future work as this effort develops.

Modeling FETCH Observations of 2005 May 13 CME

Elizabeth A. **Jensen**, [Ward B. Manchester IV](#), [David B. Wexler](#), [Jason E. Kooi](#), [Teresa Nieves-Chinchilla](#), [Lan K. Jian](#), [Alexei Pevtsov](#), [Shing Fung](#)

ApJ **2022**

<https://arxiv.org/pdf/2209.03350.pdf>

This paper evaluates the quality of CME analysis that has been undertaken with the rare Faraday rotation observation of an eruption. Exploring the capability of the FETCH instrument hosted on the MOST mission, a four-satellite Faraday rotation radio sounding instrument deployed between the Earth and the Sun, we discuss the opportunities and challenges to improving the current analysis approaches.

Plasma Interactions with the Space Environment in the Acceleration Region: Indications of CME-trailing Reconnection Regions

Astrophysical Journal, 861:118 (12pp), **2018** July 10

<http://sci-hub.tw/http://iopscience.iop.org/0004-637X/861/2/118/>

Coronal mass ejections (CMEs) are sources of major geomagnetic disturbances. On **2013 May 10**, a CME crossed the signal path between the MErcury Surface, Space ENvironment, GEOchemistry, and Ranging (MESSENGER) spacecraft and Earth. Using the MESSENGER signal, characteristics of the density, velocity, and magnetic field properties of the crossing plasma were measured. An anomalously strong event occurred in the plasma trailing the CME's passage that correlated with a wave mode conversion, indicating a potential reconnection region. We determine that the plasma following CMEs should be considered when studying how CMEs evolve in interplanetary space and the severity of their geomagnetic impact.

Faraday Rotation Response to Coronal Mass Ejection Structure

E.A. **Jensen** · P.P. Hick · M.M. Bisi · B.V. Jackson · J. Clover · T. Mulligan

Solar Phys (2010) 265: 31–48

We present the results from modeling the coronal mass ejection (CME) properties that have an effect on the Faraday rotation (FR) signatures that may be measured with an imaging radio antenna array such as the Murchison Widefield Array (MWA). These include the magnetic flux rope orientation, handedness, magnetic-field magnitude, velocity, radius, expansion rate, electron density, and the presence of a shock/sheath region. We find that simultaneous multiple radio source observations (FR imaging) can be used to uniquely determine the orientation of the magnetic field in a CME, increase the advance warning time on the geoeffectiveness of a CME by an order of magnitude from the warning time possible from *in-situ* observations at L_1 , and investigate the extent and structure of the shock/sheath region at the leading edge of fast CMEs. The magnetic field of the heliosphere is largely “invisible” with only a fraction of the interplanetary magnetic-field lines convecting past the Earth; remote sensing the heliospheric magnetic field through FR imaging from the MWA will advance solar physics investigations into CME evolution and dynamics.

Faraday rotation observations of CMEs.

Simultaneous observations obtained by the Solwind coronagraph and Faraday rotation of the Helios radio frequency carrier signal in 1979 showed that CMEs produce characteristic ‘W’ or sigmoid transients in Faraday rotation observations similar to those observed by Pioneer 6 and 9 in 1968 and 1970. We demonstrate that a relaxed flux-rope model is capable of reproducing these observations. Through fitting the model to the observations, we can obtain information on the flux rope orientation, position, size, velocity, rate of change of rope radius and pitch angle. With electron density measurements, we can also obtain a measure of the magnetic field strength. These fits demonstrate that Faraday rotation observations can provide information on the magnetic field of a CME shortly after it erupts.

Comparison of Dst forecast models for intense geomagnetic storms

Ji, Eun-Young; Moon, Y.-J.; Gopalswamy, N.; Lee, D.-H.

J. Geophys. Res., Vol. 117, No. A3, A03209, 2012, **File**

We have compared six Dst forecast models using 63 intense geomagnetic storms ($Dst \leq -100$ nT) that occurred from 1998 to 2006. For comparison, we estimated linear correlation coefficients and RMS errors between the observed Dst data and the predicted Dst during the geomagnetic storm period as well as the difference of the value of minimum Dst (ΔDst_{min}) and the difference in the absolute value of Dst minimum time (Δt_{Dst}) between the observed and the predicted. As a result, we found that the model by Temerin and Li (2002, 2006) gives the best prediction for all parameters when all 63 events are considered. The model gives the average values: the linear correlation coefficient of 0.94, the RMS error of 14.8 nT, the ΔDst_{min} of 7.7 nT, and the absolute value of Δt_{Dst} of 1.5 hour. For further comparison, we classified the storm events into two groups according to the magnitude of Dst. We found that the model of Temerin and Lee (2002, 2006) is better than the other models for the events having $-100 \leq Dst < -200$ nT, and three recent models (the model of Wang et al. (2003), the model of Temerin and Li (2002, 2006), and the model of Boynton et al. (2011b)) are better than the other three models for the events having $Dst \leq -200$ nT.

Statistical comparison of interplanetary conditions causing intense geomagnetic storms (Dst

=< -100 nT)

Ji, Eun-Young; Moon, Y.-J.; Kim, K.-H.; Lee, D.-H.

J. Geophys. Res., Vol. 115, No. A10, A10232, 2010, **File**

It is well known that intense southward magnetic field and convection electric field ($V \times B$) in the interplanetary medium are key parameters that control the magnitude of geomagnetic storms. By investigating the interplanetary conditions of 82 intense geomagnetic storms from 1998 to 2006, we have compared many different criteria of interplanetary conditions for the occurrence of the intense geomagnetic storms ($Dst \leq -100$ nT). In order to examine if the magnetosphere always favors such interplanetary conditions for the occurrence of large geomagnetic storms, we applied these conditions to all the interplanetary data during the same period. For this study, we consider three types of interplanetary conditions as follows: B_z conditions, E_y conditions, and their combination. As a result, we present contingency tables between the number of events satisfying the condition and the number of observed geomagnetic storms. Then we obtain their statistical parameters for evaluation such as probability of detection yes, false alarm ratio, bias, and critical success index. From a comparison of these statistical parameters, we suggest that three conditions are promising candidates to trigger an intense storm: $B_z \leq -10$ nT for >3 h, $E_y \geq 5$ mV/m for >2 h, and $B_z \leq -15$ nT or $E_y \geq 5$ mV/m for >2 h. Also, we found that more than half of the “miss” events, when an intense storm occurs that was not expected, are associated with sheath field structures or corotating interacting regions. Our conditions can be used for not only the real-time forecast of geomagnetic storms but also the survey of interplanetary data to identify candidate events for producing intense geomagnetic storms.

STUDY OF THE 2007 APRIL 20 CME-COMET INTERACTION EVENT WITH AN MHD MODEL

Y. D. **Jia**¹, C. T. Russell¹, L. K. Jian¹, W. B. Manchester², O. Cohen², A. Vourlidas³, K. C. Hansen², M. R. Combi², and T. I. Gombosi²

Astrophysical Journal, 696:L56–L60, 2009 May

<http://arxiv.org/pdf/0903.4942v1.pdf>

This study examines the tail disconnection event on 2007 April 20 on comet 2P/Encke, caused by a coronal mass ejection (CME) at a heliocentric distance of 0.34 AU. During their interaction, both the CME and the comet are visible with high temporal and spatial resolution by the STEREO-A spacecraft. Previously, only current sheets or shocks have been accepted as possible reasons for comet tail disconnections, so it is puzzling that the CME caused this event. The MHD simulation presented in this work reproduces the interaction process and demonstrates how the CME triggered a tail disconnection in the April 20 event. It is found that the CME disturbs the comet with a combination of a 180° sudden rotation of the interplanetary magnetic field (IMF), followed by a 90° gradual rotation. Such an interpretation applies our understanding of solar wind-comet interactions to determine the in situ IMF orientation of the CME encountering Encke.

Solar Terrestrial Relations Observatory (STEREO) Observations of Stream Interaction Regions in 2007 – 2016: Relationship with Heliospheric Current Sheets, Solar Cycle Variations, and Dual Observations

L. K. **Jian**, [J. G. Luhmann](#), [C. T. Russell](#), [A. B. Galvin](#)

[Solar Physics](#) March 2019, 294:31

<http://sci-hub.tw/https://link.springer.com/article/10.1007/s11207-019-1416-8>

We have conducted a survey of 575 slow-to-fast stream interaction regions (SIRs) using Solar Terrestrial Relations Observatory (STEREO) A and B data, analyzing their properties while extending a Level-3 data product through 2016. Among 518 pristine SIRs, 54% are associated with heliospheric current sheet (HCS) crossings, and 34% are without any HCS crossing. The other 12% of the SIRs often occur in association with magnetic sectors shorter than three days. The SIRs with HCS crossings have slightly slower speeds but higher maximum number densities, magnetic-field strengths, dynamic pressures, and total pressures than the SIRs without an HCS. The iron charge state is higher throughout the SIRs with an HCS than the SIRs without an HCS, by about 1/31/3 charge unit. In contrast with the comparable phases of Solar Cycle 23, slightly more SIRs and higher recurrence rates are observed in the years 2009 – 2016 of Cycle 24, with a lower HCS association rate, possibly attributed to persistent equatorial coronal holes and more pseudo-streamers in this recent cycle. The solar-wind speed, peak magnetic field, and peak pressures of SIRs are all lower in this cycle, but the weakening is less than for the comparable background solar-wind parameters. Before STEREO-B lost contact in October 2014, 151 SIR pairs were observed by the twin spacecraft. Of the dual observations, the maximum speed is the best correlated of the plasma parameters. We have obtained a sample of plasma-parameter differences analogous to those that would be observed by a mission at Lagrange points 4 or 5. By studying several cases with large discrepancies between the dual observations, we investigate the effects of HCS relative location, tilt of stream interface, and small

transients on the SIR properties. To resolve the physical reasons for the variability of SIR structures, mesoscale multi-point observations and time-dependent solar-wind modeling are ultimately required.

STEREO Observations of Interplanetary Coronal Mass Ejections in 2007–2016

L. K. **Jian**^{1,2}, C. T. Russell^{3,4}, J. G. Luhmann⁵, and A. B. Galvin^{6,7}

2018 ApJ 855 114

<http://sci-hub.se/http://iopscience.iop.org/0004-637X/855/2/114/>

sci-hub.se/10.3847/1538-4357/aab189

We have conducted a survey of 341 interplanetary coronal mass ejections (ICMEs) using STEREO A/B data, analyzing their properties while extending a Level 3 product through 2016. Among the 192 ICMEs with distinguishable sheath region and magnetic obstacle, the magnetic field maxima in the two regions are comparable, and the dynamic pressure peaks mostly in the sheath. The north/south direction of the magnetic field does not present any clear relationship between the sheath region and the magnetic obstacle. About 71% of ICMEs are expanding at 1 au, and their expansion speed varies roughly linearly with their maximum speed except for ICMEs faster than 700 km s⁻¹. The total pressure generally peaks near the middle of the well-defined magnetic cloud (MC) passage, while it often declines along with the non-MC ICME passage, consistent with our previous interpretation concerning the effects of sampling geometry on what is observed. The hourly average iron charge state reaches above 12+ ~31% of the time for MCs, ~16% of the time for non-MC ICMEs, and ~1% of the time for non-ICME solar wind. In four ICMEs abrupt deviations of the magnetic field from the nominal field rotations occur in the magnetic obstacles, coincident with a brief drop or increase in field strength—features could be related to the interaction with dust. In comparison with the similar phases of solar cycle 23, the STEREO ICMEs in this cycle occur less often and are generally weaker and slower, although their field and pressure compressions weaken less than the background solar wind. **2006 Dec 14-15, 2009 Nov 1-3, 2010 Feb 5-6, 2011 Apr 5-6, 2012 Jan 1-2, 2013 December 1-4**

Validation for global solar wind prediction using Ulysses comparison: Multiple coronal and heliospheric models installed at the Community Coordinated Modeling Center

L. K. **Jian**, P. J. MacNeice, M. L. Mays, A. Taktakishvili, D. Odstrcil, B. Jackson, H.-S. Yu, P. Riley, I. V. Sokolov

Space Weather Volume 14, Issue 8 August 2016 Pages 592–611

The prediction of the background global solar wind is a necessary part of space weather forecasting. Several coronal and heliospheric models have been installed and/or recently upgraded at the Community Coordinated Modeling Center (CCMC), including the Wang-Sheely-Arge (WSA)-Enlil model, MHD-Around-a-Sphere (MAS)-Enlil model, Space Weather Modeling Framework (SWMF), and heliospheric tomography using interplanetary scintillation data. Ulysses recorded the last fast latitudinal scan from southern to northern poles in 2007. By comparing the modeling results with Ulysses observations over seven Carrington rotations, we have extended our third-party validation from the previous near-Earth solar wind to middle to high latitudes, in the same late declining phase of solar cycle 23. Besides visual comparison, we have quantitatively assessed the models' capabilities in reproducing the time series, statistics, and latitudinal variations of solar wind parameters for a specific range of model parameter settings, inputs, and grid configurations available at CCMC. The WSA-Enlil model results vary with three different magnetogram inputs. The MAS-Enlil model captures the solar wind parameters well, despite its underestimation of the speed at middle to high latitudes. The new version of SWMF misses many solar wind variations probably because it uses lower grid resolution than other models. The interplanetary scintillation-tomography cannot capture the latitudinal variations of solar wind well yet. Because the model performance varies with parameter settings which are optimized for different epochs or flow states, the performance metric study provided here can serve as a template that researchers can use to validate the models for the time periods and conditions of interest to them.

Validation for solar wind prediction at Earth: Comparison of coronal and heliospheric models installed at the CCMC

L. K. **Jian**, P. J. MacNeice, A. Taktakishvili, D. Odstrcil, B. Jackson, H.-S. Yu, P. Riley, I. V. Sokolov, R. M. Evans

Space Weather [Volume 13, Issue 5](#) May 2015 Pages 316–338

Multiple coronal and heliospheric models have been recently upgraded at the Community Coordinated Modeling Center (CCMC), including the Wang-Sheely-Arge (WSA)-Enlil model, MHD-Around-a-Sphere (MAS)-Enlil model, Space Weather Modeling Framework (SWMF), and heliospheric tomography using interplanetary scintillation data. To investigate the effects of photospheric magnetograms from different sources, different coronal models, and different

model versions on the model performance, we run these models in 10 combinations. Choosing seven Carrington rotations in 2007 as the time window, we compare the modeling results with the Operating Mission as Nodes on the Internet data for near-Earth space environment during the late declining phase of solar cycle 23. Visual comparison is proved to be a necessary addition to the quantitative assessment of the models' capabilities in reproducing the time series and statistics of solar wind parameters. The MAS-Enlil model captures the time patterns of solar wind parameters better, while the WSA-Enlil model matches with the time series of normalized solar wind parameters better. Models generally overestimate slow wind temperature and underestimate fast wind temperature and magnetic field. Using improved algorithms, we have identified magnetic field sector boundaries (SBs) and slow-to-fast stream interaction regions (SIRs) as focused structures. The success rate of capturing them and the time offset vary largely with models. For this quiet period, the new version of MAS-Enlil model works best for SBs, while heliospheric tomography works best for SIRs. The new version of SWMF with more physics added needs more development. General strengths and weaknesses for each model are diagnosed to provide an unbiased reference to model developers and users.

Electromagnetic Waves near the Proton Cyclotron Frequency: STEREO Observations

L. K. [Jian](#)^{1,2}, H. Y. Wei³, C. T. Russell³, J. G. Luhmann⁴, B. Klecker⁵, N. Omid⁶, P. A. Isenberg⁷, M. L. Goldstein², A. Figueroa-Viñas², and X. Blanco-Cano
2014 ApJ 786 123

Transverse, near-circularly polarized, parallel-propagating electromagnetic waves around the proton cyclotron frequency were found sporadically in the solar wind throughout the inner heliosphere. They could play an important role in heating and accelerating the solar wind. These low-frequency waves (LFWs) are intermittent but often occur in prolonged bursts lasting over 10 minutes, named "LFW storms." Through a comprehensive survey of them from Solar Terrestrial Relations Observatory A using dynamic spectral wave analysis, we have identified 241 LFW storms in 2008, present 0.9% of the time. They are left-hand (LH) or right-hand (RH) polarized in the spacecraft frame with similar characteristics, probably due to Doppler shift of the same type of waves or waves of intrinsically different polarities. In rare cases, the opposite polarities are observed closely in time or even simultaneously. Having ruled out interplanetary coronal mass ejections, shocks, energetic particles, comets, planets, and interstellar ions as LFW sources, we discuss the remaining generation scenarios: LH ion cyclotron instability driven by greater perpendicular temperature than parallel temperature or by ring-beam distribution, and RH ion fire hose instability driven by inverse temperature anisotropy or by cool ion beams. The investigation of solar wind conditions is compromised by the bias of the one-dimensional Maxwellian fit used for plasma data calibration. However, the LFW storms are preferentially detected in rarefaction regions following fast winds and when the magnetic field is radial. This preference may be related to the ion cyclotron anisotropy instability in fast wind and the minimum in damping along the radial field.

A Disconnection Event of Comet Lulin†

[Jian](#)-chun, Shi; Chi-sheng, Lin; Zhong-wei, Hu; Hai-bin, Zhao; Yue-hua, Ma
Chinese Astronomy and Astrophysics, Volume 35, Issue 3, p. 295-303. **2011**

The cometary disconnection event (DE) is the separation of the entire cometary tail or a part of it from the cometary head. It is one of the most spectacular phenomena of comets. The driving mechanism remains unclear, and at present there are many competitive theories to explain the onset of DE. However, the variable solar wind is suspected to play a major role. Comet Lulin exhibited a DE on 4th Feb. 2009. The data around this date are analyzed, and it is found that the comet Lulin had already endured a DE on 3rd Feb. 2009. By comparing the morphologies of the plasma tails in these two DEs, it is concluded that the DE which occurred on 3rd Feb. 2009 is another DE, which is distinct from that of 4th Feb. 2009. In this paper, we describe the results of analysis on the DE dated 3rd Feb. 2009. The measured velocity of disconnection motion is about 68 km/s, and the calculated onset time of this DE is 3.635 ± 0.215 Feb. 2009 in UT decimal date. Combining the orbital characteristics of Comet Lulin before and after the DE occurrence and the solar-wind data measured by the STEREO-A spacecraft, it is concluded that the DE which occurred on 3rd Feb. 2009 was probably caused by the magnetic reconnection due to the interaction between the comet and a coronal mass ejection (CME).

Multi-Spacecraft Observations: Stream Interactions and Associated Structures

L.K. [Jian](#) · C.T. Russell · J.G. Luhmann · A.B. Galvin · P.J. MacNeice
Solar Phys (2009) 259: 345–360

The stream interaction region (SIR), formed when a fast stream overtakes a preceding slow stream, is the predominant large-scale solar wind structure at this early phase of the STEREO mission. Using multi-spacecraft observations from STEREO A and B, ACE, *Wind*, and *Ulysses* in 2007, we analyze three stream interaction events in depth in May, August, and November of 2007, respectively, when the spacecraft had quite different spatial separations. We attempt to determine the causes of the differences in the SIR properties, whether they are spatial or temporal variations, and also to examine the steepening or widening of the SIR during its radial evolution. The presence and characteristics of associated shocks, the relation to the heliospheric current sheet, and other structures are also studied.

Stream Interactions and Interplanetary Coronal Mass Ejections at 0.72 AU

L.K. **Jian** · C.T. Russell · J.G. Luhmann · R.M. Skoug · J.T. Steinberg

Solar Phys (2008) 249: 85–101

<http://www.springerlink.com/content/q86841161156n644/fulltext.pdf>

We present comprehensive surveys of 203 stream interaction regions (SIRs) and 124 interplanetary CMEs (ICMEs) during 1979 – 1988 using *Pioneer Venus Orbiter* (PVO) *in situ* solar-wind observations at 0.72 AU and examine the solar-cycle variations of the occurrence rate, shock association rate, duration, width, maximum total perpendicular pressure (P_t), maximum dynamic pressure, maximum magnetic field intensity, and maximum velocity change of these two large-scale solar-wind structures. The medians, averages, and histogram distributions of these parameters are also reported. Furthermore, we sort ICMEs into three groups based on the temporal profiles of P_t , and we investigate the variations of the fractional occurrence rate of three groups of ICMEs with solar activity. We find that the fractional occurrence rate of magnetic-cloud-like ICMEs declined with solar activity, consistent with our former 1-AU results. This study at 0.72 AU provides a point of comparison in the inner heliosphere for examining the radial evolution of SIRs and ICMEs. The width of SIRs and ICMEs increases by 0.04 and 0.1 AU, respectively, and the maximum P_t decreases to about 1/3 from Venus to Earth orbit. In addition, our work establishes the statistical properties of the solar-wind conditions at 0.72 AU that control the solar-wind interaction with Venus and its atmosphere loss by related processes.

PROPERTIES OF INTERPLANETARY CORONAL MASS EJECTIONS AT ONE AU DURING 1995 – 2004

L. **JIAN**, C.T. RUSSELL, J.G. LUHMANN, and R.M. SKOUG

Solar Physics (2006) 239: 393–436, **File**

We present a comprehensive survey of 230 interplanetary CMEs (ICMEs) during 1995 – 2004 using *Wind* and ACE *in situ* observations near one AU, and examine the solar-cycle variation of the occurrence rate, shock association rate, scale size, velocity change, and other properties of ICMEs. The ICME occurrence rate increases (from 5 in 1996 to 40 in 2001) with solar activity; and 66% of all ICMEs occurred with shock(s). A compound parameter, the total pressure perpendicular to the magnetic field (P_t), *i.e.*, the sum of magnetic and perpendicular plasma thermal pressures, assists us in effectively distinguishing ICMEs from other solar-wind structures such as stream interactions, and in quantifying the interaction strength. We interpret the characteristic signatures of the P_t temporal variation in terms of the inferred distance perpendicular to the flow to the center of the obstacle. Group 1 includes events that appear to be traversed near the ICME center, showing an apparent enhanced central P_t ; Group 3 represents ICMEs passed far away from the center, displaying a rapid rise and then gradual decay in P_t ; and Group 2 includes events with intermediate signatures. About 36% of 198 classifiable ICMEs are Group 1 events, consistent with the conventional wisdom that at one AU a magnetic cloud is found during crossings of only ~1/3 of ICMEs. Our set of Group 1 ICMEs and the set of magnetic clouds from other researchers have significant overlap and a similar solar-cycle dependence. The rough decline of the Group 1 fraction as solar activity increases, is consistent with rough increases of scale size, shock percentage, and peak P_t . These results call into question the need to have different mechanisms to create differently appearing ICMEs. Rather it is possible that all ICMEs have a central flux rope that is traversed about 33% of the time, but in the majority of cases is missed by the spacecraft.

A New Scenario of Solar Modulation Model during the Polarity Reversing

Jieteng **Jiang**, [Sujie Lin](#), [Lili Yang](#)

ApJ **2023**

<https://arxiv.org/pdf/2303.04460.pdf>

When the Galactic Cosmic Rays (GCRs) entering the heliosphere, they encounter the solar wind plasma, and their intensity is reduced, so-called solar modulation. The modulation is caused by the combination of a few factors, such as particle energies, solar activity and solar disturbance. In this work, a 2D numerical method is adopted to simulate the propagation of GCRs in the heliosphere with SOLARPROP, and to overcome the time-consuming issue, the machine learning technique is also applied. With the obtained proton local interstellar spectra (LIS) based on the observation from Voyager 1 and AMS-02, the solar modulation parameters during the solar maximum activity of cycle 24 have been found. It shows the normalization and index of the diffusion coefficient indeed reach a maximal value in February 2014. However, after taking into account the travel time of particles with different energies, the peak time was found postponed to November 2014 as expected. The nine-month late is so-called time lag.

During Two Steps of Energy Conversion in Magnetic Reconnection Exhaust Region of Solar Wind

He **Jiansen**¹, Zhu Xingyu¹, Chen Yajie¹, Salem Chadi², Stevens Michael³, Li Hui⁴, Ruan Wenzhi^{1,5}, Zhang Lei⁴, and Tu Chuanyi¹

2018 ApJ 856 148

<http://sci-hub.tw/http://iopscience.iop.org/0004-637X/856/2/148/>

The magnetic reconnection exhaust is a pivotal region with enormous magnetic energy being continuously released and converted. The physical processes of energy conversion involved are so complicated that an all-round understanding based on in situ measurements is still lacking. We present the evidence of plasma heating by illustrating the broadening of proton and electron velocity distributions, which are extended mainly along the magnetic field, in an exhaust of interchange reconnection between two interplanetary magnetic flux tubes of the same polarity on the Sun. The exhaust is asymmetric across an interface, with both sides being bounded by a pair of compound discontinuities consisting of rotational discontinuity and slow shock. The energized plasmas are found to be firehose unstable, and responsible for the emanation of Alfvén waves during the second step of energy conversion. It is realized that the energy conversion in the exhaust can be a two-step process involving both plasma energization and wave emission. **1997 November 23**

Properties of Steady Sub-Alfvénic Solar Wind in Comparison with Super-Alfvénic Wind from Measurements of Parker Solar Probe

Yiming **Jiao**, [Ying D. Liu](#), [Hao Ran](#), [Wenshuai Cheng](#)

ApJ **960** 42 **2023**

<https://arxiv.org/pdf/2311.15622.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ad0dfe/pdf>

We identify more than ten steady sub-Alfvénic solar wind intervals from the measurements of the Parker Solar Probe (PSP) from encounter 8 to encounter 14. An analysis of these sub-Alfvénic intervals reveals similar properties and similar origins. In situ measurements show that these intervals feature a decreased radial Alfvén Mach number resulting from a reduced density and a relatively low velocity, and that switchbacks are suppressed in these intervals. Magnetic source tracing indicates that these sub-Alfvénic streams generally originate from the boundaries inside coronal holes, or narrow/small regions of open magnetic fields. Such properties and origins suggest that these streams are low Mach-number boundary layers (LMBLs), which is a special component of the pristine solar wind proposed by Liu et al. (2023). We find that the LMBL wind, the fast wind from deep inside coronal holes, and the slow streamer wind constitute three typical components of the young solar wind near the Sun. In these sub-Alfvénic intervals, the Alfvén radius varies between 15 and 25 solar radii, in contrast with a typical 12 radii for the Alfvén radius of the super-Alfvénic wind. These results give a self-consistent picture interpreting the PSP measurements in the vicinity of the Sun.

Relation between Latitude-dependent Sunspot Data and Near-Earth Solar Wind Speed

Qirong **Jiao**^{1,2}, Wenlong Liu^{1,2}, Dianjun Zhang^{1,2}, and Jinbin Cao^{1,2}

2023 ApJ 958 70

<https://iopscience.iop.org/article/10.3847/1538-4357/acfc21/pdf>

Solar wind is important for the space environment between the Sun and the Earth and varies with the sunspot cycle, which is influenced by solar internal dynamics. We study the impact of latitude-dependent sunspot data on solar wind speed using the Granger causality test method and a machine-learning prediction approach. The results show that the low-latitude sunspot number has a larger effect on the solar wind speed. The time delay between the annual average solar wind speed and sunspot number decreases as the latitude range decreases. A machine-learning model is developed for the prediction of solar wind speed considering latitude and time effects. It is found that the model performs differently with latitude-dependent sunspot data. It is revealed that the timescale of the solar wind speed is more strongly influenced by low-latitude sunspots and that sunspot data have a greater impact on the 30 day average solar wind speed than on a daily basis. With the addition of sunspot data below $7^{\circ}2$ latitude, the prediction of the daily and 30 day averages is improved by 0.23% and 12%, respectively. The best correlation coefficient is 0.787 for the daily solar wind prediction model.

Assessing the Influence of Input Magnetic Maps on Global Modeling of the Solar Wind and CME-driven Shock in the 2013 April 11 Event

Meng [Jin](#), [Nariaki V. Nitta](#), [Christina M. S. Cohen](#)

Space Weather **Volume20, Issue3** e2021SW002894 2022

<https://arxiv.org/pdf/2202.07214.pdf>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2021SW002894>

In the past decade, significant efforts have been made in developing physics-based solar wind and coronal mass ejection (CME) models, which have been or are being transferred to national centers (e.g., SWPC, CCMC) to enable space weather predictive capability. However, the input data coverage for space weather forecasting is extremely limited. One major limitation is the solar magnetic field measurements, which are used to specify the inner boundary conditions of the global magnetohydrodynamic (MHD) models. In this study, using the Alfvén wave solar model (AWSoM), we quantitatively assess the influence of the magnetic field map input (synoptic/diachronic vs. synchronic magnetic maps) on the global modeling of the solar wind and the CME-driven shock in the **2013 April 11** solar energetic particle (SEP) event. Our study shows that due to the inhomogeneous background solar wind and dynamical evolution of the CME, the CME-driven shock parameters change significantly both spatially and temporally as the CME propagates through the heliosphere. The input magnetic map has a great impact on the shock connectivity and shock properties in the global MHD simulation. Therefore this study illustrates the importance of taking into account the model uncertainty due to the imperfect magnetic field measurements when using the model to provide space weather predictions.

Chromosphere to 1 AU Simulation of the 2011 March 7th Event: A Comprehensive Study of Coronal Mass Ejection Propagation

M. [Jin](#), W. B. Manchester, B. van der Holst, I. Sokolov, G. Toth, A. Vourlidas, C. A. de Koning, T. I. Gombosi

ApJ **834** 172 2016

<https://arxiv.org/pdf/1611.08897v1.pdf>

http://www.lmsal.com/~jinmeng/papers/mjin17a_apj.pdf

We perform and analyze results of a global magnetohydrodynamic (MHD) simulation of the fast coronal mass ejection (CME) that occurred on **2011 March 7**. The simulation is made using the newly developed Alfvén Wave Solar Model (AWSoM), which describes the background solar wind starting from the upper chromosphere and extends to $24 R_{\odot}$. Coupling AWSoM to an inner heliosphere (IH) model with the Space Weather Modeling Framework (SWMF) extends the total domain beyond the orbit of Earth. Physical processes included in the model are multi-species thermodynamics, electron heat conduction (both collisional and collisionless formulations), optically thin radiative cooling, and Alfvén-wave turbulence that accelerates and heats the solar wind. The Alfvén-wave description is physically self-consistent, including non-Wentzel-Kramers-Brillouin (WKB) reflection and physics-based apportioning of turbulent dissipative heating to both electrons and protons. Within this model, we initiate the CME by using the Gibson-Low (GL) analytical flux rope model and follow its evolution for days, in which time it propagates beyond STEREO A. A detailed comparison study is performed using remote as well as *in situ* observations. Although the flux rope structure is not compared directly due to lack of relevant ejecta observation at 1 AU in this event, our results show that the new model can reproduce many of the observed features near the Sun (e.g., CME-driven extreme ultraviolet (EUV) waves, deflection of the flux rope from the coronal hole, "double-front" in the white light images) and in the heliosphere (e.g., shock propagation direction, shock properties at STEREO A).

Data Constrained Coronal Mass Ejections in A Global Magnetohydrodynamics Model

M. **Jin**, W. B. Manchester, B. van der Holst, I. Sokolov, G. Toth, R. E. Mullinix, A. Taktakishvili, A. Chulaki, T. I. Gombosi

<http://arxiv.org/pdf/1605.05360v1.pdf>

http://www.lmsal.com/~jinmeng/papers/mjin17b_apj.pdf

We present a first-principles-based coronal mass ejection (CME) model suitable for both scientific and operational purposes by combining a global magnetohydrodynamics (MHD) solar wind model with a flux rope-driven CME model. Realistic CME events are simulated self-consistently with high fidelity and forecasting capability by constraining initial flux rope parameters with observational data from GONG, SOHO/LASCO, and STEREO/COR. We automate this process so that minimum manual intervention is required in specifying the CME initial state. With the newly developed data-driven Eruptive Event Generator Gibson-Low (EEGGL), we present a method to derive Gibson-Low (GL) flux rope parameters through a handful of observational quantities so that the modeled CMEs can propagate with the desired CME speeds near the Sun. A test result with CMEs launched with different Carrington rotation magnetograms are shown. Our study shows a promising result for using the first-principles-based MHD global model as a forecasting tool, which is capable of predicting the CME direction of propagation, arrival time, and ICME magnetic field at 1 AU (see companion paper by Jin et al. 2016b).

Intense Flare-CME Event of the Year 2015: Propagation and Interaction Effects between Sun and Earth's Orbit

Abhishek **Johri**, P.K. Manoharan

Solar Phys. Volume 291, Issue 5, pp 1433-1446

2016

<http://arxiv.org/pdf/1603.04555v1.pdf>

sci-hub.tw/10.1007/s11207-016-0900-7

In this paper, We report the interplanetary effects of a fast coronal mass ejection (CME) associated with the intense X2.7 flare that occurred on **05 May 2015**. The near-Sun signatures of the CME at low-coronal heights $< 2 \{R_{\odot}\}$ are obtained from the EUV images at 171 $\{AA\}$ and metric radio observations. The intensity and duration of the CME-driven radio bursts in the near-Sun and interplanetary medium indicate this CME event to be an energetic one. The interplanetary scintillation data, along with the low-frequency radio spectrum, played a crucial role in understanding the radial evolution of the speed and expansion of the CME in the inner heliosphere as well as its interaction with a preceding slow CME. The estimation of the speed of the CME at several points along the Sun to 1 AU shows that i) the CME went through a rapid acceleration as well as expansion up to a height of $\approx 6 \{R_{\odot}\}$, and ii) the CME continued to propagate at speed $\geq 800 \text{ kms}^{-1}$ between the Sun and 1 AU. These results show that the CME likely overcame the drag exerted by the ambient/background solar-wind with the support of its internal magnetic energy. When the CME interacted with a slow preceding CME, the turbulence level associated with the CME-driven disturbance increased significantly.

The visual complexity of coronal mass ejections follows the solar cycle

S. R. Jones, **C. J. Scott**, **L. A. Barnard**, **R. Highfield**, **C. J. Lintott**, **E. Baeten**

Space Weather e2020SW002556 **2020**

<https://doi.org/10.1029/2020SW002556>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2020SW002556>

The Heliospheric Imagers on board NASA's twin STEREO spacecraft show that coronal mass ejections (CMEs) can be visually complex structures. To explore this complexity, we created a citizen science project with the UK Science Museum, in which participants were shown pairs of CME images and asked to decide which image in each pair appeared the most 'complicated'. A Bradley-Terry model was then applied to these data to rank the CMEs by their 'complicatedness', or 'visual complexity'. This complexity ranking revealed that the annual average visual complexity values follow the solar activity cycle, with a higher level of complexity being observed at the peak of the cycle. The average complexity of CMEs observed by STEREO-A was also found to be significantly higher than those observed by STEREO-B. Visual complexity was found to be associated with CME size and brightness, but our results suggest that complexity may be influenced by the scale-sizes of structure in the CMEs. **15 June 2011**

The Science of Sungrazers, Sunskirters, and Other Near-Sun Comets

Review

Geraint H. **Jones**, **Matthew M. Knight**, **Karl Battams**, **Daniel C. Boice**...

Space Science Reviews February **2018**, 214:20–86 pp.

<https://link.springer.com/content/pdf/10.1007%2Fs11214-017-0446-5.pdf>

This review addresses our current understanding of comets that venture close to the Sun, and are hence exposed to much more extreme conditions than comets that are typically studied from Earth. The extreme solar heating and plasma environments that these objects encounter change many aspects of their behaviour, thus yielding valuable information on both the comets themselves that complements other data we have on primitive solar system bodies, as well as on the near-solar environment which they traverse. We propose clear definitions for these comets: We use the term near-Sun comets to encompass all objects that pass sunward of the perihelion distance of planet Mercury (0.307 AU). Sunskirters are defined as objects that pass within 33 solar radii of the Sun's centre, equal to half of Mercury's perihelion distance, and the commonly-used phrase sungrazers to be objects that reach perihelion within 3.45 solar radii, i.e. the fluid Roche limit. Finally, comets with orbits that intersect the solar photosphere are termed sundivers. We summarize past studies of these objects, as well as the instruments and facilities used to study them, including space-based platforms that have led to a recent revolution in the quantity and quality of relevant observations. Relevant comet populations are described, including the Kreutz, Marsden, Kracht, and Meyer groups, near-Sun asteroids, and a brief discussion of their origins. The importance of light curves and the clues they provide on cometary composition are emphasized, together with what information has been gleaned about nucleus parameters, including the sizes and masses of objects and their families, and their tensile strengths. The physical processes occurring at these objects are considered in some detail, including the disruption of nuclei, sublimation, and ionisation, and we consider the mass, momentum, and energy loss of comets in the corona and those that venture to lower altitudes. The different components of comae and tails are described, including dust, neutral and ionised gases, their chemical reactions, and their contributions to the near-Sun environment. Comet-solar wind interactions are discussed, including the use of comets as probes of solar wind and coronal conditions in their vicinities. We address the relevance of work on comets near the Sun to similar objects orbiting other stars, and conclude with a discussion of future directions for the field and the planned ground- and space-based facilities that will allow us to address those science topics.

Interaction between coronal mass ejections and the solar wind

Jones, R. A.; Breen, A. R.; Fallows, R. A.; Canals, A.; Bisi, M. M.; Lawrence, G.
J. Geophys. Res., Vol. 112, No. A8, A08107

Interplanetary scintillation measurements (IPS).

The European Incoherent Scatter Radar and the Multi Element Radio Linked Interferometer Network systems, with a field of view covering 10–120 solar radii, can provide information on iCMEs in the inner regions of the solar wind. The results provide additional confirmation that iCMEs converge toward the velocity of the solar wind ahead of the event and that most of the resulting acceleration or deceleration occurs in the innermost regions of the solar wind.

The interaction of comet 153P/Ikeya-Zhang with interplanetary coronal mass ejections: Identification of fast ICME signatures

Geraint H. **Jones**¹ and John C. Brandt

Geophysical Research Letters, Volume 31, Issue 20, CiteID L20805, **2004**

The active comet 153P/Ikeya-Zhang possessed a highly-variable plasma tail. Favorable circumstances allowed the identification of the impact of fast ICMEs with the comet. The impact produces a specific morphology including a characteristic scalloped appearance which suggests that the ICME magnetic field drapes around preexisting tail density enhancements. This appears to be the first direct association between fast ICMEs and plasma tail structure and the specific structure should permit the identification of fast ICME locations in the heliosphere.

Revisiting two-step Forbush decreases

Jordan, A. P.; Spence, H. E.; Blake, J. B.; Shaul, D. N. A.

J. Geophys. Res., Vol. 116, No. A11, A11103, **2011**

<http://dx.doi.org/10.1029/2011JA016791>

Interplanetary coronal mass ejections (ICMEs) and their shocks can sweep out galactic cosmic rays (GCRs), thus creating Forbush decreases (FDs). The traditional model of FDs predicts that an ICME and its shock decrease the GCR intensity in a two-step profile. This model, however, has been the focus of little testing. Thus, our goal is to discover whether a passing ICME and its shock inevitably lead to a two-step FD, as predicted by the model. We use cosmic ray data from 14 neutron monitors and, when possible, high time resolution GCR data from the spacecraft International Gamma Ray Astrophysical Laboratory (INTEGRAL). We analyze 233 ICMEs that should have created two-step FDs. Of these, only 80 created FDs, and only 13 created two-step FDs. FDs are thus less common than predicted by the model. The majority of events indicates that profiles of FDs are more complicated, particularly within the ICME sheath, than predicted by the model. We conclude that the traditional model of FDs as having one or two steps should be

discarded. We also conclude that generally ignored small-scale interplanetary magnetic field structure can contribute to the observed variety of FD profiles.

Multipoint, high time resolution galactic cosmic ray observations associated with two interplanetary coronal mass ejections

Jordan, A. P.; Spence, H. E.; Blake, J. B.; Mulligan, T.; Shaul, D. N. A.; Galametz, M. J. *Geophys. Res.*, Vol. 114, No. A7, A07107, **2009**

<http://dx.doi.org/10.1029/2008JA013891>

Galactic cosmic rays (GCRs) play an important role in our understanding of the interplanetary medium (IPM). The causes of their short timescale variations, however, remain largely unexplored. In this paper, we compare high time resolution, multipoint space-based GCR data to explore structures in the IPM that cause these variations. To ensure that features we see in these data actually relate to conditions in the IPM, we look for correlations between the GCR time series from two instruments onboard the Polar and INTEGRAL (International Gamma Ray Astrophysical Laboratory) satellites, respectively inside and outside Earth's magnetosphere. We analyze the period of 18–24 August 2006 during which two interplanetary coronal mass ejections (ICMEs) passed Earth and produced a Forbush decrease (Fd) in the GCR flux. We find two periods, for a total of 10 h, of clear correlation between small-scale variations in the two GCR time series during these 7 days, thus demonstrating that such variations are observable using space-based instruments. The first period of correlation lasted 6 h and began 2 h before the shock of the first ICME passed the two spacecraft. The second period occurred during the initial decrease of the Fd, an event that did not conform to the typical one- or two-step classification of Fds. We propose that two planar magnetic structures preceding the first ICME played a role in both periods: one structure in driving the first correlation and the other in initiating the Fd.

A Major Geoeffective CME from NOAA 12371: Initiation, CME–CME Interactions, and Interplanetary Consequences

Bhuwan **Joshi**, M. Syed Ibrahim, A. Shanmugaraju, D. Chakrabarty

Solar Physics July **2018**, 293:107

<http://sci-hub.tw/http://link.springer.com/10.1007/s11207-018-1325-2>

In this article, we present a multi-wavelength and multi-instrument investigation of a halo coronal mass ejection (CME) from active region NOAA 12371 on **21 June 2015** that led to a major geomagnetic storm of minimum $Dst = -204$ nT. The observations from the Atmospheric Imaging Assembly onboard the Solar Dynamics Observatory in the hot EUV channel of 94 Å confirm the CME to be associated with a coronal sigmoid that displayed an intense emission ($T \sim 6$ MK) from its core before the onset of the eruption. Multi-wavelength observations of the source active region suggest tether-cutting reconnection to be the primary triggering mechanism of the flux rope eruption. Interestingly, the flux rope eruption exhibited a two-phase evolution during which the “standard” large-scale flare reconnection process originated two composite M-class flares. The eruption of the flux rope is followed by the coronagraphic observation of a fast, halo CME with linear projected speed of 1366 km s⁻¹. The dynamic radio spectrum in the decameter-hectometer frequency range reveals multiple continuum-like enhancements in type II radio emission which imply the interaction of the CME with other preceding slow speed CMEs in the corona within ≈ 10 –90 R_{\odot} . The scenario of CME–CME interaction in the corona and interplanetary medium is further confirmed by the height–time plots of the CMEs occurring during 19–21 June. In situ measurements of solar wind magnetic field and plasma parameters at 1 AU exhibit two distinct magnetic clouds, separated by a magnetic hole. Synthesis of near-Sun observations, interplanetary radio emissions, and in situ measurements at 1 AU reveal complex processes of CME–CME interactions right from the source active region to the corona and interplanetary medium that have played a crucial role towards the large enhancement of the geoeffectiveness of the halo CME on 21 June 2015.

Energetic particle evolution during coronal mass ejection passage from 0.3 to 1 AU

C. J. **Joyce**¹, D. J. McComas^{1,2}, N. A. Schwadron^{1,2}, A. Vourlidas³,

A&A 651, A2 (**2021**)

<https://www.aanda.org/articles/aa/pdf/2021/07/aa39933-20.pdf>

<https://doi.org/10.1051/0004-6361/202039933>

We provide analysis of a coronal mass ejection (CME) that passed over Parker Solar Probe (PSP) on January 20, 2020 when the spacecraft was at just 0.32 AU. The Integrated Science Investigation of the Sun instrument suite measures energetic particle populations associated with the CME before, during, and after its passage over the spacecraft. We observe a complex evolution of energetic particles, including a brief ~ 2 h period where the energetic particle fluxes are enhanced and the nominal orientation of the energetic particle streaming outward from the Sun (from 30 to 100 keV

nuc-1) abruptly reverses inward toward the Sun. This transient and punctuated evolution highlights the importance of magnetic field structures that connect the spacecraft to different acceleration sites, one of which is likely more distant from the Sun than PSP during the evolution of the CME. We discuss these characteristics and what they tell us about the source of the energetic particles. During this period, PSP was radially aligned with the Solar Terrestrial Relations Observatory A (STEREO-A), which measured the same CME when it passed 1 AU. The magnetic field measurements at both spacecraft are remarkably similar, indicating that the spacecraft are likely encountering the same portion of the magnetic structure that has not evolved significantly in transit. The energetic particle observations on the other hand, are quite different at STEREO-A, showing how transport effects have acted on the energetic particle populations and obscured the detailed properties present earlier in the development of the CME. This event provides a unique case study in how energetic particle populations evolve as CMEs propagate through the heliosphere.

MAGNETIC FIELD-LINE LENGTHS IN INTERPLANETARY CORONAL MASS EJECTIONS INFERRED FROM ENERGETIC ELECTRON EVENTS

S. W. [Kahler](#)¹, D. K. Haggerty² and I. G. Richardson

2011 ApJ 736 106

About one quarter of the observed interplanetary coronal mass ejections (ICMEs) are characterized by enhanced magnetic fields that smoothly rotate in direction over timescales of about 10-50 hr. These ICMEs have the appearance of magnetic flux ropes and are known as "magnetic clouds" (MCs). The total lengths of MC field lines can be determined using solar energetic particles of known speeds when the solar release times and the 1 AU onset times of the particles are known. A recent examination of about 30 near-relativistic (NR) electron events in and near 8 MCs showed no obvious indication that the field-line lengths were longest near the MC boundaries and shortest at the MC axes or outside the MCs, contrary to the expectations for a flux rope. Here we use the impulsive beamed NR electron events observed with the Electron Proton and Alpha Monitor instrument on the Advanced Composition Explorer spacecraft and type III radio bursts observed on the Wind spacecraft to determine the field-line lengths inside ICMEs included in the catalog of Richardson & Cane. In particular, we extend this technique to ICMEs that are not MCs and compare the field-line lengths inside MCs and non-MC ICMEs with those in the ambient solar wind outside the ICMEs. No significant differences of field-line lengths are found among MCs, ICMEs, and the ambient solar wind. The estimated number of ICME field-line turns is generally smaller than those deduced for flux-rope model fits to MCs. We also find cases in which the electron injections occur in solar active regions (ARs) distant from the source ARs of the ICMEs, supporting CME models that require extensive coronal magnetic reconnection with surrounding fields. The field-line lengths are found to be statistically longer for the NR electron events classified as ramps and interpreted as shock injections somewhat delayed from the type III bursts. The path lengths of the remaining spike and pulse electron events are compared with model calculations of solar wind field-line lengths resulting from turbulence and found to be in good agreement.

Solar energetic electron probes of magnetic cloud field line lengths

[Kahler](#), S. W.; Krucker, S.; Szabo, A.

J. Geophys. Res., Vol. 116, No. A1, A01104, 2011

Magnetic clouds (MCs) are large interplanetary coronal mass ejections of enhanced and low-variance fields with rotations indicative of magnetic flux ropes originally connected to the Sun. The MC flux rope models require field lines with larger pitch angles and longer lengths with increasing distance from the MC axis. While the models can provide good fits to the in situ solar wind observations, there have not been definitive observational tests of the global magnetic field geometry, particularly for the field line lengths. However, impulsive solar energetic ($E > 10$ keV) electron events occasionally occur within an MC, and the electron onsets can be used to infer L_e , the magnetic field line lengths traveled by the electrons from the Sun to the points in the MC where the electron onsets occur. We selected 8 MCs in and near which 30 solar electron events were observed by the 3DP instrument on the Wind spacecraft. We compared the corresponding L_e values with calculated model field line lengths to test two MC models. Some limitations on the technique are imposed by variations of the models and uncertainty about MC boundary locations. We found generally poor correlations between the computed electron path lengths and the model field line lengths. Only one value of L_e inside an MC, that of 18 October 1995, exceeded 3.2 AU, indicating an absence of the long path lengths expected in the highly wound outer regions of MC models. We briefly consider the implications for MC models.

V arc interplanetary coronal mass ejections observed with the Solar Mass Ejection Imager

Kahler, S. W.; Webb, D. F.

J. Geophys. Res., Vol. 112, No. A9, A09103, 2007

<http://dx.doi.org/10.1029/2007JA012358>

Since February 2003, the Solar Mass Ejection Imager (SMEI) has been observing interplanetary coronal mass ejections (ICMEs) at solar elongation angles $> 20^\circ$. The ICMEs generally appear as loops or arcs in the sky, but five show distinct outward concave shapes that we call V arcs. We expect to observe some V arcs, formed by trailing edges of ICME flux ropes or by leading ICME edges sheared by solar wind (SW) speed gradients at the heliospheric current sheet. We characterize the properties of these V arcs and compare them with average properties of all SMEI ICMEs. The typical V arc speeds argue against a slow MHD shock interpretation for their structures. We estimate the V arc solar source locations and their opening angle dynamics as tests for SW shearing. The first test contradicts but the second supports the SW shearing explanation. The implications of the small number of V arcs observed with SMEI is considered. The point P approximation used to determine the V arc locations and inferred solar source regions is critically examined in Appendix A.

Imaging Interplanetary Disturbances Causing Forbush Decreases

Kahler, S.W. and G.M. Simnett,

in Proc. of the 29th Intl. Cosmic Ray Conference, Pune, India, 2, 267-270 (2005), **File**

Forbush decreases (FDs) in neutron monitor (NM) counting rates are caused by enhanced magnetic fields in interplanetary shocks and solar ejecta that shield the Earth from galactic cosmic rays (GCRs). The solar origins of those ejecta can be observed as coronal mass ejections (CMEs) in coronagraphs, but their propagation through interplanetary space near or past the Earth has not been previously observable. The Solar Mass Ejection Imager (SMEI), launched into polar Earth orbit in January 2003, now allows us to search for the white light signatures of interplanetary CMEs (ICMEs) responsible for FDs. SMEI is unique in that it can monitor the progress of CMEs through the inner heliosphere out to distances beyond 1 AU and distinguish those which hit the Earth from those that do not. For comparison with SMEI observations, we selected all FDs of $\geq 2\%$ observed with the Oulu, Finland, NM. We find an excellent association of SMEI CMEs with those FDs and for each of the associated SMEI CMEs a good candidate associated LASCO CME was also found. The SMEI observations provide information on the approximate spatial locations and trajectories of large ICMEs that may result in FDs and hence can be useful as a space weather tool.

Solar flares and coronal mass ejections. (Review)

Kahler, S.W.,

1992. Ann Rev. Astron. Astrophys. 30, 113–141.

<http://sci-hub.ru/10.1146/annurev.aa.30.090192.000553>

This review addresses two basic questions. First, how did we form such a fundamentally incorrect view of the effects of flares after so much observational and theoretical work? Second, what is the observational and theoretical evidence to support a primary role for CMEs, and what can we say about the relationship between flares and CMEs? In Section 2 we present flare and CME observations in a historical context to show the changing perspective between the two phenomena. In Section 3 we discuss the coronal phenomena that bear on the relationship between flares and CMEs. Interplanetary effects are discussed in Section 4.

Transient Upstream Mesoscale Structures: Drivers of Solar-Quiet Space Weather

Primož **Kajdič**, [Xóchitl Blanco-Cano](#), [Lucile Turc](#), [Martin Archer](#), [Savvas Raptis](#), [Terry Z. Liu](#), [Yann Pfau-Kempf](#), [Adrian T. LaMoury](#), [Yufei Hao](#), [Philippe C. Escoubet](#), [Nojan Omid](#), [David G. Sibeck](#), [Boyi Wang](#), [Hui Zhang](#), [Yu Lin](#)

Front. Astron. Space Sci., (2024), Sec. Space Physics, Volume 11 - 2024

<https://arxiv.org/pdf/2411.07145>

In recent years, it has become increasingly clear that space weather disturbances can be triggered by transient upstream mesoscale structures (TUMS), independently of the occurrence of large-scale solar wind (SW) structures, such as interplanetary coronal mass ejections and stream interaction regions. Different types of magnetospheric pulsations, transient perturbations of the geomagnetic field and auroral structures are often observed during times when SW monitors indicate quiet conditions, and have been found to be associated to TUMS. In this mini-review we describe the space weather phenomena that have been associated with four of the largest-scale and the most energetic TUMS, namely hot flow anomalies, foreshock bubbles, travelling foreshocks and foreshock compressional boundaries. The space weather phenomena associated with TUMS tend to be more localized and less intense compared to geomagnetic storms.

However, the quiet time space weather may occur more often since, especially during solar minima, quiet SW periods prevail over the perturbed times. **14 Aug 2007, 14 Jul 2008**

Waves upstream and downstream of interplanetary shocks driven by coronal mass ejections

Kajdic, P.; Blanco-Cano, X.; Aguilar-Rodriguez, E.; Russell, C. T.; Jian, L. K.; Luhmann, J. G.

J. Geophys. Res., Vol. 117, No. A6, A06103, **2012**

<http://dx.doi.org/10.1029/2011JA017381>

In this work we study the waves in regions adjacent to ten interplanetary (IP) shocks formed by the interactions between interplanetary coronal mass ejections and the solar wind. We analyze the STEREO data for the years 2007–2010. Shocks in our sample have low magnetosonic Mach numbers ($M_{ms} \leq 2.3$), their criticality ratios range between 0.8 and 2.3 and θ_{Bn} are between 38° and 85° . We find ultra-low frequency (ULF, 0.01 Hz–0.05 Hz) waves and higher-frequency (HF, ≥ 1 Hz) whistler precursors upstream of these shocks. Downstream of them we observe irregular ULF fluctuations and regular HF waves with similar frequencies as in the upstream case. We find that IP shocks with relatively small M_{ms} can excite waves in large regions in front of them (2.2×10^{-3} AU– 4.6×10^{-3} AU), thereby forming large ULF wave foreshocks. We do not find any evidence for the steepening of these waves. We do observe suprathermal ($E \leq 30$ keV) proton foreshocks upstream of some of the shocks in the sample. The extensions of suprathermal proton foreshocks range between 0.02 AU and 0.1 AU. However, not all foreshocks with suprathermal ions show ULF waves or vice versa. The extensions of ULF and proton foreshocks can be very different. Enhanced ULF waves and suprathermal protons can be observed upstream of local quasi-perpendicular shocks. We propose that the observed discordance between the shock geometries and the presence of the foreshock phenomena may be explained in terms of temporal and spatial variations of the local geometry of the IP shocks.

The Earth's magnetosphere response to interplanetary medium conditions on January 21–22, 2005 and on December 14–15, 2006

V.V. **Kalegaev**, N.A. Vlasova

Advances in Space Research, **2014**

The Earth's magnetosphere response to interplanetary medium conditions on January 21–22, 2005 and on December 14–15, 2006 has been studied. The analysis of solar wind parameters measured by ACE spacecraft, of geomagnetic indices variations, of geomagnetic field measured by GOES 11, 12 satellites, and of energetic particle fluxes measured by POES 15, 16, 17 satellites was performed together with magnetospheric modeling based in terms of A2000 paraboloid model. We found the similar dynamics of three particle populations (trapped, quasi-trapped, and precipitating) during storms of different intensities developed under different external conditions: the maximal values of particle fluxes and the latitudinal positions of the isotropic boundaries were approximately the same. The main sources caused RC build-up have been determined for both magnetic storms. Global magnetospheric convection controlled by IMF and substorm activity driven magnetic storm on December 14–15, 2006. Extreme solar wind pressure pulse was mainly responsible for RC particle injection and unusual January 21, 2005 magnetic storm development under northward IMF during the main phase.

An analysis of large Forbush decrease events using phase diagrams of view channels of the Nagoya multidirectional muon telescope

G. **Kalugin**, K. Kabin

Journal of Atmospheric and Solar-Terrestrial Physics, Volume 123, February **2015**, Pages 124–136

Large Forbush decrease (FD) events are analysed using data recorded by the ground-based Nagoya multi-directional muon telescope in Japan. As a part of the analysis we introduce a phase diagram for the channels of telescope, which provides more robust information about characteristics of events. Specifically, the slope of the regression line in the phase diagram represents the FD amplitude which can be computed for different channels. This allows us to analyze the dependence of the FD amplitude on the rigidity of CR particles. Two models for this dependence are considered, a power law and exponential and the former is found to be more suitable for the considered events. In terms of the power-law index and the FD amplitude the events are split into two groups. It is shown that the larger events are characterized by smaller power-law index than the smaller ones.

No Major Solar Flares but the Largest Geomagnetic Storm in the Present Solar Cycle

Y. **Kamide**, K. Kusano

Space Weather Volume 13, Issue 6 June **2015** Pages 365–367

<http://onlinelibrary.wiley.com/doi/10.1002/2015SW001213/full>

A severe geomagnetic storm, and the largest in solar cycle 24, occurred on **17–18 March 2015** without significant precursor X- or M-type solar flares.

In summary, we suggest that the most recent case of a severe geomagnetic storm, which is the largest to date in solar cycle 24, represents a distinct class of two-step main phase storms. It is crucial to realize that instead of the simple assumption that an intense storm be generated by an intense solar/interplanetary disturbance, our suggestion indicates that an intense storm can result from the superposition of two successive, moderate storms, driven by two successive, southward IMF structures.

Evolution of Cosmic-Ray Intensities While the Earth Was Engulfed by the Interplanetary Storm (Blob) of 1–3 October 2013

R. P. [Kane](#)

Solar Phys., **2014**, Volume 289, Issue 7, pp 2669-2675 July 2014, Volume 289, Issue 7, pp 2669-2675

When a Coronal Mass Ejection (CME) is ejected by the Sun, it reaches the Earth orbit in a modified state and is called an ICME (Interplanetary CME). When an ICME blob engulfs the Earth, short-scale cosmic-ray (CR) storms (Forbush decreases, FDs) occur, sometimes accompanied by geomagnetic Dst storms, if the B_z component in the blob is negative. Generally, this is a sudden process that causes abrupt changes. However, sometimes before this abrupt change (FD) due to strong ICME blobs, there are slow, small changes in interplanetary parameters such as steady increases in solar wind speed V , which are small, but can last for several hours. In the present communication, CR changes in such an event are illustrated in the period 1–3 October 2013, when V increased steadily from $\sim 200 \text{ km s}^{-1}$ to $\sim 400 \text{ km s}^{-1}$ during 24 hours on 1 October 2013. The CR intensities decreased by 1–2 % during some hours of this 24-hour interval, indicating that CR intensities do respond to these weak but long-lasting increases in interplanetary solar wind speed.

Interplanetary and geomagnetic parameters during January 16-26, 2005

R. P. [Kane](#)

Planetary and Space Science, Volume 62, Issue 1, p. 97-99, **2012**

The interplanetary $B_z(\text{min})$ and geomagnetic $\text{Dst}(\text{min})$ are well related. There is no large negative B_z without causing large negative Dst. Similarly, large negative Dst is not expected to occur without a large negative B_z ; but recently, Du et al. (2008) reported that the Dst storm of Jan. 21-22, 2005 was anomalous because the Dst storm main phase developed during northward interplanetary magnetic field (positive B_z). Here, we examined this event (storm 3) and compared it with earlier events of Jan. 16-20, 2005 (storms 1 and 2, in quick succession). It was noticed that storms 1 and 2 had large negative Dst deviations (-121 nT and -93 nT, separated by 26 hours) but the B_z fluctuated between +21 nT and -17 nT. For storm 3 where negative Dst deviations were large (-105 nT), the B_z was not completely positive (northward) as mentioned by Du et al. (2008) but had negative values (-7 nT) for an hour, followed by positive values (13 nT). Thus, the need of a negative B_z (albeit small) was satisfied.

Relationship between Dst(min) magnitudes and characteristics of ICMEs

Severe geomagnetic storms and Forbush decreases: interplanetary relationships reexamined

R. P. [Kane](#)

Ann. Geophys., 28, 479–489, **2010**, [File](#)

Severe storms (Dst) and Forbush decreases (FD) during cycle 23 showed that maximum negative Dst magnitudes usually occurred almost simultaneously with the maximum negative values of the B_z component of interplanetary magnetic field B , but the maximum magnitudes of negative Dst and B_z were poorly correlated (+0.28). A parameter $B_z(\text{CP})$ was calculated (cumulative partial B_z) as sum of the hourly negative values of B_z from the time of start to the maximum negative value. The correlation of negative Dst maximum with $B_z(\text{CP})$ was higher (+0.59) as compared to that of Dst with B_z alone (+0.28). When the product of B_z with the solar wind speed V (at the hour of negative B_z maximum) was considered, the correlation of negative Dst maximum with VB_z was +0.59 and with $VB_z(\text{CP})$, 0.71. Thus, including V improved the correlations. However, ground-based Dst values have a considerable contribution from magnetopause

currents (several tens of nT, even exceeding 100 nT in very severe storms). When their contribution is subtracted from Dst(nT), the residue Dst* representing true ring current effect is much better correlated with B_z and $B_z(\text{CP})$, but not with VB_z or $VB_z(\text{CP})$, indicating that these are unimportant parameters and the effect of V is seen only through the solar wind ram pressure causing magnetopause currents. Maximum negative Dst (or Dst*) did not occur at the same hour as maximum FD. The time evolutions of Dst and FD were very different. The correlations were almost zero. Basically, negative Dst (or Dst*) and FDs are uncorrelated, indicating altogether different mechanism.

Coronal mass ejection geoeffectiveness depending on field orientation and interplanetary coronal mass ejection classification

Seung-Mi [Kang](#),^{1,2} Y.-J. Moon,³ K.-S. Cho,³ Yeon-Han Kim,³ Y. D. Park,³ Ji-Hye Baek,³ and Heon-Young Chang¹

JOURNAL OF GEOPHYSICAL RESEARCH, VOL. 111, A05102, doi:10.1029/2005JA011445, **2006, File**
In this study, we have examined the coronal mass ejection (CME) geoeffectiveness characterized by $\text{Dst} \leq -50$ nT according to the field orientation (N or S) in a CME source region and its dependence on interplanetary CME (ICME) classification (magnetic clouds or ejecta). We first considered 133 CME-ICME pairs (1996 to 2001) whose CME source locations are identified by SOHO Large-Angle Spectrometric Coronagraph (SOHO/LASCO) and extreme ultraviolet imaging telescope (SOHO/EIT) data. Then we identified the shapes (S or Inverse-S) of the X-ray sigmoids associated with 63 of these CMEs using Yohkoh/Soft X-Ray Telescope (SXT) data. To determine the field orientation in the sigmoids, we applied the coronal flux rope (CFR) model and the force-free field (FFF) model to these 63 sigmoids using SOHO/Michelson Doppler Imager (MDI) images. We present the results in contingency tables, classified according to solar field orientation and geomagnetic storm strength/occurrence. We found that (1) the prediction of geomagnetic storms ($\text{Dst} \leq -50$ nT) based on the CFR model is much better than that on the FFF model, (2) the prediction for magnetic clouds (MCs) is much better than that for ejecta (EJ), which implies that the field orientation of the MCs is well conserved through the heliosphere, and (3) for about 86% of the magnetic clouds, the directions of their leading fields are consistent with those in the CME source regions. Our results support the findings that the southward orientations of the magnetic field in the CME source regions plays an important role in the production of geomagnetic storms.

Murchison Widefield Array Observations of Anomalous Variability: A Serendipitous Night-time Detection of Interplanetary Scintillation

ApJL **2015**

<http://arxiv.org/pdf/1507.08236v1.pdf>

We present observations of high-amplitude rapid (2 s) variability toward two bright, compact extragalactic radio sources out of several hundred of the brightest radio sources in one of the 30x30 deg MWA Epoch of Reionization fields using the Murchison Widefield Array (MWA) at 155 MHz. After rejecting intrinsic, instrumental, and ionospheric origins we consider the most likely explanation for this variability to be interplanetary scintillation (IPS), likely the result of a large coronal mass ejection propagating from the Sun. This is confirmed by roughly contemporaneous observations with the Ooty Radio Telescope. We see evidence for structure on spatial scales ranging from <1000 km to $>1e6$ km. The serendipitous night-time nature of these detections illustrates the new regime that the MWA has opened for IPS studies with sensitive night-time, wide-field, low-frequency observations. This regime complements traditional dedicated strategies for observing IPS and can be utilized in real-time to facilitate dedicated follow-up observations. At the same time, it allows large-scale surveys for compact (arcsec) structures in low-frequency radio sources despite the 2 arcmin resolution of the array. **2014 November 06**

Alfvénic velocity spikes and rotational flows in the near-Sun solar wind

J. C. [Kasper](#), [S. D. Bale](#), [...] [N. A. Schwadron](#)

[Nature](#) volume 576, pages228–231 (2019)

<https://www.nature.com/articles/s41586-019-1813-z.pdf>

The prediction of a supersonic solar wind¹ was first confirmed by spacecraft near Earth^{2,3} and later by spacecraft at heliocentric distances as small as 62 solar radii⁴. These missions showed that plasma accelerates as it emerges from the corona, aided by unidentified processes that transport energy outwards from the Sun before depositing it in the wind. Alfvénic fluctuations are a promising candidate for such a process because they are seen in the corona and solar wind and contain considerable energy^{5,6,7}. Magnetic tension forces the corona to co-rotate with the Sun, but any residual rotation far from the Sun reported until now has been much smaller than the amplitude of waves and deflections from interacting wind streams⁸. Here we report observations of solar-wind plasma at heliocentric distances of about 35 solar radii^{9,10,11}, well within the distance at which stream interactions become important. We find that Alfvén waves organize into structured velocity spikes with duration of up to minutes, which are associated with propagating S-like bends in the magnetic-field lines. We detect an increasing rotational component to the flow velocity of the solar wind around the Sun, peaking at 35 to 50 kilometres per second—considerably above the amplitude of the waves. These flows exceed classical velocity predictions of a few kilometres per second, challenging models of circulation in the corona and calling into question our understanding of how stars lose angular momentum and spin down as they age^{12,13,14}.

A Zone of Preferential Ion Heating Extends Tens of Solar Radii from the Sun

J. C. **Kasper**^{1,7}, K. G. Klein^{1,8}, T. Weber², M. Maksimovic³, A. Zaslavsky³, S. D. Bale⁴, B. A. Maruca⁵, M. L. Stevens⁶, and A. W. Case⁶

2017 ApJ 849 126

<http://iopscience.iop.org/article/10.3847/1538-4357/aa84b1/pdf>

The extreme temperatures and nonthermal nature of the solar corona and solar wind arise from an unidentified physical mechanism that preferentially heats certain ion species relative to others. Spectroscopic indicators of unequal temperatures commence within a fraction of a solar radius above the surface of the Sun, but the outer reach of this mechanism has yet to be determined. Here we present an empirical procedure for combining interplanetary solar wind measurements and a modeled energy equation including Coulomb relaxation to solve for the typical outer boundary of this zone of preferential heating. Applied to two decades of observations by the Wind spacecraft, our results are consistent with preferential heating being active in a zone extending from the transition region in the lower corona to an outer boundary 20–40 solar radii from the Sun, producing a steady-state super-mass-proportional α -to-proton temperature ratio of 5.2–5.3. Preferential ion heating continues far beyond the transition region and is important for the evolution of both the outer corona and the solar wind. The outer boundary of this zone is well below the orbits of spacecraft at 1 au and even closer missions such as Helios and MESSENGER, meaning it is likely that no existing mission has directly observed intense preferential heating, just residual signatures. We predict that the Parker Solar Probe will be the first spacecraft with a perihelion sufficiently close to the Sun to pass through the outer boundary, enter the zone of preferential heating, and directly observe the physical mechanism in action.

Pileup accident hypothesis of magnetic storm on 17 March 2015

Kataoka, Ryuho ; [Shiota, Daikou](#) ; [Kilpua, Emilia](#) ; [Keika, Kunihiro](#)

Geophysical Research Letters, Volume 42, Issue 13, pp. 5155-5161, 2015

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1002/2015GL064816>

We propose a "pileup accident" hypothesis, based on the solar wind data analysis and magnetohydrodynamics modeling, to explain unexpectedly geoeffective solar wind structure which caused the largest magnetic storm so far during the solar cycle 24 on **17 March 2015**: First, a fast coronal mass ejection with strong southward magnetic fields both in the sheath and in the ejecta was followed by a high-speed stream from a nearby coronal hole. This combination resulted in less adiabatic expansion than usual to keep the high speed, strong magnetic field, and high density within the coronal mass ejection. Second, preceding slow and high-density solar wind was piled up ahead of the coronal mass ejection just before the arrival at the Earth to further enhance its magnetic field and density. Finally, the enhanced solar wind speed, magnetic field, and density worked all together to drive the major magnetic storm.

Probability of occurrence of extreme magnetic storms†

Ryuho **Kataoka**

Space Weather, 2013, VOL. 11, 214–218,

<http://onlinelibrary.wiley.com/doi/10.1002/swe.20044/pdf>

To calculate the probability of extreme magnetic storms in the solar cycle 24, cumulative distribution functions are investigated using an 89 year list of magnetic storms recorded at Kakioka Magnetic Observatory. It is found that the probability of occurrence of extreme magnetic storms can be modeled as a function of maximum sunspot number of a solar cycle, and the probability of another Carrington storm occurring within the next decade is estimated to be 4–6%.

Three-dimensional MHD modeling of the solar wind structures associated with 13 December 2006 coronal mass ejection

Kataoka, R.; Ebisuzaki, T.; Kusano, K.; Shiota, D.; Inoue, S.; Yamamoto, T. T.; Tokumaru, M
J. Geophys. Res., Vol. 114, No. A10, A10102, **2009**
<http://dx.doi.org/10.1029/2009JA014167>

A 3-D magnetohydrodynamic (MHD) simulation is performed to reconstruct the interplanetary propagation of a coronal mass ejection (CME) that occurred on **13 December 2006**. A spheromak-type magnetic field is superposed on a realistic ambient solar wind to reproduce the large-scale interplanetary magnetic field (IMF) associated with the CME. Here we show that a westward and southward directed spheromak CME with reasonable geometric, dynamic, and magnetic parameters reproduces the magnetic cloud, interplanetary shock, and sheath profiles as observed by in situ spacecraft. We suggest that the simple solar wind model developed in this study is topologically complex enough to be consistent with in situ observations, such as southward IMF associated with CMEs.

A Wavelet Based Approach to Solar-Terrestrial Coupling

Ch. **Katsavriasis**, A. Hillaris, P. Preka-Papadema
Advances in Space Research, Volume 57, Issue 10, p. 2234-2244. **2016**
<https://arxiv.org/pdf/1605.04005.pdf>

Transient and recurrent solar activity drive geomagnetic disturbances; these are quantified (amongst others) by DST, AE indices time-series. Transient disturbances are related to the Interplanetary Coronal Mass Ejections (ICMEs) while recurrent disturbances are related to corotating interaction regions (CIR). We study the relationship of the geomagnetic disturbances to the solar wind drivers within solar cycle 23 where the drivers are represented by ICMEs and CIRs occurrence rate and compared to the DST and AE as follows: terms with common periodicity in both the geomagnetic disturbances and the solar drivers are, firstly, detected using continuous wavelet transform (CWT). Then, common power and phase coherence of these periodic terms are calculated from the cross-wavelet spectra (XWT) and wavelet-coherence (WTC) respectively. In time-scales of ≈ 27 days our results indicate an anti-correlation of the effects of ICMEs and CIRs on the geomagnetic disturbances. The former modulates the DST and AE time series during the cycle maximum the latter during periods of reduced solar activity. The phase relationship of these modulation is highly non-linear. Only the annual frequency component of the ICMEs is phase-locked with DST and AE. In time-scales of ≈ 1.3 -1.7 years the CIR seem to be the dominant driver for both geomagnetic indices throughout the whole solar cycle 23.

Wavelet Analysis on Solar Wind Parameters and Geomagnetic Indices

C. **Katsavriasis**, P. Preka-Papadema, X. Moussas
Solar Physics, October **2012**, Volume 280, Issue 2, pp 623-640

The geomagnetic activity is the result of the solar wind-magnetosphere interaction. It varies following the basic 11-year solar cycle; yet shorter time-scale variations appear intermittently. We study the quasi-periodic behavior of the characteristics of solar wind (speed, temperature, pressure, density) and the interplanetary magnetic field (B_x , B_y , B_z , β , Alfvén Mach number) and the variations of the geomagnetic activity indices (DST, AE, Ap and Kp). In the analysis of the corresponding 14 time series, which span four solar cycles (1966–2010), we use both a wavelet expansion and the Lomb/Scargle periodograms. Our results verify intermittent periodicities in our time-series data, which correspond to already known solar activity variations on timescales shorter than the sunspot cycle; some of these are shared between the solar wind parameters and geomagnetic indices.

Statistical analysis of the geomagnetic response to different solar wind drivers and the dependence on storm intensity

R. M. **Katus**^{1,2,*}, M. W. Liemohn¹, E. L. Ionides¹, R. Ilie¹, D. Welling¹ and L. K. Sarno-Smith
JGR Volume 120, Issue 1, pages 310–327, January **2015**

Geomagnetic storms start with activity on the Sun that causes propagation of magnetized plasma structures in the solar wind. The type of solar activity is used to classify the plasma structures as being either interplanetary coronal mass ejection (ICME) or corotating interaction region (CIR) driven. The ICME-driven events are further classified as either

magnetic cloud (MC) driven or sheath (SH) driven by the geoeffective structure responsible for the peak of the storm. The geoeffective solar wind flow then interacts with the magnetosphere producing a disturbance in near-Earth space. It is commonly believed that a SH-driven event behaves more like a CIR-driven event than a MC-driven event; however, in our analysis this is not the case. In this study, geomagnetic storms are investigated statistically with respect to the solar wind driver and the intensity of the events. We use the Hot Electron and Ion Drift Integrator (HEIDI) model to simulate the inner magnetospheric hot ion population during all of the storms classified as intense ($Dst_{min} \leq -100$ nT) within solar cycle 23 (1996–2005). HEIDI is configured four different ways using either the Volland-Stern or self-consistent electric field and either event-based Los Alamos National Laboratory (LANL) magnetospheric plasma analyzer (MPA) data or a reanalyzed lower resolution version of the data that provides spatial resolution. Presenting the simulation results, geomagnetic data, and solar wind data along a normalized epoch timeline shows the average behavior throughout a typical storm of each classification. The error along the epoch timeline for each HEIDI configuration is used to rate the model's performance. We also subgrouped the storms based on the magnitude of the minimum Dst. We found that typically the LANL MPA data provide the best outer boundary condition. Additionally, the self-consistent electric field better reproduces SH- and MC-driven events throughout most of the storm timeline, but the Volland-Stern electric field better reproduces CIR-driven events. Contrary to what we expect, examination of the HEIDI model results and solar wind data shows that SH-driven events behave more like MC-driven events than CIR-driven storms.

Similarities and differences in low- to middle-latitude geomagnetic indices

R. M. [Katus*](#), M. W. Liemohn

Volume 118, Issue 8, pages 5149–5156, August 2013

[1] Several versions of low- to middle-latitude geomagnetic indices are examined throughout a 24 year interval and during storm time with respect to a normalized epoch timeline based on several key storm features. In particular, we conduct a quantitative comparison of the storm time superpositioning of the Dst, SYM-H, and 1 min U.S. Geological Survey Dst indices using error analysis and employing descriptive statistics to assess the similarities and differences between them. The events are then categorized by storm intensity and examined as a function of the storm phase. While the indices are highly correlated with each other, dramatic deviation between the indices exists at certain storm epoch times. In particular, the error increases at storm peak and especially for more intense storms. The differences at storm peak are, on average, 20% of the peak value of the indices. These differences arise from the choice of magnetometer stations to include in each index and the various methodologies used to compile the individual perturbation measurements into a global value. The conclusions are that multiple indices should be considered when determining low- to middle-latitude magnetic perturbations and that the difference between the indices should be considered as an error estimate on these values.

Unexpected Behavior of the Solar Wind Mass Flux During Solar Maxima: Two Peaks at Middle Heliolatitudes

Olga [Katushkina](#), Vladislav Izmodenov, Dimitra Koutroumpa, Eric Quémerais, Lan K. Jian

[Solar Physics](#) January 2019, 294:17

<https://link.springer.com/content/pdf/10.1007%2Fs11207-018-1391-5.pdf>

In this work we study the temporal and latitudinal variations of the solar wind mass flux at 1 AU derived from SOHO/SWAN data on backscattered solar Lyman- α radiation in 1996 – 2018. Previously Katushkina et al. (*J. Geophys. Res.* 118, 2800, 2013) have shown that the latitudinal profiles of the solar wind mass flux during the solar maximum 2001 – 2003 have two separate peaks at middle heliolatitudes. In this work we provide the data for the last solar maximum in 2014 – 2016 and show that the specific latitudinal distribution appears again. However, in 2014 – 2016 the two peaks are less separated and sometimes merged to one peak. For several years we have performed a comparison of SWAN observations with the results of the WSA-Enlil model, which is a coupled 3D time-dependent model of the solar wind propagation from the solar corona to the heliosphere. It is shown that the WSA-Enlil model confirms qualitatively the latitudinal distribution of the solar wind found from the SWAN data, although there are some quantitative differences. Physical reasons for the formation of this latitudinal structure at the solar maxima are discussed. Further investigation is needed and could provide new links between the solar corona and the heliospheric environment.

On the Usage of Geomagnetic Indices for Data Selection in Internal Field Modelling

K. [Kauristie](#), A. Morschhauser, N. Olsen, C. C. Finlay, R. L. McPherron, J. W. Gjerloev, H. J. Opgenoorth
Space Science Reviews 2017

We present a review on geomagnetic indices describing global geomagnetic storm activity (K_p , a_m , Dst and $dDst/dt$) and on indices designed to characterize high latitude currents and substorms (PC and AE-indices and their variants). The focus in our discussion is in main field modelling, where indices are primarily used in data selection criteria for weak magnetic activity. The publicly available extensive data bases of index values are used to derive joint conditional Probability Distribution Functions (PDFs) for different pairs of indices in order to investigate their mutual consistency in describing quiet conditions. This exercise reveals that Dst and its time derivative yield a similar picture as K_p on quiet conditions as determined with the conditions typically used in internal field modelling. Magnetic quiescence at high latitudes is typically searched with the help of Merging Electric Field (MEF) as derived from solar wind observations. We use in our PDF analysis the PC-index as a proxy for MEF and estimate the magnetic activity level at auroral latitudes with the AL-index. With these boundary conditions we conclude that the quiet time conditions that are typically used in main field modelling ($\mathit{PC} < 0.8$), ($\mathit{Kp} < 2$) and ($\mathit{Dst} < 30 \sim \text{nT}$) correspond to weak auroral electrojet activity quite well: Standard size substorms are unlikely to happen, but other types of activations (e.g. pseudo breakups ($\mathit{AL} > -300 \sim \text{nT}$)) can take place, when these criteria prevail. Although AE-indices have been designed to probe electrojet activity only in average conditions and thus their performance is not optimal during weak activity, we note that careful data selection with advanced AE-variants may appear to be the most practical way to lower the elevated RMS-values which still exist in the residuals between modeled and observed values at high latitudes. Recent initiatives to upgrade the AE-indices, either with a better coverage of observing stations and improved baseline corrections (the SuperMAG concept) or with higher accuracy in pinpointing substorm activity (the Midlatitude Positive Bay-index) will most likely be helpful in these efforts.

Updating Measures of CME Arrival Time Errors

C. Kay, E. Palmerio, P. Riley, M. L. Mays, T. Nieves-Chinchilla, M. Romano, Y. M. Collado-Vega, C. Wiegand, A. Chulaki

Space Weather [Volume22, Issue7](#) e2024SW003951 2024

<https://doi.org/10.1029/2024SW003951>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2024SW003951>

Coronal mass ejections (CMEs) drive space weather effects at Earth and the heliosphere. Predicting their arrival is a major part of space weather forecasting. In 2013, the Community Coordinated Modeling Center started collecting predictions from the community, developing an Arrival Time Scoreboard (ATSB). Riley et al. (2018, <https://doi.org/10.1029/2018sw001962>) analyzed the first 5 years of the ATSB, finding a bias of a few hours and uncertainty of order 15 hr. These metrics have been routinely quoted since 2018, but have not been updated despite continued predictions. We revise analysis of the ATSB using a sample 3.5 times the size of that in the original study. We find generally the same overall metrics, a bias of -2.5 hr, mean absolute error of 13.2 hr, and standard deviation of 17.4 hr, with only a slight improvement comparing between the previously-used and new sets. The most well-established, frequently-submitted model results tend to outperform those from seldomly-contributed models. These “best” models show a slight improvement over the 11 year span, with more scatter between the models during early times and a convergence toward the same error metrics in recent years. We find little evidence of any correlations between the arrival time errors and any other properties. The one noticeable exception is a tendency for late predictions for short transit times and vice versa. We propose that any model-driven systematic errors may be washed out by the uncertainties in CME reconstructions in characterization of the background solar wind, and suggest that improving these may be the key to better predictions.

A Series of Advances in Analytic Interplanetary CME Modeling

C. Kay, T. Nieves-Chinchilla, S. J. Hofmeister, E. Palmerio, V. E. Ledvina

Space Weather [Volume21, Issue11](#) November 2023 e2023SW003647

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2023SW003647>

Coronal mass ejections (CMEs) and high speed streams (HSSs) are large-scale transient structures that routinely propagate away from the Sun. Individually, they can cause space weather effects at the Earth, or elsewhere in space, but many of the largest events occur when these structures interact during their interplanetary propagation. We present the initial coupling of Open Solar Physics Rapid Ensemble Information (OSPREDI), a model for CME evolution, with Mostly Empirical Operational Wind with a High Speed Stream, a time-dependent HSS model that can serve as a background for the OSPREDI CME. We present several improvements made to OSPREDI in order to take advantage of the new time-dependent, higher-dimension background. This includes an update in the drag calculation and the ability to determine the rotation of a yaw-like angle. We present several theoretical case studies, describing the difference in the CME behavior between a HSS background and a quiescent one. This behavior includes interplanetary CME propagation, expansion, deformation, and rotation, as well as the formation of a CME-driven sheath. We also determine how the

CME behavior changes with the HSS size and initial front distance. Generally, for a fast CME, we see that the drag is greatly reduced within the HSS, leading to faster CMEs and shorter travel times. The drag reappears stronger if the CME reaches the stream interaction region or upstream solar wind, leading to a stronger shock with more compression until the CME sufficiently decelerates. We model a CME–HSS interaction event observed by Parker Solar Probe in January 2022. The model improvements create a better match to the observed in situ profiles. **26 Jan 2022**

Beyond Basic Drag in Interplanetary CME Modeling: Effects of Solar Wind Pile-Up and High Speed Streams

C. Kay, [T. Nieves-Chinchilla](#), [S. J. Hofmeister](#), [E. Palmerio](#)

Space Weather e2022SW003165 **Volume20, Issue9** 2022

<https://doi.org/10.1029/2022SW003165>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2022SW003165>

Coronal mass ejections (CMEs) cause severe space weather effects throughout our solar system. As a fast CME propagates through interplanetary space it accumulates solar wind material at its front. This pile-up of material, or CME-driven sheath, can be important in determining the geoeffectiveness of a CME. We take an existing arrival time model that includes expansion and deformation of the CME flux rope (ANTEATR; Kay & Gopalswamy, 2018; Kay & Nieves-Chinchilla, 2021a) and add a pile-up procedure (PUP) as a physics-based approach to modeling the CME-driven sheath. ANTEATR-PUP solves the Rankine–Hugoniot equations for an oblique shock to determine the shock speed and sheath density, magnetic field, temperature. The extra sheath mass affects the background drag calculation. Additionally, ANTEATR can now use any 1D profile for the background solar wind, as opposed to the simple empirical models it previously relied upon. We present initial results from ANTEATR-PUP and compare with previous ANTEATR findings. Using results from an MHD simulation, we explore the effects of interactions with a static high speed stream (HSS) on the CME's and sheath's interplanetary evolution. The drag forces essentially disappear while a CME remains within the HSS, but reappear stronger once the CME exits. The HSS–CME interaction produces the largest changes in the CME and sheath properties at 1 au when it occurs either close to the Sun near the inner simulation boundary at 0.1 au) or right before the CME reaches 1 au. We estimate that these changes could significantly affect the geoeffectiveness.

OSPREDI: A Coupled Approach to Modeling CME-Driven Space Weather with Automatically-Generated, User-Friendly Outputs

C. Kay, [M. L. May](#), [Y. M. Collado-Vega](#)

Space Weather e2021SW002914 2022

<https://arxiv.org/pdf/2109.06960.pdf>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2021SW002914>

<https://doi.org/10.1029/2021SW002914>

Coronal Mass Ejections (CMEs) drive space weather activity at Earth and throughout the solar system. Current CME-related space weather predictions rely on information reconstructed from coronagraphs, sometimes from only a single viewpoint, to drive a simple interplanetary propagation model, which only gives the arrival time or limited additional information. We present the coupling of three established models into OSPREDI (Open Solar Physics Rapid Ensemble Information), a new tool that describes Sun-to-Earth CME behavior, including the location, orientation, size, shape, speed, arrival time, and internal thermal and magnetic properties, on the timescale needed for forecasts. First, ForeCAT describes the trajectory that a CME takes through the solar corona. Second, ANTEATR simulates the propagation, including expansion and deformation, of a CME in interplanetary space and determines the evolution of internal properties via conservation laws. Finally, FIDO produces in situ profiles for a CME's interaction with a synthetic spacecraft. OSPREDI includes ensemble modeling by varying each input parameter to probe any uncertainty in their values, yielding probabilities for all outputs. Standardized visualizations are automatically generated, providing easily-accessible, essential information for space weather forecasting. We show OSPREDI results for a CME observed in the corona on **2021 April 22** and at Earth on **2021 April 25**. We approach this CME as a forecasting proof-of-concept, using information analogous to what would be available in real time rather than fine-tuning input parameters to achieve a best fit for a detailed scientific study. The OSPREDI prediction shows good agreement with the arrival time and in situ properties. **9 May 2021**

Modeling Interplanetary Expansion and Deformation of Coronal Mass Ejections With ANTEATR-PARADE: Sensitivity to Input Parameters

C. Kay, [T. Nieves-Chinchilla](#)

JGR **Volume126, Issue6** June 2021 e2020JA028966

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2020JA028966> <https://doi.org/10.1029/2020JA028966>

Space weather predictions related to coronal mass ejections (CMEs) requires understanding how a CME is initiated and how its properties change as it propagates. Most predictions have been limited to the arrival time of a CME and include little to no information about the CME's internal properties. ANother Type of Ensemble Arrival Time Results-Physics-driven Approach to Realistic Axis Deformation and Expansion (ANTEATR-PARADE) represents the most thorough description of the interplanetary evolution of CMEs in a highly computationally-efficient model (Kay & Nieves-Chinchilla, 2020, <https://doi.org/10.1029/2020JA028911>). presents the derivation of this model, where we have added an elliptical cross section to the original arrival time model ANTEATR and introduced internal magnetic and thermal forces that, combined with the drag, can alter the shape of the central axis and cross section. ANTEATR-PARADE results include the transit time of CMEs, as well as the shape and size, propagation and expansion velocities, density, and magnetic field properties upon impact. We determine the dependence of each output on each of the ANTEATR-PARADE input parameters. For a fast CME, we see that the parameterization of our thermal and magnetic models tends to be more important than the actual initial temperature or magnetic field strength. We extend to other CMEs and find that the sensitivities change with CME scale with thermal forces being more important for a weaker CME and magnetic forces being more important for a stronger CME. The most critical parameters for space weather predictions are the CME mass, the initial magnetic field strength, the adiabatic index, and the profile of the axial magnetic field strength.

Modeling Interplanetary Expansion and Deformation of CMEs with ANTEATR-PARADE I: Relative Contribution of Different Forces

C. Kay, T. Nieves-Chinchilla

JGR [Volume126, Issue5](#) May 2021 e2020JA028911

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2020JA028911>

<https://arxiv.org/pdf/2011.06030.pdf>

Coronal Mass Ejections (CMEs) are key drivers of space weather activity but most predictions have been limited to the expected arrival time of a CME, rather than the internal properties that affect the severity of an impact. Many properties, such as the magnetic field density and mass density, follow conservation laws and vary systematically with changes in the size of a CME. We present ANTEATR-PARADE, the newest version of the ANTEATR arrival time model, which now includes physics-driven changes in the size and shape of both the CME's central axis and its cross section. Internal magnetic and external drag forces affect the acceleration of the CME in different directions, inducing asymmetries between the radial and perpendicular directions. These improvements should lead to more realistic CME velocities, both bulk and expansion, sizes and shapes, and internal properties. ANTEATR-PARADE is the first model of its kind that provides this level of detail on the time scales needed for future space weather predictions. We present the model details, an initial illustration of the general behavior, and a study of the relative importance of the different forces. The model shows a pancaking of both the cross section and central axis of the CME so that their radial extent becomes smaller than their extent in the perpendicular direction. For a single parameterization of our magnetic field model we find that the drag forces tend to exceed the magnetic forces and the results are very sensitive to the initial velocities of the CME.

FIDO-SIT: The First Forward Model for the In Situ Magnetic Field of CME-Driven Sheaths

C. Kay, T. Nieves-Chinchilla, L. K. Jian

JGR [Volume125, Issue2](#) February 2020 e2019JA027423

<https://agupubs.onlinelibrary.wiley.com/doi/pdf/10.1029/2019JA027423>

We have shown previously that the in situ magnetic field of coronal mass ejections (CMEs) can be well reproduced by simple, physics-driven flux rope models using the ForeCAT In situ Data Observer (FIDO, Kay et al., 2017). Here, we show that a similar approach can be taken to forward model the shock and sheath of a CME (Sheath Induced by Transient [SIT]). We develop a relation between the downstream density and magnetic field strength that only depends on the upstream properties and downstream speed. Next, we establish a set of well-observed CME-driven shocks combining results from several online catalogs. We establish a baseline using the observed downstream speed and show that the mean absolute errors only increase slightly to 3.4 cm⁻³ and 3.8 nT when using a predicted downstream velocity. We also develop a model for the sheath duration or the standoff distance of the CME-driven shock. While there is certainly room for improvement, our model does perform better than those currently available, reducing the error from 7.0 to 4.6 hr. We couple our flux rope and sheath models as FIDO-SIT and present results for four observed cases. For three of the four cases, FIDO-SIT reproduces the sheath magnetic field with an error of one third the total magnitude for each individual vector component.

Identifying Critical Input Parameters for Improving Drag-Based CME Arrival Time Predictions

C. Kay , [M.L. Mays](#) , [C. Verbeke](#)

Space Weather **Volume18, Issue1** January 2020 e2019SW002382 **File**

sci-hub.se/10.1029/2019SW002382

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2019SW002382>

Coronal mass ejections (CMEs) typically cause the strongest geomagnetic storms so a major focus of space weather research has been predicting the arrival time of CMEs. Most arrival time models fall into two categories: (1) drag-based models that integrate the drag force between a simplified CME structure and the background solar wind and (2) full magnetohydrodynamic (MHD) models. Drag-based models typically are much more computationally efficient than MHD models, allowing for ensemble modeling. While arrival time predictions have improved since the earliest attempts, both types of models currently have difficulty achieving mean absolute errors below 10 hours. Here we use a drag-based model ANTEATR (Another Type of Ensemble Arrival Time Results, Kay & Gopal-swamy, 2018) to explore the sensitivity of arrival times to various input parameters. We consider CMEs of different strengths from average to extreme size, speed, and mass (kinetic energies between 9×10^{29} and 6×10^{32} erg). For each scale CME we vary the input parameters to reflect the current observational uncertainty in each and determine how accurately each must be known to achieve predictions that are accurate within 5 hours. We find that different scale CMEs are the most sensitive to different parameters. The transit time of average strength CMEs depends most strongly on the CME speed whereas an extreme strength CME is the most sensitive to the angular width. A precise CME direction is critical for impacts near the flanks, but not near the CME nose. We also show that the Drag Based Model (Vršnak et al., 2013) has similar sensitivities, suggesting that these results are representative for all drag-based models.

Frequency of Coronal Mass Ejection Impacts with Early Terrestrial Planets and Exoplanets around Active Solar-like Stars

Christina Kay, Vladimir S. Airapetian, Theresa Lüftinger, and Oleg Kochukhov
2019 ApJL 886 L37

<https://iopscience.iop.org/article/10.3847/2041-8213/ab551f/pdf>

Energetic flares and associated coronal mass ejections (CMEs) from young magnetically active solar-like stars can play a critical role in setting conditions for atmospheric escape as well as penetration of accelerated particles into their atmospheres that promotes formation of biologically relevant molecules. We have used the observationally reconstructed magnetic field of the 0.7 Gyr young Sun's twin, κ 1 Ceti, to study the effects of CME deflections in the magnetic corona of the young Sun and their effects on the impact frequency on the early Venus, Earth, and Mars. We find that the coronal magnetic field deflects the CMEs toward the astrospheric current sheet. This effect suggests that CMEs tend to propagate within a small cone about the ecliptic plane increasing the impact frequency of CMEs with planetary magnetospheres near this plane to $\sim 30\%$ or by a factor of 6 as compared to previous estimate by Airapetian et al. Our model has important implications for the rise of prebiotic chemistry on early terrestrial planets as well as terrestrial-type exoplanets around young G-K dwarfs.

The Effects of Uncertainty in Initial CME Input Parameters on Deflection, Rotation, Bz, and Arrival Time Predictions

C. Kay , [N. Gopalswamy](#)

JGR v. 123 September 2018 Pages 7220-7240

sci-hub.tw/10.1029/2018JA025780

Understanding the effects of coronal mass ejections (CMEs) requires knowing if and when they will impact and their properties upon impact. Of particular importance is the strength of a CME's southward magnetic field component (B_z). Kay et al. (2013, <https://doi:10.1088/0004-637X/775/1/5>, 2015, <https://doi:10.1088/9480004-637X/805/2/168>) have shown that the simplified analytic model Forecasting a CME's Altered Trajectory (ForeCAT) can reproduce the deflection and rotation of CMEs. Kay, Gopalswamy, Reinard, and Opher (2017, <https://doi.org/10.3847/1538-4357/835/2/117>) introduced ForeCAT In situ Data Observer, which uses ForeCAT results to simulate magnetic field profiles. ForeCAT In situ Data Observer reproduces the in situ observations on roughly hourly time scales, suggesting that these models could be extremely useful for predictions of B_z . However, as with all models, both models are sensitive to their input parameters, which may not be precisely known for predictions. We explore this sensitivity using ensembles having small changes in the initial latitude, longitude, and orientation of the erupting CME. We explore the effects of different background magnetic field models and find that the changes in deflection and rotation resulting from the uncertainty in the initial parameters tend to exceed the changes from different magnetic backgrounds. The range in

the in situ profiles tends to scale with the range in the deflection and rotation. We also consider a simple arrival time model using ForeCAT results and find an average absolute error of only 3 hr. We show that an uncertainty in the CME position of $8.1^\circ \pm 6.9^\circ$ leads to variations of 6 hr in the arrival time. This measure depends strongly on the location of impact within the CME with the arrival time changing less for impacts near the nose. **06 September 2011, 12 July 2012, 28 September 2012, 23 November 2012, 29 September 2013, 12 February 2014**

Using the Coronal Evolution to Successfully Forward Model CMEs' In Situ Magnetic Profiles

C. Kay, N. Gopalswamy

JGR Volume 122, Issue 12 December 2017 Pages 11,810–11,834

[\[hub.tw/http://onlineibrary.wiley.com/doi/10.1002/2017JA024541/abstract;jsessionid=2DF604EC239663BA90D09F3C3BE44317.f01t04\]\(http://onlineibrary.wiley.com/doi/10.1002/2017JA024541/abstract;jsessionid=2DF604EC239663BA90D09F3C3BE44317.f01t04\)](http://sci-</p></div><div data-bbox=)

Predicting the effects of a coronal mass ejection (CME) impact requires knowing if impact will occur, which part of the CME impacts, and its magnetic properties. We explore the relation between CME deflections and rotations, which change the position and orientation of a CME, and the resulting magnetic profiles at 1 AU. For 45 STEREO-era, Earth-impacting CMEs, we determine the solar source of each CME, reconstruct its coronal position and orientation, and perform a ForeCAT (Forecasting a CME's Altered Trajectory) simulation of the coronal deflection and rotation. From the reconstructed and modeled CME deflections and rotations, we determine the solar cycle variation and correlations with CME properties. We assume no evolution between the outer corona and 1 AU and use the ForeCAT results to drive the ForeCAT In situ Data Observer (FIDO) in situ magnetic field model, allowing for comparisons with ACE and Wind observations. We do not attempt to reproduce the arrival time. On average FIDO reproduces the in situ magnetic field for each vector component with an error equivalent to 35% of the average total magnetic field strength when the total modeled magnetic field is scaled to match the average observed value. Random walk best fits distinguish between ForeCAT's ability to determine FIDO's input parameters and the limitations of the simple flux rope model. These best fits reduce the average error to 30%. The FIDO results are sensitive to changes of order a degree in the CME latitude, longitude, and tilt, suggesting that accurate space weather predictions require accurate measurements of a CME's position and orientation. **24 May 2010.**

Predicting the Magnetic Field of Earth-impacting CMEs

C. Kay¹, N. Gopalswamy¹, A. Reinard², and M. Opher³

2017 ApJ 835 117 **File**

<http://sci-hub.cc/doi/10.3847/1538-4357/835/2/117>

Predicting the impact of coronal mass ejections (CMEs) and the southward component of their magnetic field is one of the key goals of space weather forecasting. We present a new model, the ForeCAT In situ Data Observer (FIDO), for predicting the in situ magnetic field of CMEs. We first simulate a CME using ForeCAT, a model for CME deflection and rotation resulting from the background solar magnetic forces. Using the CME position and orientation from ForeCAT, we then determine the passage of the CME over a simulated spacecraft. We model the CME's magnetic field using a force-free flux rope and we determine the in situ magnetic profile at the synthetic spacecraft. We show that FIDO can reproduce the general behavior of four observed CMEs. FIDO results are very sensitive to the CME's position and orientation, and we show that the uncertainty in a CME's position and orientation from coronagraph images corresponds to a wide range of in situ magnitudes and even polarities. This small range of positions and orientations also includes CMEs that entirely miss the satellite. We show that two derived parameters (the normalized angular distance between the CME nose and satellite position and the angular difference between the CME tilt and the position angle of the satellite with respect to the CME nose) can be used to reliably determine whether an impact or miss occurs. We find that the same criteria separate the impacts and misses for cases representing all four observed CMEs. **2010 April 3, 2011 Feb 15, 2012 Jul 12, 2014 Sep 10**

Forecasting a coronal mass ejection's altered trajectory: ForeCAT.

Continuous vector magnetic-field measurements by the Helioseismic and Magnetic Imager (HMI) onboard the Solar Dynamics Observatory (SDO) allow us to study magnetic-field properties of many flares. Here, we review new observational aspects of flare magnetism described using SDO data, including statistical properties of magnetic-reconnection fluxes and their rates, magnetic fluxes of flare dimmings, and magnetic-field changes during flares. We summarize how these results, along with statistical studies of coronal mass ejections (CMEs), have improved our understanding of flares and the flare/CME feedback relationship. Finally, we highlight future directions to improve the current state of understanding of solar-flare magnetism using observations. **14 Sep 2011, 7 March 2012, Sep 2014**

Predictions of Energy and Helicity in Four Major Eruptive Solar Flares

Maria D. [Kazachenko](#), Richard C. Canfield, Dana W. Longcope and Jiong Qiu

[Solar Physics](#), Volume 277, Number 1, 165-183, **2012**, **File**

In order to better understand the solar genesis of interplanetary magnetic clouds (MCs), we model the magnetic and topological properties of four large eruptive solar flares and relate them to observations. We use the three-dimensional Minimum Current Corona model (Longcope, 1996, *Solar Phys.* 169, 91) and observations of pre-flare photospheric magnetic field and flare ribbons to derive values of reconnected magnetic flux, flare energy, flux rope helicity, and orientation of the flux-rope poloidal field. We compare model predictions of those quantities to flare and MC observations, and within the estimated uncertainties of the methods used find the following: The predicted model reconnection fluxes are equal to or lower than the reconnection fluxes inferred from the observed ribbon motions. Both observed and model reconnection fluxes match the MC poloidal fluxes. The predicted flux-rope helicities match the MC helicities. The predicted free energies lie between the observed energies and the estimated total flare luminosities. The direction of the leading edge of the MC's poloidal field is aligned with the poloidal field of the flux rope in the AR rather than the global dipole field. These findings compel us to believe that magnetic clouds associated with these four solar flares are formed by low-corona magnetic reconnection during the eruption, rather than eruption of pre-existing structures in the corona or formation in the upper corona with participation of the global magnetic field. We also note that since all four flares occurred in active regions without significant pre-flare flux emergence and cancellation, the energy and helicity that we find are stored by shearing and rotating motions, which are sufficient to account for the observed radiative flare energy and MC helicity.

On the azimuthal evolution and geoeffectiveness of the SIR-associated stream interface[†]

A. C. [Kellerman](#), R. L. McPherron and J. M. Weygand

[JGR](#) [Volume 120, Issue 3](#) March 2015 Pages 1489–1508 **2015**

In this study, the azimuthal evolution of stream interaction regions are investigated, with the goal of predicting the time of arrival of an interface at some later position near 1 AU. A new SIR dataset is constructed from ACE, STEREO A and STEREO B in situ measurements, and it is demonstrated that the magnetic pressure and azimuthal flow angle provide the most simple robust estimation of the interface time. This dataset was applied in the investigation. In the analysis, the geometric effects of the magnetic spiral angle, and the tilt angle of stream interfaces are considered, and it is demonstrated how they may be used to improve forecasts of the arrival time of stream interaction regions from a spacecraft located at 1 AU. The polarity of the interplanetary magnetic field, towards or away from the Sun, observed by consecutive spacecraft measurements is considered for the slow and fast streams straddling a stream interface, in order to investigate whether the geoeffectiveness of the two streams may also be forecast from 1 AU. It is found that the polarity of the magnetic field, associated with a given stream interface, is conserved when observed by two separate spacecraft at azimuthal separations of 20° or less and while in the fast wind, however, the field polarity was not always conserved when observed in the slow wind ahead of the interface. An analysis of tilt angles evolution during 2008 showed that while the azimuthal tilt angles were generally similar between observations in the same Carrington rotation and in consecutive rotations of the same CIR, the meridional tilt angles may differ significantly. The forecast analysis showed that the azimuthal evolution of a SIR at 1 AU may be predicted to within a day or two of the actual evolution

time, while any discrepancy was most likely caused by changes at the coronal hole on the solar surface, leading azimuthal and radial evolution of the SIR.

Heating of the Solar Wind by Ion Acoustic Waves

Paul J. Kellogg

2020 ApJ 891 51

<https://doi.org/10.3847/1538-4357/ab7003>

Calculations are made of the energy supplied to the solar wind by the rapid decay of density fluctuations, identified as ion acoustic waves. It is shown that this process supplies an appreciable fraction, perhaps nearly all, of the observed heating of the solar wind. This process may be an important step in the conversion of magnetic turbulence to particle energy.

Inherent Length Scales of Periodic Mesoscale Density Structures in the Solar Wind Over Two Solar Cycles

L. Kepko [N. M. Viall](#) [K. Wolfinger](#)

JGR [Volume 125, Issue 8](#) August 2020 e2020JA028037

<https://agupubs.onlinelibrary.wiley.com/doi/10.1029/2020JA028037>

It is now well established through multiple event and statistical studies that the solar wind at 1 AU contains periodic, mesoscale ($L \sim 100\text{--}1,000$ Mm) structures in the proton density. Composition variations observed within these structures and remote sensing observations of similar structures in the young solar wind indicate that at least some of these periodic structures originate in the solar atmosphere as a part of solar wind formation. Viall et al. (2008, <https://doi.org/10.1029/2007JA012881>) analyzed 11 years of data from the Wind spacecraft near L1 and demonstrated a recurrence to the observed length scales of periodic structures in the solar wind proton density. In the time since that study, Wind has collected 14 additional years of solar wind data, new moment analysis of the Wind SWE data is available, and new methods for spectral background approximation have been developed. In this study, we analyze 25 years of Wind data collected near L1 and produce occurrence distributions of statistically significant periodic length scales in proton density. The results significantly expand upon the Viall et al. (2008, <https://doi.org/10.1029/2007JA012881>) study and further show a possible relation of the length scales to solar “termination” events.

Implications of L1 observations for slow solar wind formation by solar reconnection

L. Kepko, N. M. Viall, S. K. Antiochos, S. T. Lepri, J. C. Kasper, M. Weberg

Geophys. Res. Lett. 2016

<http://onlinelibrary.wiley.com/doi/10.1002/2016GL068607/full>

While the source of the fast solar wind is known to be coronal holes, the source of the slow solar wind has remained a mystery. Long time scale trends in the composition and charge states show strong correlations between solar wind velocity and plasma parameters, yet these correlations have proved ineffective in determining the slow wind source. We take advantage of new high time resolution (12 min) measurements of solar wind composition and charge state abundances at L1 and previously identified 90 min quasiperiodic structures to probe the fundamental timescales of slow wind variability. The combination of new high temporal resolution composition measurements and the clearly identified boundaries of the periodic structures allows us to utilize these distinct solar wind parcels as tracers of slow wind origin and acceleration. We find that each 90 min (2000 Mm) parcel of slow wind has near-constant speed yet exhibits repeatable, systematic charge state and composition variations that span the entire range of statistically determined slow solar wind values. The classic composition-velocity correlations do not hold on short, approximately hourlong, time scales. Furthermore, the data demonstrate that these structures were created by magnetic reconnection. Our results impose severe new constraints on slow solar wind origin and provide new, compelling evidence that *the slow wind results from the sporadic release of closed field plasma via magnetic reconnection at the boundary between open and closed flux in the Sun's atmosphere.*

Front. Astron. Space Sci., 10: 1254235. 2023

<https://www.frontiersin.org/articles/10.3389/fspas.2023.1254235/pdf>

The present Research Topic opens the series of “Reviews in space physics” with a Research Topic comprising a limited number of submissions discussing the current state of research in the wide domain of Space Physics. Within the framework of this Research Topic, Frontiers will publish reviews, covering diverse aspects of heliospheric, solar, magnetospheric, and ionospheric physics. Reviews included in this Research Topic are aimed at covering processes from the upper terrestrial atmosphere to distant astronomical space, critically discussing past and future developments in theory, observation, analysis, and instrumentation.

This first 2023 Research Topic of Reviews in Space Physics contains six articles written by 60 authors. Its Research Topic focus on 1) space weather, its geo-effective mechanisms and possible threats to civilization, including radiation hazards; 2) studies of dynamical structures in the small- and large-scale solar wind and the consequences of their interaction with the terrestrial magnetosphere, with special focus on processes in Earth’s magnetosheath (MSH); 3) observations and modelling of MSH plasma jets, and 4) acceleration and propagation of solar energetic particles (SEPs) and cosmic rays (CRs) in the heliosphere and beyond.

Current sheets, plasmoids and flux ropes in the heliosphere.

Recent accumulation of a critical mass of observational material from different spacecraft complete with the enhanced abilities of numerical methods have led to a boom of studies revealing the high complexity of processes occurring in the heliosphere. Views on the solar wind filling the interplanetary medium have dramatically developed from the beginning of the space era. A 2-D picture of the freely expanding solar corona and non-interacting solar wind structures described as planar or spherically-symmetric objects has dominated for decades. Meanwhile, the scientific community gradually moved to a modern understanding of the importance of the 3-D nature of heliospheric processes and their studies via MHD/kinetic simulations, as well as observations of large-scale flows and streams both in situ and remotely, in white light and/or via interplanetary scintillations. The new 3-D approach has provided an opportunity to understand the dynamics of heliospheric structures and processes that could not even be imagined before within the 2-D paradigm. In this review, we highlight a piece of the puzzle, showing the evolution of views on processes related to current sheets, plasmoids, blobs and flux ropes of various scales and origins in the heliosphere. The first part of the review focuses on introducing these plasma structures, discussing their key properties, and paying special attention to their observations in different space plasmas. 29 May 1995, 30 Oct 2003, 24-26 Jun 2004, February 24, 2011 ...

Counterstreaming Strahls and Heat Flux Dropouts as Possible Signatures of Local Particle Acceleration in the Solar Wind

O. **Khabarova**¹, V. Zharkova², Q. Xia², and O. E. Malandraki³

2020 ApJL 894 L12

<https://iopscience.iop.org/article/10.3847/2041-8213/ab8cb8/pdf>

Suprathermal electrons with energies of ~70 eV and above are observed at 1 au as dispersionless halo electrons and magnetic field-aligned beams of strahls. For a long time, it has been thought that both populations originate only from the solar corona, and that the only active process impacting their properties in the solar wind is scattering. This view has consequently impacted the interpretation of typical patterns of pitch-angle distributions (PADs) of suprathermal electrons. Meanwhile, recent observational studies supported by numerical simulations have shown that there is an unaccounted population of electrons accelerated to suprathermal energies at reconnecting current sheets (RCSs) and 3D dynamical plasmoids (or 2D magnetic islands (MIs)) directly in the heliosphere. We present multispacecraft observations of counterstreaming strahls and heat flux dropouts in PADs within a region filled with plasmoids and RCSs unaffected by interplanetary shocks, comparing observed PAD features with those predicted by particle-in-cell simulations. We show typical PAD patterns determined by local acceleration of thermal-core electrons up to hundreds of electron volts. Resulting PAD views depend on properties and topology of particular RCSs, MIs, and plasma/magnetic field parameters. Our study suggests that solar wind-borne suprathermal electrons coexist with those of solar origin. Therefore, some of heat flux dropout and bidirectional strahl events can be explained by local dynamical processes involving magnetic reconnection. Possible implications of the results for the interpretation of the actively debated

decrease in the strahl/halo relative density with heliocentric distance and puzzling features of suprathermal electrons observed at crossings of the heliospheric current sheet and cometary comas are also discussed.

Observational evidence for local particle acceleration associated with magnetically confined magnetic islands in the heliosphere – a review

Olga V. [Khabarova](#) 1 , Gary P. Zank 2,3, Olga E. Malandraki 4 , Gang Li 2, 3 , Jakobus A. le Roux 2,3, Gary M. Webb

Sun and Geosphere, **2017**; 12/1: 23 -30

http://newserver.stil.bas.bg/SUNGEO//00SGArhiv/SG_v12_No1_2017-pp-23-30.pdf

The occurrence of unusual energetic particle enhancements up to several MeV/nuc at leading edges of corotating interaction regions (CIRs), near the heliospheric current sheet and downstream of interplanetary shocks at 1AU has puzzled observers for a long time. Commonly accepted mechanisms of particle energization, such as a classical diffusive shock acceleration mechanism or magnetic reconnection at current sheets, are unable to explain these phenomena. We present a review of recently obtained observational results that attribute these atypical energetic particle events to local acceleration of particles in regions filled with small-scale magnetic islands confined by currents sheets of various origins. The observations are in very good accordance with the theory of stochastic particle energization in the supersonic solar wind via a sea of small-scale flux-ropes interacting dynamically (Zank et al., 2014, 2015; le Roux et al., 2015, 2016). **07-09-1999, March 1st, 2006 , August 24-26, 2007**

SMALL-SCALE MAGNETIC ISLANDS IN THE SOLAR WIND AND THEIR ROLE IN PARTICLE ACCELERATION. II. PARTICLE ENERGIZATION INSIDE MAGNETICALLY CONFINED CAVITIES

Olga V. [Khabarova](#)1, Gary P. Zank2,3, Gang Li2,3, Olga E. Malandraki4, Jakobus A. le Roux2,3, and Gary M. Webb2

2016 ApJ 827 122

We explore the role of heliospheric magnetic field configurations and conditions that favor the generation and confinement of small-scale magnetic islands associated with atypical energetic particle events (AEPEs) in the solar wind. Some AEPEs do not align with standard particle acceleration mechanisms, such as flare-related or simple diffusive shock acceleration processes related to interplanetary coronal mass ejections (ICMEs) and corotating interaction regions (CIRs). As we have shown recently, energetic particle flux enhancements may well originate locally and can be explained by particle acceleration in regions filled with small-scale magnetic islands with a typical width of ~ 0.01 au or less, which is often observed near the heliospheric current sheet (HCS). The particle energization is a consequence of magnetic reconnection-related processes in islands experiencing either merging or contraction, observed, for example, in HCS ripples. Here we provide more observations that support the idea and the theory of particle energization produced by small-scale-flux-rope dynamics (Zank et al. and Le Roux et al.). If the particles are pre-accelerated to keV energies via classical mechanisms, they may be additionally accelerated up to 1–1.5 MeV inside magnetically confined cavities of various origins. The magnetic cavities, formed by current sheets, may occur at the interface of different streams such as CIRs and ICMEs or ICMEs and coronal hole flows. They may also form during the HCS interaction with interplanetary shocks (ISs) or CIRs/ICMEs. Particle acceleration inside magnetic cavities may explain puzzling AEPEs occurring far beyond ISs, within ICMEs, before approaching CIRs as well as between CIRs.

Dynamical small-scale magnetic islands as a source of local acceleration of particles in the solar wind

http://computing.unn.ac.uk/staff/slmv5/kinetics/Tampa15_Olga_v2.pdf

We present observations of energetic particle flux increases up to 1 MeV at 1 AU, which cannot be associated with ordinary mechanisms of particle acceleration, such as acceleration at shocks or at the Sun. Such unusual energetic particle events very likely have a local origin. Multi-spacecraft observations show that numerous cases of energetic particle flux enhancements and spikes correspond to passages of spacecraft through areas filled with magnetic islands with a typical width $\sim 0.01 \square 0.001$ AU that experience dynamical merging or/and contraction. The presence of magnetic islands inside magnetically confined cavities in the solar wind may lead to local particle energization, especially in the case when the particles have already been pre-accelerated to keV energies, for example, at shocks or due to magnetic reconnection at the heliospheric current sheet. We consider different magnetic configurations that provide favourable conditions for both the appearance of small-scale magnetic islands and their confinement.

Study of cosmic ray intensity and geomagnetic storms with solar wind parameters during the period 1998–2005

Hema [Kharayat](#), Lalan Prasad

[Astrophysics and Space Science](#) January 2017, 362:20

<http://sci-hub.cc/10.1007/s10509-016-2996-5>

The aim of this paper is to study the effect of solar wind parameters (solar wind speed VV , plasma flow pressure, and plasma density) on cosmic ray intensity and on geomagnetic storms for the period 1998–2005 (solar cycle 23). A Chree analysis by the superposed epoch method has been done for the study. From the present study we have found that the solar wind speed is a highly effective parameter in producing cosmic ray intensity decreases and geomagnetic storms. No time lag is found between cosmic ray intensity decreases, geomagnetic storms, and peak value of solar wind speed. Further, we have found that the plasma flow pressure is effectively correlated with geomagnetic storms but it is weakly correlated with cosmic ray intensity. The cosmic ray intensity and geomagnetic storms are found to be weakly correlated with plasma density. The decrease in cosmic ray intensity and geomagnetic storms takes place one day after the peak values of plasma flow pressure and plasma density. There is a time lag of one day between solar wind parameters (plasma flow pressure and plasma density) and cosmic ray intensity decrease, geomagnetic storms. Also, we have found a high correlation of cosmic ray intensity and geomagnetic storms with the product of interplanetary magnetic field BB and solar wind speed VV i.e. $B \cdot VB \cdot V$. This study may be useful in predicting the space-weather phenomena.

Study of Cosmic Ray Intensity in Relation to the Interplanetary Magnetic Field and Geomagnetic Storms for Solar Cycle 23

Hema [Kharayat](#), Lalan Prasad, Rajesh Mathpal, Suman Garia, Beena Bhatt

Solar Phys. Vol. 291, Issue 2 2016

We investigate the association of the cosmic-ray intensity (CRI) with the interplanetary magnetic field (IMF, B) and geomagnetic storms (GS) for the period 1997–2006 (Solar Cycle 23). To do this, we conducted a Chree analysis by the superposed-epoch method. A transient decrease in CRI is found on the occurrence days of GS, and this decrease shows a similar pattern to that of the disturbance storm-time index (Dst). In addition, we show that the CRI decreases with the increase in IMF. The time lag between the decrease in CRI and increase in IMF is about one day or less. Furthermore, an increase in IMF B is found with the decrease in Dst index. IMF and Dst index are highly anti-correlated to each other, while the sunspot number is not found to be correlated with IMF, Dst index, or CRI for the period studied. The IMF is found to be an effective parameter combination for producing GS and Forbush decrease. We also found two types of decrease in CRI for Solar Cycle 23: i) symmetric and ii) asymmetric decreases. The study of CRI decreases may be useful for studying space-weather effects.

Radar detection of interplanetary shocks: Scattering by anisotropic Langmuir turbulence

Mykola V. [Khotyaintsev](#), Valentin N. Mel'nik, Bo Thidé, Yuri V. Khotyaintsev

[Advances in Space Research](#), Volume 45, Issue 6, 15 March 2010, Pages 804-811

Earth-directed interplanetary shocks associated with coronal mass ejections (CMEs) are known to have a severe impact on the magnetosphere, causing strong geomagnetic storms and substorms. Hence, early detection of such shocks is important. Here we study the feasibility of radar detection of interplanetary shocks. We consider a scattering mechanism, which is based on the induced scattering $t+l \leftrightarrow t$ of a radar wave by anisotropic Langmuir turbulence, being generated by the shock-accelerated electrons. The problem is studied for an arbitrary angle between the electron beam and the incident radar wave, $\mathbf{v}_b \wedge \mathbf{k}_t$, and special emphasis is put on the study of a dependence of the scattering process on this angle. We obtain and analyze analytical expressions for the frequency shift, scattering cross-section of the turbulence, coefficient of absorption (due to scattering), and the optical depth. We show that the detection of such shocks is possible if the turbulence energy density exceeds $W = 10^{-5} nT$ (nT is the thermal energy density of a plasma), which is quite realistic according to our estimations. The altitudes in the solar corona where reflections may occur depend on the angle $\mathbf{v}_b \wedge \mathbf{k}_t$. If expressed in local plasma frequencies, ω_p , the altitudes span is $\omega_t/8 \lesssim \omega_p \lesssim \omega_t$ for $\mathbf{v}_b \wedge \mathbf{k}_t = \pi$ and $\omega_t/120 \lesssim \omega_p \lesssim \omega_t$ for $\mathbf{v}_b \wedge \mathbf{k}_t = \pi/2$, where ω_t is a frequency of the transmitted radar wave. Thus the scattering occurs much closer to the radar in the second case than in the first. Detection of the scattered signal, in the general case, requires a remote receiver, since the radar wave backscatters only for $\mathbf{v}_b \wedge \mathbf{k}_t = \pi$.

Physics-based model of solar wind stream interaction regions: Interfacing between Multi-VP and 1D MHD for operational forecasting at L1

Our current capability of space weather prediction in the Earth's radiation belts is limited to only an hour in advance using the real-time solar wind monitoring at the Lagrangian L1 point. To mitigate the impacts of space weather on telecommunication satellites, several frameworks were proposed to advance the lead time of the prediction. We develop a prototype pipeline called "Helio1D" to forecast ambient solar wind conditions (speed, density, temperature, tangential magnetic field) at L1 with a lead time of 4 days. This pipeline predicts Corotating Interaction Regions (CIRs) and high-speed streams that can increase high-energy fluxes in the radiation belts. The Helio1D pipeline connects the Multi-VP model, which provides real-time solar wind emergence at 0.14 AU, and a 1D MHD model of solar wind propagation. We benchmark the Helio1D pipeline for solar wind speed against observations for the intervals in 2004 - 2013 and 2017 - 2018. We developed a framework based on the Fast Dynamic Time Warping technique that allows us to continuously compare time-series outputs containing CIRs to observations to measure the pipeline's performance. In particular, we use this framework to calibrate and improve the pipeline's performance for operational forecasting. To provide timing and magnitude uncertainties, we model several solar wind conditions in parallel, for a total of 21 profiles corresponding to the various virtual targets including the Earth. This pipeline can be used to feed real-time, daily solar wind forecasting that aims to predict the dynamics of the inner magnetosphere and the radiation belts.

A Peculiar ICME Event in August 2018 Observed with the Global Muon Detector Network

We demonstrate that global observations of high-energy cosmic rays contribute to understanding unique characteristics of a large-scale magnetic flux rope causing a magnetic storm in August 2018. Following a weak interplanetary shock on 25 August 2018, a magnetic flux rope caused an unexpectedly large geomagnetic storm. It is likely that this event became geoeffective because the flux rope was accompanied by a corotating interaction region and compressed by high-speed solar wind following the flux rope. In fact, a Forbush decrease was observed in cosmic-ray data inside the flux rope as expected, and a significant cosmic-ray density increase exceeding the unmodulated level before the shock was also observed near the trailing edge of the flux rope. The cosmic-ray density increase can be interpreted in terms of the adiabatic heating of cosmic rays near the trailing edge of the flux rope, as the corotating interaction region prevents free expansion of the flux rope and results in the compression near the trailing edge. A northeast-directed spatial gradient in the cosmic-ray density was also derived during the cosmic-ray density increase, suggesting that the center of the heating near the trailing edge is located northeast of Earth. This is one of the best examples demonstrating that the observation of high-energy cosmic rays provides us with information that can only be derived from the cosmic ray measurements to observationally constrain the three-dimensional macroscopic picture of the interaction between coronal mass ejections and the ambient solar wind, which is essential for prediction of large magnetic storms. **25-26 Aug 2018**

Solar and Geomagnetic Activity Relation for the Last two Solar Cycles

Sun and Geosphere, **2017**; 12/1: 31-39

http://newserver.stil.bas.bg/SUNGEO/00SGArhiv/SG_v12_No1_2017-pp-31-39.pdf

The long-term relationship between solar (sunspot counts in different Zurich sunspot groups, International Sunspot Number (ISSN), solar wind, and X-Ray solar flare index and geomagnetic indices (Ap and Dst) is investigated. Data sets used in this study cover a time period from January 1996 to March 2014. Our main findings are as follows: 1) The best correlation between the sunspot counts and the Ap index are obtained for the large group time series, while the other categories exhibited lower (final and medium) or no correlation at all (small). It is interesting to note that Ap index is

delayed by about 13 months relatively to all sunspot count series and ISSN data. 2) The best correlation between the sunspot counts and the Dst index was as well obtained for the large AR time series. The Dst index delays with respect to the large group by about 2 months. 3) The highest correlation between the solar and geomagnetic indices were obtained between the solar wind speed and Ap and Dst indices with zero time delays ($r = 0.76$, $r = 0.52$, respectively). 4) The correlation coefficients between the geomagnetic indices (Ap, Dst) and X-Ray solar flare index ($r = 0.59$, $r = -0.48$, respectively) are a little higher than the correlation coefficients between these geomagnetic indices and ISSN ($r = 0.57$, $r = -0.43$, respectively). 5) The magnitude of all solar and geomagnetic indices (except the solar wind speed) has significantly decreased during the current solar cycle as compared to the same phase of the previous cycle.

Maximum CME speed as an indicator of solar and geomagnetic activities

BBSO Preprint #1456, 2010; Ap. J. 727:44 (6pp), 2011 January, **File**

We investigate the relationship between the monthly averaged maximal speeds of coronal mass ejections (CMEs), international sunspot number (ISSN) and the geomagnetic Dst and Ap indices covering the 1996-2008 time interval (solar cycle 23). Our new findings are as follows. i) There is a noteworthy relationship between monthly averaged maximum CME speeds and sunspot numbers, Ap and Dst indices. Various peculiarities in the monthly Dst index are better correlated with the fine structures in the CME speed profile than that in the ISSN data. ii) Unlike the sunspot numbers, the CME speed index does not exhibit a double peak maximum. Instead, the CME speed profile peaks during the declining phase of solar cycle 23. Similar to the Ap index, both CME speed and the Dst indices lag behind the sunspot numbers by several months. iii) CME number shows a double peak similar to that seen in the sunspot numbers. The CME occurrence rate remained very high even near the minimum of the solar cycle 23, when both sunspot number and the CME average maximum speed were reaching their minimum values. iv) A well defined peak of the Ap index between May 2002 and August 2004 was co-temporal with the excess of the mid-latitude coronal holes during solar cycle 23. The above findings suggest that the CME speed index may be a useful indicator of both solar and geomagnetic activity. It may have advantages over the sunspot numbers, because it better reflects the intensity of Earth directed solar eruptions.

A Statistical Study of the Relationship Between the Sunspot Number, Maximum CME Speed and Geomagnetic Indices

A [Kilcik](#), V.B. Yurchyshyn, V. Abramenko, P.R. Goode, N. Gopalswamy, A. Ozguc and J.P. Rozelot
BBSO Preprint #1424, 2010; **File**

We investigated the relationship between the monthly averaged maximal speeds of coronal mass ejections (CMEs), sunspot number (SSN) and the geomagnetic Dst and Ap indices covering the 1996-2008 time interval. The study was carried out using frequency and correlation analyses. Frequency analysis of the maximum speed of CMEs (or CME speed index) shows a cyclic behavior similar to that found for SSN and the Ap index. Our new findings are as follows. 1) Unlike the SSN, the CME speed index does not exhibit a double peak maximum. 2) The CME speed index has a correlative relationship with SSN and Dst and Ap indices (correlation coefficients are 0.76, -0.53, 0.68 respectively). Various peculiarities in the monthly Dst index are better correlated with the fine structures in the CME speed profile than that in the SSN data. 3) Similar to the Ap index, both CME speed and the Dst indices lag behind the sunspot numbers by several months. We thus conclude that CME speed index may be a good parameter to describe the geo-effectiveness of solar activity.

Structure and fluctuations of a slow ICME sheath observed at 0.5 au by the Parker Solar Probe

<https://www.aanda.org/articles/aa/pdf/2022/07/aa42191-21.pdf>

Sheaths ahead of interplanetary coronal mass ejections (ICMEs) are turbulent heliospheric structures. Knowledge of their structure and fluctuations is important for understanding their geoeffectiveness, their role in accelerating particles, and the interaction of ICMEs with the solar wind. We studied observations from the Parker Solar Probe of a sheath observed at 0.5 au in March 2019, ahead of a slow streamer blowout CME. To examine the MHD-scale turbulent properties, we calculated fluctuation amplitudes, magnetic compressibility, partial variance of increments (PVI), cross helicity (σ_c), residual energy (σ_r), and the Jensen-Shannon permutation entropy and complexity. The sheath consisted of

slow and fast flows separated by a 15-min change in magnetic sector that coincided with current sheet crossings and a velocity shear zone. Fluctuation amplitudes and PVI were greater through the sheath than upstream. Fluctuations had mostly negative σ_r and positive σ_c in the sheath, the latter indicating an anti-sunward sense of propagation. The velocity shear region marked an increase in temperature and specific entropy, and the faster flow behind had local patches of positive σ_r as well as higher fluctuation amplitudes and PVI. Fluctuations in the preceding wind and sheath were stochastic, with the sheath fluctuations showing lower entropy and higher complexity than upstream. The two-part sheath structure likely resulted from a warp in the heliospheric current sheet (HCS) being swept up and compressed. The ejecta accelerated and heated the wind at the sheath rear, which then interacted with the slower wind ahead of the HCS warp. This caused differences in fluctuation properties across the sheath. Sheaths of slow ICMEs can thus have complex structure where fluctuation properties are not just downstream shock properties, but are generated within the sheath.

Multi-spacecraft observations of the structure of the sheath of an interplanetary coronal mass ejection and related energetic ion enhancement

E. K. J. Kilpua, S. W. Good, N. Dresing, R. Vainio, + + +

Astronomy & Astrophysics, Solar Orbiter First Results (Cruise Phase) special issue 2021

<https://arxiv.org/pdf/2112.09472.pdf>

Sheaths ahead of coronal mass ejections (CMEs) are large heliospheric structures that form with CME expansion and propagation. Turbulent and compressed sheaths contribute to the acceleration of particles in the corona and in interplanetary space, but the relation of their internal structures to particle energization is still relatively little studied. In particular, the role of sheaths in accelerating particles when the shock Mach number is low is a significant open problem. This work seeks to provide new insights on the internal structure of CME sheaths with regard to energetic particle enhancements. A good opportunity to achieve this aim was provided by observations of a sheath made by radially aligned spacecraft at 0.8 and ~ 1 AU (Solar Orbiter, Wind, ACE and BepiColombo) on **19-21 April 2020**. The sheath was preceded by a weak shock. Energetic ion enhancements occurred at different locations within the sheath structure at Solar Orbiter and L1. Magnetic fluctuation amplitudes at inertial-range scales increased in the sheath relative to the upstream wind. However, when normalised to the local mean field, fluctuation amplitudes did not increase significantly; magnetic compressibility of fluctuation also did not increase. Various substructures were embedded within the sheath at the different spacecraft, including multiple heliospheric current sheet (HCS) crossings and a small-scale flux rope. At L1, the ion flux enhancement was associated with the HCS crossings, while at Solar Orbiter, the enhancement occurred within the rope. Substructures that are swept from the upstream solar wind and compressed in the sheath can act as particularly effective acceleration sites. A possible acceleration mechanism is betatron acceleration associated with the small-scale flux rope and the warped HCS in the sheath.

Statistical Analysis of Magnetic Field Fluctuations in Coronal Mass Ejection-Driven Sheath Regions

E. K. J. Kilpua^{1*}, S. W. Good¹, M. Ala-Lahti¹, A. Osmane¹, D. Fontaine², L. Hadid², M. Janvier³ and E. Yordanova⁴

Front. Astron. Space Sci., 04 February 2021 |

<https://doi.org/10.3389/fspas.2020.610278>

<https://www.frontiersin.org/articles/10.3389/fspas.2020.610278/full>

We report a statistical analysis of magnetic field fluctuations in 79 coronal mass ejection- (CME-) driven sheath regions that were observed in the near-Earth solar wind. Wind high-resolution magnetic field data were used to investigate 2 h regions adjacent to the shock and ejecta leading edge (Near-Shock and Near-LE regions, respectively), and the results were compared with a 2 h region upstream of the shock. The inertial-range spectral indices in the sheaths are found to be mostly steeper than the Kolmogorov $-5/3$ index and steeper than in the solar wind ahead. We did not find indications of an $f^{-1}f^{-1}$ spectrum, implying that magnetic fluctuation properties in CME sheaths differ significantly from planetary magnetosheaths and that CME-driven shocks do not reset the solar wind turbulence, as appears to happen downstream of planetary bow shocks. However, our study suggests that new compressible fluctuations are generated in the sheath for a wide variety of shock/upstream conditions. Fluctuation properties particularly differed between the Near-Shock region and the solar wind ahead. A strong positive correlation in the mean magnetic compressibility was found between the upstream and downstream regions, but the compressibility values in the sheaths were similar to those in the slow solar wind (<0.2), regardless of the value in the preceding wind. However, we did not find clear correlations between the inertial-range spectral indices in the sheaths and shock/preceding solar wind properties, nor with the mean normalized fluctuation amplitudes. Correlations were also considerably lower in the Near-LE region than in the Near-Shock region. Intermittency was also considerably higher in the sheath than in the upstream wind according to several proxies,

particularly so in the Near-Shock region. Fluctuations in the sheath exhibit larger rotations than upstream, implying the presence of strong current sheets in the sheath that can add to intermittency. **September 12, 2014**

Multipoint Observations of the June 2012 Interacting Interplanetary Flux Ropes

<https://doi.org/10.3389/fspas.2019.00050>

We report a detailed analysis of interplanetary flux ropes observed at Venus and subsequently at Earth's Lagrange L1 point between **June 15 and 17, 2012**. The observation points were separated by about 0.28 AU in radial distance and 5° in heliographic longitude at this time. The flux ropes were associated with three coronal mass ejections (CMEs) that erupted from the Sun on **June 12–14, 2012** (SOL2012-06-12, SOL2012-06-13, and SOL2012-06-14). We examine the CME–CME interactions using in-situ observations from the almost radially aligned spacecraft at Venus and Earth, as well as using heliospheric modeling and imagery. The June 14 CME reached the June 13 CME near the orbit of Venus and significant interaction occurred before they both reached Earth. The shock driven by the June 14 CME propagated through the June 13 CME and the two CMEs coalesced, creating the signatures of one large, coherent flux rope at L1. We discuss the origin of the strong interplanetary magnetic fields related to this sequence of events, the complexity of interpreting solar wind observations in the case of multiple interacting CMEs, and the coherence of the flux ropes at different observation points.

Solar wind properties and geospace impact of coronal mass ejection-driven sheath regions: variation and driver dependence

sci-hub.se/10.1029/2019SW002217

We present a statistical study of interplanetary conditions and geospace response to 89 coronal mass ejection (CME)-driven sheaths observed during Solar Cycles 23 and 24. We investigate in particular the dependencies on the driver properties and variations across the sheath. We find that the ejecta speed principally controls the sheath geoeffectiveness and shows the highest correlations with sheath parameters, in particular in the region closest to the shock. Sheaths of fast ejecta have on average high solar wind speeds, magnetic (B)-field magnitudes, and fluctuations and they generate efficiently strong out-of-ecliptic fields. Slow-ejecta sheaths are considerably slower, have weaker fields and field fluctuations and therefore they cause primarily moderate geospace activity. Sheaths of weak and strong B-field ejecta have distinct properties but differences in their geoeffectiveness are less drastic. Sheaths of fast and strong ejecta push the subsolar magnetopause significantly earthward, often even beyond geostationary orbit. Slow-ejecta sheaths also compress the magnetopause significantly due to their large densities that likely result of their relatively long propagation times and source near the streamer belt. We find the regions near the shock and ejecta leading edge to be the most geoeffective parts of the sheath. These regions are also associated with the largest B-field magnitudes, out-of-ecliptic fields, and field fluctuations as well as largest speeds and densities. The variations, however, depend on driver properties. Forecasting sheath properties is challenging due to their variable nature, but the dependence on ejecta properties determined in this work could help to estimate sheath geoeffectiveness through remote-sensing CME observations. **April 13-14, 2013,**

Outer Van Allen Radiation Belt Response to Interacting Interplanetary Coronal Mass Ejections

JGR [Volume124, Issue3](#) March **2019** Pages 1927-1947

sci-hub.se/10.1029/2018JA026238

We study the response of the outer Van Allen radiation belt during an intense magnetic storm on **15–22 February 2014**. Four interplanetary coronal mass ejections (ICMEs) arrived at Earth, of which the three last ones were interacting. Using data from the Van Allen Probes, we report the first detailed investigation of electron fluxes from source (tens of kiloelectron volts) to core (megaelectron volts) energies and possible loss and acceleration mechanisms as a response to

substructures (shock, sheath and ejecta, and regions of shock-compressed ejecta) in multiple interacting ICMEs. After an initial enhancement induced by a shock compression of the magnetosphere, core fluxes strongly depleted and stayed low for 4 days. This sustained depletion can be related to a sequence of ICME substructures and their conditions that influenced the Earth's magnetosphere. In particular, the main depletions occurred during a high-dynamic pressure sheath and shock-compressed southward ejecta fields. These structures compressed/eroded the magnetopause close to geostationary orbit and induced intense and diverse wave activity in the inner magnetosphere (ULF Pc5, electromagnetic ion cyclotron, and hiss) facilitating both effective magnetopause shadowing and precipitation losses. Seed and source electrons in turn experienced stronger variations throughout the studied interval. The core fluxes recovered during the last ICME that made a glancing blow to Earth. This period was characterized by a concurrent lack of losses and sustained acceleration by chorus and Pc5 waves. Our study highlights that the seemingly complex behavior of the outer belt during interacting ICMEs can be understood by the knowledge of electron dynamics during different substructures.

Forecasting the Structure and Orientation of Earthbound Coronal Mass Ejections

[sci-hub.se/10.1029/2018SW001944](https://doi.org/10.1029/2018SW001944)

Coronal Mass Ejections (CMEs) are the key drivers of strong to extreme space weather storms at the Earth that can have drastic consequences for technological systems in space and on ground. The ability of a CME to drive geomagnetic disturbances depends crucially on the magnetic structure of the embedded flux rope, which is thus essential to predict. The current capabilities in forecasting in advance (at least half-a-day before) the geoeffectiveness of a given CME is however severely hampered by the lack of remote-sensing measurements of the magnetic field in the corona and adequate tools to predict how CMEs deform, rotate and deflect during their travel through the coronal and interplanetary space as they interact with the ambient solar wind and other CMEs. These problems can lead not only to over- or underestimation of the severity of a storm, but also to forecasting “misses” and “false alarms” that are particularly difficult for the end-users. In this paper, we discuss the current status and future challenges and prospects related to forecasting of the magnetic structure and orientation of CMEs. We focus both on observational and modeling (first-principle and semi-empirical) based approaches, and discuss the space- and ground-based observations that would be the most optimal for making accurate space weather predictions. We also cover the gaps in our current understanding related to the formation and eruption of the CME flux rope and physical processes that govern its evolution in the variable ambient solar wind background that complicate the forecasting. **27–31 October 2013, 19–20 November 2007, 24–29 May 2010, 16 June 2010, 2010-12-12, 2013-04-11-13**

Coronal mass ejections and their sheath regions in interplanetary space

Review

Emilia [Kilpua](#), Hannu E. J. Koskinen & Tuija I. Pulkkinen

Living Reviews in Solar Physics December 2017, 14:5 **File**

<https://link.springer.com/content/pdf/10.1007%2Fs41116-017-0009-6.pdf>

Interplanetary coronal mass ejections (ICMEs) are large-scale heliospheric transients that originate from the Sun. When an ICME is sufficiently faster than the preceding solar wind, a shock wave develops ahead of the ICME. The turbulent region between the shock and the ICME is called the sheath region. ICMEs and their sheaths and shocks are all interesting structures from the fundamental plasma physics viewpoint. They are also key drivers of space weather disturbances in the heliosphere and planetary environments. ICME-driven shock waves can accelerate charged particles to high energies. Sheaths and ICMEs drive practically all intense geospace storms at the Earth, and they can also affect dramatically the planetary radiation environments and atmospheres. This review focuses on the current understanding of observational signatures and properties of ICMEs and the associated sheath regions based on five decades of studies. In addition, we discuss modelling of ICMEs and many fundamental outstanding questions on their origin, evolution and effects, largely due to the limitations of single spacecraft observations of these macro-scale structures. We also present current understanding of space weather consequences of these large-scale solar wind structures, including effects at the other Solar System planets and exoplanets. We specially emphasize the different origin, properties and consequences of the sheaths and ICMEs. **February 7, 1981 , 5 Dec 1981, 13-14 July 1982, 14 Aug 1982, February 27, 2000 , June 10, 2000 , 16–22 Sept 2000. , 4-5 Apr 2004, 20-21 May 2005, 27-29 Dec 2004, 14–15 December, 2006 , 28 May 2010, 15 Sept 2010, 9 July 2013, 19-20 Aug 2014**

Geoeffective Properties of Solar Transients and Stream Interaction Regions Review

E. K. J. **Kilpua**, A. Balogh, R. von Steiger, Y. D. Liu

[Space Science Reviews](#) 212, 1271 **2017**

<https://link.springer.com/content/pdf/10.1007%2Fs11214-017-0411-3.pdf>

Interplanetary Coronal Mass Ejections (ICMEs), their possible shocks and sheaths, and co-rotating interaction regions (CIRs) are the primary large-scale heliospheric structures driving geospace disturbances at the Earth. CIRs are followed by a faster stream where Alfvénic fluctuations may drive prolonged high-latitude activity. In this paper we highlight that these structures have all different origins, solar wind conditions and as a consequence, different geomagnetic responses. We discuss general solar wind properties of sheaths, ICMEs (in particular those showing the flux rope signatures), CIRs and fast streams and how they affect their solar wind coupling efficiency and the resulting magnetospheric activity. We show that there are two different solar wind driving modes: (1) Sheath-like with turbulent magnetic fields, and large Alfvén Mach (MAMA) numbers and dynamic pressure, and (2) flux rope-like with smoothly varying magnetic field direction, and lower MAMA numbers and dynamic pressure. We also summarize the key properties of interplanetary shocks for space weather and how they depend on solar cycle and the driver.

Sources of The Slow Solar wind During the Solar Cycle 23/24 Minimum

E.K.J. **Kilpua**, M. S. Madjarska, N. Karna, T. Wiegelmann, C. Farrugia, W. Yu, K. Andreeova

Solar Phys. **2016**

<http://arxiv.org/pdf/1606.05142v1.pdf>

We investigate the characteristics and the sources of the slow (< 450 km/s) solar wind during the four years (2006-2009) of low solar activity between Solar Cycles 23 and 24. We use a comprehensive set of in-situ observations in the near-Earth solar wind (Wind and ACE) and remove the periods when large-scale interplanetary coronal mass ejections were present. The investigated period features significant variations in the global coronal structure, including the frequent presence of low-latitude active regions in 2006-2007, long-lived low- and mid-latitude coronal holes in 2006 - mid-2008 and mostly the quiet Sun in 2009. We examine both Carrington Rotation averages of selected solar plasma, charge state and compositional parameters and distributions of these parameters related to Quiet Sun, Active Region Sun and the Coronal Hole Sun. While some of the investigated parameters (e.g., speed, the C^{+6}/C^{+4} and He/H ratio) show clear variations over our study period and with solar wind source type, some (Fe/O) exhibit very little changes. Our results highlight the difficulty in distinguishing between the slow solar wind sources based on the inspection of the solar wind conditions.

Statistical Study of Strong and Extreme Geomagnetic Disturbances and Solar Cycle Characteristics

<https://iopscience.iop.org/article/10.1088/0004-637X/806/2/272/pdf>

We study the relation between strong and extreme geomagnetic storms and solar cycle characteristics. The analysis uses an extensive geomagnetic index AA data set spanning over 150 yr complemented by the Kakioka magnetometer recordings. We apply Pearson correlation statistics and estimate the significance of the correlation with a bootstrapping technique. We show that the correlation between the storm occurrence and the strength of the solar cycle decreases from a clear positive correlation with increasing storm magnitude toward a negligible relationship. Hence, the quieter Sun can also launch superstorms that may lead to significant societal and economic impact. Our results show that while weaker storms occur most frequently in the declining phase, the stronger storms have the tendency to occur near solar maximum. Our analysis suggests that the most extreme solar eruptions do not have a direct connection between the solar large-scale dynamo-generated magnetic field, but are rather associated with smaller-scale dynamo and resulting turbulent magnetic fields. The phase distributions of sunspots and storms becoming increasingly in phase with increasing storm strength, on the other hand, may indicate that the extreme storms are related to the toroidal component of the solar large-scale field.

Properties and drivers of fast interplanetary shocks near the orbit of the Earth (1995-2013)

E. K. J. **Kilpua**, E. Lumme, K. Andreeova, A. Isavnin and H.E.J. Koskinen

JGR [Volume 120, Issue 6](#) Pages 4112–4125 **2015**

We present a comprehensive statistical analysis spanning over a solar cycle of the properties and drivers of traveling fast forward and fast reverse interplanetary shocks. We combine statistics of 679 shocks between 1995–2013 identified from the near-Earth (Wind and ACE) and STEREO-A observations. We find that fast forward shocks dominate over fast reverse shocks in all solar cycle phases except during solar minimum. Nearly all fast reverse shocks are driven by slow-fast stream interaction regions (SIRs), while coronal mass ejections (CMEs) are the principal drivers of fast forward shocks in all phases except at solar minimum. The occurrence rate and median speeds of CME-driven fast forward shocks follow the sunspot cycle, while SIR-associated shocks do not show such correspondence. The strength of the shock (characterized by the magnetosonic Mach number and by the upstream to downstream magnetic field and density ratio) shows relatively little variations over solar cycle. However, the shocks were slightly stronger during the ascending phase of a relatively weak solar cycle 24 than during the previous ascending phase. The CME- and SIR-driven fast forward shocks and reverse shocks have distinct upstream solar wind conditions, which reflect to their relative strengths. We found that CME-driven shocks are on average stronger and faster, and they show broader distributions of shock parameters than the shocks driven by SIRs.

Solar Sources of Interplanetary Coronal Mass Ejections During the Solar Cycle 23/24 Minimum

E. K. J. [Kilpua](#), M. Mierla, A. N. Zhukov, L. Rodriguez, A. Vourlidas, B. Wood
Solar Phys., Volume 289, Issue 10, pp 3773-3797, 2014

We examine solar sources for 20 interplanetary coronal mass ejections (ICMEs) observed in 2009 in the near-Earth solar wind. We performed a detailed analysis of coronagraph and extreme ultraviolet (EUV) observations from the Solar Terrestrial Relations Observatory (STEREO) and Solar and Heliospheric Observatory (SOHO). Our study shows that the coronagraph observations from viewpoints away from the Sun–Earth line are paramount to locate the solar sources of Earth-bound ICMEs during solar minimum. SOHO/LASCO detected only six CMEs in our sample, and only one of these CMEs was wider than 120° . This demonstrates that observing a full or partial halo CME is not necessary to observe the ICME arrival. Although the two STEREO spacecraft had the best possible configuration for observing Earth-bound CMEs in 2009, we failed to find the associated CME for four ICMEs, and identifying the correct CME was not straightforward even for some clear ICMEs. Ten out of 16 (63 %) of the associated CMEs in our study were “stealth” CMEs, i.e. no obvious EUV on-disk activity was associated with them. Most of our stealth CMEs also lacked on-limb EUV signatures. We found that stealth CMEs generally lack the leading bright front in coronagraph images. This is in accordance with previous studies that argued that stealth CMEs form more slowly and at higher coronal altitudes than non-stealth CMEs. We suggest that at solar minimum the slow-rising CMEs do not draw enough coronal plasma around them. These CMEs are hence difficult to discern in the coronagraphic data, even when viewed close to the plane of the sky. The weak ICMEs in our study were related to both intrinsically narrow CMEs and the non-central encounters of larger CMEs. We also demonstrate that narrow CMEs (angular widths $\leq 20^\circ$) can arrive at Earth and that an unstructured CME may result in a flux rope-type ICME.

Why have geomagnetic storms been so weak during the recent solar minimum and the rising phase of cycle 24?

E.K.J. [Kilpua](#), J.G. Luhmann, L.K. Jian, C.T. Russell, Y. Li
JASTP, Volume 107, January 2014, Pages 12–19, 2013

The minimum following solar cycle 23 was the deepest and longest since the dawn of the space age. In this paper we examine geomagnetic activity using Dst and AE indices, interplanetary magnetic field (IMF) and plasma conditions, and the properties and occurrence rate of interplanetary coronal mass ejections (ICMEs) during two periods around the last two solar minima and rising phases (Period 1: 1995–1999 and Period 2: 2006–2012). The data is obtained from the 1-h OMNI database. Geomagnetic activity was considerably weaker during Period 2 than during Period 1, in particular in terms of Dst. We show that the responses of AE and Dst depend on whether it is solar wind speed or the southward IMF component (BS) that controls the variations in solar wind driving electric field (EY). We conclude that weak Dst activity during Period 2 was primarily a consequence of weak BS and presumably further weakened due to low solar wind densities. In contrast, solar wind speed did not show significant differences between our two study periods and the high-speed solar wind during Period 2 maintained AE activity despite of weak BS. The weakness of BS during Period 2 was attributed in particular to the lack of strong and long-duration ICMEs. We show that for our study periods there was a clear annual north–south IMF asymmetry, which affected in particular the intense Dst activity. This implies that the annual amount of intense Dst activity may rather be determined by the coincidence of what magnetic structure the strong ICMEs encountering the Earth have than by the solar cycle size.

On the relationship between interplanetary coronal mass ejections and magnetic clouds

E.K.J. [Kilpua](#), A. Isavnin, A. Vourlidas, H.E.J Koskinen, and L. Rodriguez
Ann. Geophys., 31, 1251-1265, 2013, [File](#)

The relationship of magnetic clouds (MCs) to interplanetary coronal mass ejections (ICMEs) is still an open issue in space research. The view that all ICMEs would originate as magnetic flux ropes has received increasing attention, although near the orbit of the Earth only about one-third of ICMEs show clear MC signatures and often the MC occupies only a portion of the more extended region showing ICME signatures. In this work we analyze 79 events between 1996 and 2009 reported in existing ICME/MC catalogs (Wind magnetic cloud list and the Richardson and Cane ICME list) using near-Earth observations by ACE (Advanced Composition Explorer) and Wind. We perform a systematic comparison of cases where ICME and MC signatures coincided and where ICME signatures extended significantly beyond the MC boundaries. We find clear differences in the characteristics of these two event types. In particular, the events where ICME signatures continued more than 6 h past the MC rear boundary had 2.7 times larger speed difference between the ICME's leading edge and the preceding solar wind, 1.4 times higher magnetic fields, 2.1 times larger widths and they experienced three times more often strong expansion than the events for which the rear boundaries coincided. The events with significant mismatch in MC and ICME boundary times were also embedded in a faster solar wind and the majority of them were observed close to the solar maximum. Our analysis shows that the sheath, the MC and the regions of ICME-related plasma in front and behind the MC have different magnetic field, plasma and charge state characteristics, thus suggesting that these regions separate already close to the Sun. Our study shows that the geometrical effect (the encounter through the CME leg and/or far from the flux rope center) does not contribute much to the observed mismatch in the MC and ICME boundary times.

Observations of ICMEs and ICME-like Solar Wind Structures from 2007 – 2010 Using Near-Earth and STEREO Observations

E. K. J. [Kilpua](#), L. K. Jian, Y. Li, J. G. Luhmann, C. T. Russell
Solar Physics, November 2012, Volume 281, Issue 1, pp 391-409, [File](#)

The generally low interplanetary magnetic field magnitude around the minimum between Solar Cycles 23 and 24 (SC 23/24 minimum) allows us to identify weak and small solar wind structures. We use observations from near-Earth and twin STEREO spacecraft to study solar wind conditions from January 2007 through December 2010. In addition to 84 clear interplanetary coronal mass ejections (ICMEs), we identified 58 ICME-like transients, which exhibit some classical ICME signatures but have weak magnetic fields (<7 nT) and/or short durations (<10 hours). The number of ICME-like transients peaked during the SC 23/24 minimum, while the ICME rate increased with increasing solar activity. The magnetic structures of flux rope type ICMEs and transients show similar solar cycle variation trends, suggesting that ICMEs and transients originate from similar polarity regions at the Sun. We observed a gradual transition from ICME-like structures to ICMEs. The identified events display continuous distributions in duration and magnetic field magnitude ranging from a few hours to several days and from a few nanoteslas to a few tens of nanoteslas, respectively. Our ICME-like transient rate (less than one event/month) is considerably smaller than that suggested by solar observations of narrow CMEs. This implies that the majority of small coronal ejections are merged as a part of the solar wind by the time they reach 1 AU. We found that ICME-like transients generally occur closer to stream interaction regions (SIRs) than ICMEs, and the majority of the events we identified in declining parts of fast solar wind streams were ICME-like structures. This suggests that ICME-like transients tend to arise close to coronal hole boundaries and thus may have an important role in coronal hole dynamics. Diverse solar wind transients presumably manifest the variation of solar eruptions from small-scale blobs to wide CMEs. [Tables](#).

On the relationship between magnetic cloud field polarity and geoeffectiveness,

[Kilpua](#), E. K. J., Li, Y., Luhmann, J. G., Jian, L. K., and Russell, C. T.:
Ann. Geophys., 30, 1037-1050, 2012

In this paper, we have investigated geoeffectivity of near-Earth magnetic clouds during two periods concentrated around the last two solar minima. The studied magnetic clouds were categorised according to the behaviour of the Z-component of the interplanetary magnetic field (BZ) into bipolar (BZ changes sign) and unipolar (BZ maintains its sign) clouds. The magnetic structure of bipolar clouds followed the solar cycle rule deduced from observations over three previous solar cycles, except during the early rising phase of cycle 24 when both BZ polarities were identified almost with the same frequency. We found a clear difference in the number of unipolar clouds whose axial field points south (S-type) between our two study periods. In particular, it seems that the lack of S-type unipolar clouds contributed to relatively low geomagnetic activity in the early rising phase of cycle 24. We estimated the level of magnetospheric activity using a Dst prediction formula with the measured BZ and by reversing the sign of BZ. We found that bipolar clouds with fields

rotating south-to-north (SN) and north-to-south (NS) were equally geoeffective, but their geoeffectiveness was clearly modified by the ambient solar wind structure. Geoeffectivity of NS-polarity clouds was enhanced when they were followed by a higher-speed solar wind, while the majority of geoeffective SN-polarity clouds lacked the trailing faster wind. A leading shock increased the geoeffectiveness of both NS- and SN-polarity clouds, in particular, in the case of an intense storm. We found that in 1995–1998, SN-polarity clouds were more geoeffective, while in 2006–2011 NS-polarity clouds produced more storms. A considerably larger fraction of events were trailed by a higher-speed solar wind during our latter study period, which presumably increased geoeffectivity of NS-polarity. Thus, our study demonstrates that during low and moderate solar activity, geoeffectivity of opposite polarity bipolar clouds may depend significantly on the surrounding solar wind structure. In addition, different polarities also give different temporal storm evolutions: a storm from an SN-polarity cloud is expected to occur, on average, half-a-day earlier than a storm from an NS-polarity cloud.

Estimating Travel Times of Coronal Mass Ejections to 1 AU Using Multi-spacecraft Coronagraph Data

E. K. J. [Kilpua](#), M. Mierla, L. Rodriguez, A. N. Zhukov, N. Srivastava and M. J. West
Solar Physics, **2012**, Volume 279, Number 2, 477-496

We study the relationship between the speeds of coronal mass ejections (CMEs) obtained close to the Sun and in the interplanetary medium during the low solar-activity period from 2008 to 2010. We use a multi-spacecraft forward-modeling technique to fit a flux-rope-like model to white-light coronagraph images from the STEREO and SOHO spacecraft to estimate the geometrical configuration, propagation in three-dimensions (3D), and the radial speeds of the observed CMEs. The 3D speeds obtained in this way are used in existing CME travel-time prediction models. The results are compared to the actual CME transit times from the Sun to STEREO, ACE, and Wind spacecraft as well as to the transit times calculated using projected CME speeds. CME 3D speeds give slightly better predictions than projected CME speeds, but a large scatter is observed between the predicted and observed travel times, even when 3D speeds are used. We estimate the possible sources of errors and find a weak tendency for large interplanetary CMEs (ICMEs) with high magnetic fields to arrive faster than predicted and small, low-magnetic-field ICMEs to arrive later than predicted. The observed CME transit times from the Sun to 1 AU show a particularly good correlation with the upstream solar-wind speed. Similar trends have not been observed in previous studies using data sets near solar maximum. We suggest that near solar minimum a relatively narrow range of CME initial speeds, sizes, and magnetic-field magnitudes led to a situation where aerodynamic drag between CMEs and ambient solar wind was the primary cause of variations in CME arrival times from the Sun to 1 AU.

Multipoint ICME encounters: Pre-STEREO and STEREO observations

E.K.J. [Kilpua](#), , , L.K. Jianb, Y. Lic, J.G. Luhmannc and C.T. Russellb

Journal of Atmospheric and Solar-Terrestrial Physics, Volume 73, Issue 10, **2011**, Pages 1228-1241

The knowledge of the global properties of interplanetary coronal mass ejections (ICMEs) is of great interest for heliospheric research and space weather forecasting. Due to the large dimensions of ICMEs and the lack of systematic multipoint measurements the true three-dimensional configuration of ICMEs is still poorly understood. The launch of the STEREO twin observatory in October 2006 opened important new opportunities for ICME research. One of the scientific goals of the STEREO mission is to study the large-scale structure of ICMEs. In this paper we [review](#) the multi-spacecraft ICME observations conducted before the STEREO era and discuss the ICME properties that were identified at least by one of the STEREO spacecraft and those at the Lagrangian point L1 (Wind/ACE) from April 2007 through March 2008. The multi-spacecraft observations emphasize that ICMEs cannot be explained in terms of a simple flux rope model. The characteristics of ICMEs and the structure of the solar wind in which they were embedded varied significantly from event to event. The observations show that ICMEs can have cross-sectional shapes from almost circular to significantly distended. In the ecliptic plane ICMEs may span at least up to 40° in longitude, consistent with the angular span of the average CME close to the Sun. However, the association between the ICME observations at different spacecraft is not straightforward as significant differences were observed even when the spacecraft were separated by only a few degrees in longitude. In addition, multipoint observations confirm that the identification of the flux rope structure is modified by the spacecraft crossing distance from the center of the ICME. We show examples of the events where one spacecraft crosses the central flux rope, but the other spacecraft traverses the ICME close to the edge where the flux rope structure is no longer obvious.

Research Highlights

► We examine multi-spacecraft observations of interplanetary coronal mass ejections (ICMEs). ► We review the events during the pre-STEREO era and analyze STEREO observations. ► Observations emphasize that ICMEs cannot be

explained by simple flux rope model. ► ICMEs span at least 40° in longitude and their cross-sectional shapes can vary drastically. ► Flux rope signature depends strongly on the spacecraft crossing distance from the ICME center.

STEREO observations of interplanetary coronal mass ejections and prominence deflection during solar minimum period

Ann. Geophys., 27, 4491-4503, 2009, **File**

www.ann-geophys.net/27/4491/2009/

In this paper we study the occurrence rate and solar origin of interplanetary coronal mass ejections (ICMEs) using data from the two Solar TERrestrial RELation Observatory (STEREO) and the Wind spacecraft. We perform a statistical survey of ICMEs during the late declining phase of solar cycle 23. Observations by multiple, well-separated spacecraft show that even at the time of extremely weak solar activity a considerable number of ICMEs were present in the interplanetary medium. Soon after the beginning of the STEREO science mission in January 2007 the number of ICMEs declined to less than one ICME per month, but in late 2008 the ICME rate clearly increased at each spacecraft although no apparent increase in the number of coronal mass ejections (CMEs) occurred. We suggest that the near-ecliptic ICME rate can increase due to CMEs that have been guided towards the equator from their high-latitude source regions by the magnetic fields in the polar coronal holes.

We consider two case studies to highlight the effects of the polar magnetic fields and CME deflection taking advantage of STEREO observations when the two spacecraft were in the quadrature configuration (i.e. separated by about 90 degrees). We study in detail the solar and interplanetary consequences of two CMEs that both originated from high-latitude source regions on **2 November 2008**. The first CME was slow (radial speed 298 km/s) and associated with a huge polar crown prominence eruption. The CME was guided by polar coronal hole fields to the equator and it produced a clear flux rope ICME in the near-ecliptic solar wind. The second CME (radial speed 438 km/s) originated from an active region 11007 at latitude 35° N. This CME propagated clearly north of the first CME and no interplanetary consequences were identified. The two case studies suggest that slow and elongated CMEs have difficulties overcoming the straining effect of the overlying field and as a consequence they are guided by the polar coronal fields and cause in-situ effects close to the ecliptic plane. The 3-D propagation directions and CME widths obtained by using the forward modelling technique were consistent with the solar and in-situ observations.

Table 1. ICMEs identified from the solar wind measurements by STA (A), STB (B) and Wind (W).

Multispacecraft Observations of Magnetic Clouds and Their Solar Origins between 19 and 23 May 2007

E. K. J. **Kilpua**, P. C. Liewer, C. Farrugia, J. G. Luhmann, C. Möstl, Y. Li, Y. Liu, B. J. Lynch, C. T. Russell, A. Vourlidas, M. H. Acuna, A. B. Galvin, D. Larson, J. A. Sauvaud

Solar Phys (2009) 254: 325–344

We analyze a series of complex interplanetary events and their solar origins that occurred between **19 and 23 May 2007** using observations by the STEREO and *Wind* satellites. The analyses demonstrate the new opportunities offered by the STEREO multispacecraft configuration for diagnosing the structure of *in situ* events and relating them to their solar sources. The investigated period was characterized by two high-speed solar wind streams and magnetic clouds observed in the vicinity of the sector boundary. The observing satellites were separated by a longitudinal distance comparable to the typical radial extent of magnetic clouds at 1 AU (fraction of an AU), and, indeed, clear differences were evident in the records from these spacecraft. Two partial-halo coronal mass ejections (CMEs) were launched from the same active region less than a day apart, the first on 19 May and the second on 20 May 2007. The clear signatures of the magnetic cloud associated with the first CME were observed by STEREO B and *Wind* while only STEREO A recorded clear signatures of the magnetic cloud associated with the latter CME. Both magnetic clouds appeared to have interacted strongly with the ambient solar wind and the data showed evidence that they were a part of the coronal streamer belt. *Wind* and STEREO B also recorded a shocklike disturbance propagating inside a magnetic cloud that compressed the field and plasma at the cloud's trailing portion. The results illustrate how distant multisatellite observations can reveal the complex structure of the extension of the coronal streamer into interplanetary space even during the solar activity minimum.

Electronic Supplementary Material The online version of this article ([10.1007/s11207-008-9300-y](https://doi.org/10.1007/s11207-008-9300-y)) contains supplementary material, which is available to authorized users.

Two-step forecast of geomagnetic storm using coronal mass ejection and solar wind condition†

R.-S. Kim^{1,*}, Y.-J. Moon², N. Gopalswamy³, Y.-D. Park¹ and Y.-H. Kim
Space Weather, Volume 12, Issue 4, pages 246–256, April 2014

To forecast geomagnetic storms we had examined initially-observed parameters of coronal mass ejections (CMEs) and introduced an empirical storm forecast model in a previous study (Kim et al. 2010). Now, we suggest a two-step forecast considering not only CME parameters observed in the solar vicinity, but also solar wind conditions near Earth to improve the forecast capability. We consider the empirical solar wind criteria derived in this study ($B_z \leq -5$ nT or $E_y \geq 3$ mV/m for $t \geq 2$ hr for moderate storms with minimum Dst less than -50 nT) and a Dst model developed by Temerin and Li (TL model, 2002; 2006).

Using 55 CME-Dst pairs during 1997 to 2003, our solar wind criteria produces slightly better forecasts for 31 storm events (90%) than the forecasts based on the TL model (87%). However, the latter produces better forecasts for 24 non-storm events (88%), while the former correctly forecasts only 71% of them.

We then performed the two-step forecast. The results are as follows: i) for 15 events that are incorrectly forecasted using CME parameters, 12 cases (80%) can be properly predicted based on solar wind conditions; ii) if we forecast a storm when both CME and solar wind conditions are satisfied (\cap), the critical success index (CSI) becomes higher than that from the forecast using CME parameters alone, however, only 25 storm events (81%) are correctly forecasted; iii) if we forecast a storm when either set of these conditions is satisfied (\cup), all geomagnetic storms are correctly forecasted.

Propagation Characteristics of CMEs Associated with Magnetic Clouds and Ejecta

R.-S. Kim, N. Gopalswamy, K.-S. Cho, Y.-J. Moon, S. Yashiro
Solar Phys., Volume 284, Issue 1, pp 77-88, 2013, File online first

We have investigated the characteristics of magnetic cloud (MC) and ejecta (EJ) associated coronal mass ejections (CMEs) based on the assumption that all CMEs have a flux rope structure. For this, we used 54 CMEs and their interplanetary counterparts (interplanetary CMEs: ICMEs) that constitute the list of events used by the NASA/LWS Coordinated Data Analysis Workshop (CDAW) on CME flux ropes. We considered the location, angular width, and speed as well as the direction parameter, D . The direction parameter quantifies the degree of asymmetry of the CME shape in coronagraph images, and shows how closely the CME propagation is directed to Earth. For the 54 CDAW events, we found the following properties of the CMEs: i) the average value of D for the 23 MCs (0.62) is larger than that for the 31 EJs (0.49), which indicates that the MC-associated CMEs propagate more directly toward the Earth than the EJ-associated CMEs; ii) comparison between the direction parameter and the source location shows that the majority of the MC-associated CMEs are ejected along the radial direction, while many of the EJ-associated CMEs are ejected non-radially; iii) the mean speed of MC-associated CMEs (946 km s⁻¹) is faster than that of EJ-associated CMEs (771 km s⁻¹). For seven very fast CMEs (≥ 1500 km s⁻¹), all CMEs with large D (≥ 0.4) are associated with MCs and the CMEs with small D are associated with EJs. From the statistical analysis of CME parameters, we found the superiority of the direction parameter. Based on these results, we suggest that the CME trajectory essentially determines the observed ICME structure.

Table List of shock-driving ICMEs during Solar Cycle 23 ($E15^\circ \leq l \leq W15^\circ$).

An Empirical Model for the Prediction of Geomagnetic Storms Using Initially Observed CME Parameters at the Sun

R.-S. Kim, K.S. Cho, Y.-J. Moon, M. Dryer, J. Lee, Y. Yi, K.-H. Kim, H. Wang and Y.-D. Park
BBSO preprint #1439, 2010; JGR VOL. 115, A12108, 9 PP., 2010, File

In this study, we discuss the general behaviors of geomagnetic storm strength associated with observed parameters of coronal mass ejection (CME) such as speed (V) and earthward direction (D) of CMEs and the longitude (L) and magnetic field orientation (M) of over laying potential fields of the CME source region and we develop an empirical model to predict the geomagnetic storm occurrence with its strength (gauged by the Dst index) in terms of these CME parameters. For this we select 66 halo or partial halo CMEs associated with M and X class solar flares, which have clearly identifiable source regions from 1997 to 2003. After examining how each of these CME parameters correlates with the geoeffectiveness of the CMEs, we find several properties as follows: (1) it is the parameter, D , that best correlates with the storm strength, Dst; (2) the majority of geoeffective CMEs have been originated from the solar longitude $W15^\circ$, and CMEs originated away from this longitude tend to produce weaker storms; (3) correlations between Dst and the CME parameters improve if CMEs are separated into two groups depending on whether their magnetic fields are oriented southward or northward in their source regions. Based on these observations, we present two empirical expressions for the Dst in terms of L , V , and D for the two groups of CMEs, respectively. This is a new attempt to predict not only the occurrence of geomagnetic storms but also the storm strength (Dst) solely based on the CME parameters.

CME Earthward Direction as an Important Geoeffectiveness Indicator

R.-S. **Kim**, K.-S. Cho, K.-H. Kim, Y.-D. Park, Y.-J. Moon, Y. Yi, J. Lee, H. Wang, H. Song, and M. Dryer

The Astrophysical Journal, Vol. 677, No. 2: 1378-1384, **2008**.

<http://www.journals.uchicago.edu/doi/pdf/10.1086/528928>

Recently Moon et al.

suggested that the degree of CME asymmetries, as defined by the ratio of the shortest to the longest distances of the CME front measured from the solar center, be used as a parameter for predicting their geoeffectiveness. They called this quantity a direction parameter, D , as it suggests how much CME propagation is directed to Earth, and examined its forecasting capability using 12 fast halo CMEs. In this paper, we extend this test by using a much larger database (486 frontside halo CMEs from 1997 to 2003) and more robust statistical tools (contingency table and statistical parameters).

We compared the forecast capability of this direction parameter to those of other CME parameters, such as location and speed. We found the following results: (1) The CMEs with large direction parameters ($D \geq 0.4$) are highly associated with geomagnetic storms. (2) If the direction parameter increases from 0.4 to 1.0, the geoeffective probability rises from 52% to 84%. (3) All CMEs associated with strong geomagnetic storms ($Dst \leq -200$ nT) are found to have large direction parameters ($D \geq 0.6$). (4) CMEs causing strong geomagnetic storms ($Dst \leq -100$ nT), in spite of their northward magnetic field, have large direction parameters ($D \geq 0.6$). (5) Forecasting capability improves when statistical parameters (e.g., “probability of detection—yes” and “critical success index”) are employed, in comparison with the forecast solely based on the location and speed of CMEs. *These results indicate that the CME direction parameter can be an important indicator for forecasting CME geoeffectiveness.*

Prediction of the 1-AU arrival times of CME-associated interplanetary shocks: Evaluation of an empirical interplanetary shock propagation model

Kim, K.-H.; Moon, Y.-J.; Cho, K.-S.

Forecast evaluation of the coronal mass ejection (CME) geoeffectiveness using halo CMEs from 1997 to 2003

R.-S. **Kim**, K.-S. Cho,³ Y.-J. Moon,³ Y.-H. Kim,³ Y. Yi,¹ M. Dryer,^{4,5} Su-Chan Bong,³ and Y.-D. Park³

JOURNAL OF GEOPHYSICAL RESEARCH, VOL. 110, A11104, doi:10.1029/2005JA011218, **2005**, File

In this study we have made a forecast evaluation of geoeffective coronal mass ejections (CMEs) by using frontside halo CMEs and the magnetospheric ring current index, Dst . This is the first time, to our knowledge, that an attempt has been made to construct contingency tables depending on the geoeffectiveness criteria as well as to estimate the probability of CME geoeffectiveness depending on CME location and/or speed. For this, we consider 7742 CMEs observed by SOHO/LASCO and select 305 frontside halo CMEs with their locational information from 1997 to 2003 using SOHO/EIT images and GOES data. To select CME-geomagnetic storm ($Dst < -50$ nT) pairs, we adopt a CME propagation model for estimating the arrival time of each CME at the Earth and then choose the nearest Dst minimum value within the window of ± 24 hours. For forecast evaluation, we present contingency tables to estimate statistical parameters such as probability of detection yes (PODy) and false alarm ratio (FAR). We examine the probabilities of CME geoeffectiveness according to their locations, speeds, and their combination. From these studies, we find that (1) the total probability of geoeffectiveness for frontside halo CMEs is 40% (121/305); (2) PODys for the location ($L < 50^\circ$) and the speed (> 400 km s⁻¹) are estimated to be larger than 80% but their FARs are about

60%; (3) the most probable areas (or coverage combinations) whose geoeffectiveness fraction is larger than the mean probability (~40%), are $0_ < L < +30_$ for slower speed CMEs ($< 800 \text{ km s}^{-1}$), and $_{30} < L < +60_$ for faster CMEs ($> 800 \text{ km s}^{-1}$); (4) when the most probable area is adopted as the new criteria, the PODy becomes slightly lower, but all other statistical parameters such as FAR and bias are significantly improved. Our results can give us some criteria to select geoeffective CMEs with the probability of geoeffectiveness depending on the location, speed, and their combination.

Nonlinear Analysis of Radial Evolution of Solar Wind in the Inner Heliosphere

K. Kiran, K. C. Ajithprasad, V. M. Ananda Kumar & K. P. Harikrishnan

Solar Physics volume 296, Article number: 23 (2021)

<https://link.springer.com/content/pdf/10.1007/s11207-021-01761-0.pdf>

We analyzed the radial evolution of solar wind in the inner heliosphere using nonlinear time series tools such as correlation dimension D2D2, correlation entropy K2K2 and multifractal analysis, to get information regarding the inherent nonlinearity associated with the solar wind data and to know how it is affected by the radial distance from the Sun. Our study provides some detailed information regarding the change of dynamics of the fast solar wind with radial distance in the inner heliosphere, apart from confirming the previous observation about the chaotic nature in the dynamics of the slow solar wind. Also we found that the fast wind in the inner heliosphere is dominated by stochastic fluctuations. As the wind is flowing radially away from the Sun, stochastic fluctuation in the fast wind decreases. The stochastic fluctuation present in the data is a clear indication of the Alfvénic fluctuation associated with the solar wind. Finally, our analysis suggests that Alfvénic fluctuation strongly influences the solar wind as it flows radially outwards to mask the nonlinear component associated with the fast wind.

On the Interaction of Galactic Cosmic Rays with Heliospheric Shocks During Forbush Decreases

Anamarija Kirin, Bojan Vršnak, Mateja Dumbović, Bernd Heber

Solar Physics February 2020, 295:28

<https://doi.org/10.1007/s11207-020-1593-5>

<https://arxiv.org/pdf/2002.09454.pdf>

Forbush decreases (FDs) are depletions in the galactic cosmic ray (GCR) count rate that last typically for about a week and can be caused by coronal mass ejections (CMEs) or corotating interacting regions (CIRs). Fast CMEs that drive shocks cause large FDs that often show a two-step decrease where the first step is attributed to the shock/sheath region, while the second step is attributed to the closed magnetic structure. Since the difference in size of shock and sheath region is significant, and since there are observed effects that can be related to shocks and not necessarily to the sheath region we expect that the physical mechanisms governing the interaction with GCRs in these two regions are different. We therefore aim to analyze interaction of GCRs with heliospheric shocks only. We approximate the shock by a structure where the magnetic field linearly changes with position within this structure. We assume protons of different energy, different pitch angle and different incoming direction. We also vary the shock parameters such as the magnetic field strength and orientation, as well as the shock thickness. The results demonstrate that protons with higher energies are less likely to be reflected. Also, thicker shocks and shocks with stronger field reflect protons more efficiently.

Combining STEREO SECCHI COR2 and HI1 images for automatic CME front edge tracking

Vladimir Kirnosov^{1*}, Lin-Ching Chang¹ and Antti Pulkkinen

J. Space Weather Space Clim., 6, A41 (2016)

<http://www.swsc-journal.org/articles/swsc/pdf/2016/01/swsc150079.pdf>

COR2 coronagraph images are the most commonly used data for coronal mass ejection (CME) analysis among the various types of data provided by the STEREO (Solar Terrestrial Relations Observatory) SECCHI (Sun-Earth Connection Coronal and Heliospheric Investigation) suite of instruments. The field of view (FOV) in COR2 images covers 2–15 solar radii (Rs) that allow for tracking the front edge of a CME in its initial stage to forecast the lead-time of a CME and its chances of reaching the Earth. However, estimating the lead-time of a CME using COR2 images gives a larger lead-time, which may be associated with greater uncertainty. To reduce this uncertainty, CME front edge tracking should be continued beyond the FOV of COR2 images. Therefore, heliospheric imager (HI1) data that covers 15–90 Rs FOV must be included. In this paper, we propose a novel automatic method that takes both COR2 and HI1 images into account and combine the results to track the front edges of a CME continuously. The method consists of two modules: pre-processing and tracking. The pre-processing module produces a set of segmented images, which contain the

signature of a CME, for both COR2 and HI1 separately. In addition, the HI1 images are resized and padded, so that the center of the Sun is the central coordinate of the resized HI1 images. The resulting COR2 and HI1 image set is then fed into the tracking module to estimate the position angle (PA) and track the front edge of a CME. The detected front edge is then used to produce a height-time profile that is used to estimate the speed of a CME. The method was validated using 15 CME events observed in the period from January 1, 2008 to August 31, 2009. The results demonstrate that the proposed method is effective for CME front edge tracking in both COR2 and HI1 images. Using this method, the CME front edge can now be tracked automatically and continuously in a much larger range, i.e., from 2 to 90 Rs, for the first time. These improvements can greatly help in making the quantitative CME analysis more accurate and have the potential to assist in space weather forecasting. **2008.04.26-27**

Quasi-stationary current sheets of the solar origin in the heliosphere

Roman **Kislov**

EGU2020-466 May **2020**

<https://meetingorganizer.copernicus.org/EGU2020/displays/36057>

The solar magnetic field (SMF) has historically been considered as dipole in order to build models of the radially expanding corona, that is, the solar wind in the solar minimum. The simplified approach suggests the existence of only one quasi-stationary current sheet (QCS) of solar origin in the heliosphere, namely, the heliospheric current sheet (HCS). However, the SMF becomes more complicated over the solar cycle, comprising higher-order components. The overlapping of the dipole and multipole components of the SMF suggests a formation of more than one QCS in the corona, which may expand further to the heliosphere. We study the impact of the quadrupole and octupole harmonics of the SMF on the formation and spatial characteristics of QCSs, building a stationary axisymmetric MHD model of QCSs in the heliosphere. It is shown that if the dipole component dominates, a single QCS appears in the solar wind at low heliolatitudes as the classic HCS. In other cases, the number of QCSs varies from one to three, depending on the relative input of the quadrupole and octupole components. QCSs possess a conic form and may occur at a wide variety of heliolatitudes. The existence of QCSs opens wide opportunities for explanations of puzzling observations of cosmic rays and energetic particles in the heliosphere and, at the same time, raises a risk of misinterpretation of in situ crossings of QCSs because of mixing up the HCS and higher-heliolatitude QCSs, which can be significantly disturbed in the dynamical solar wind.

Quasi-stationary Current Sheets of the Solar Origin in the Heliosphere

Roman A. **Kislov**^{1,2}, Olga V. Khabarova², and Helmi V. Malova^{1,3}

2019 *ApJ* 875 28

[sci-hub.se/10.3847/1538-4357/ab0dff](https://doi.org/10.3847/1538-4357/ab0dff)

The solar magnetic field (SMF) has historically been considered as dipole in order to build models of the radially expanding corona, that is, the solar wind in the solar minimum. The simplified approach suggests the existence of only one quasi-stationary current sheet (QCS) of solar origin in the heliosphere, namely, the heliospheric current sheet (HCS). However, the SMF becomes more complicated over the solar cycle, comprising higher-order components. The overlapping of the dipole and multipole components of the SMF suggests a formation of more than one QCS in the corona, which may expand further to the heliosphere. We study the impact of the quadrupole and octupole harmonics of the SMF on the formation and spatial characteristics of QCSs, building a stationary axisymmetric MHD model of QCSs in the heliosphere. It is shown that if the dipole component dominates, a single QCS appears in the solar wind at low heliolatitudes as the classic HCS. In other cases, the number of QCSs varies from one to three, depending on the relative input of the quadrupole and octupole components. QCSs possess a conic form and may occur at a wide variety of heliolatitudes. The existence of QCSs opens wide opportunities for explanations of puzzling observations of cosmic rays and energetic particles in the heliosphere and, at the same time, raises a risk of misinterpretation of in situ crossings of QCSs because of mixing up the HCS and higher-heliolatitude QCSs, which can be significantly disturbed in the dynamical solar wind.

A new stationary analytical model of the heliospheric current sheet and the plasma sheet

Roman A. **Kislov**, Olga V. Khabarova, Helmi V. Malova

We develop a single-fluid 2-D analytical model of the axially symmetric thin heliospheric current sheet (HCS) embedded into the heliospheric plasma sheet (HPS). A HCS-HPS system has a shape of a relatively thin plasma disk limited by separatrices that also represent current sheets, which is in agreement with Ulysses observations in the aphelion, when it crossed the HCS perpendicular to its plane. Our model employs a differential rotation of the solar photosphere that leads to unipolar induction in the corona. Three components of the interplanetary magnetic field (IMF), the solar wind speed, and the thermal pressure are taken into account. Solar corona conditions and a HCS-HPS system state are tied by boundary conditions and the “frozen-in” equation. The model allows finding spatial distributions of the magnetic field, the speed within the HPS, and electric currents within the HCS. An angular plasma speed is low within the HPS due to the angular momentum conservation (there is no significant corotation with the Sun), which is consistent with observations. We found that the HPS thickness L decreases with distance r , becoming a constant far from the Sun ($L \sim 2.5$ solar radii (R_0) at 1 AU). Above the separatrices and at large heliocentric distances, the solar wind behavior obeys Parker's model, but the magnetic field spiral form may be different from Parker's one inside the HPS. At $r \leq 245 R_0$, the IMF spiral may undergo a turn simultaneously with a change of the poloidal current direction (from sunward to antisunward).

4pi Models of CMEs and ICMEs **A Review**

Jens **Kleimann**

E-print, 11 Apr 2012, **File**; Solar Phys.

Coronal mass ejections (CMEs), which dynamically connect the solar surface to the far reaches of interplanetary space, represent a major manifestation of solar activity. They are not only of principal interest but also play a pivotal role in the context of space weather predictions. The steady improvement of both numerical methods and computational resources during recent years has allowed for the creation of increasingly realistic models of interplanetary CMEs (ICMEs), which can now be compared to high-quality observational data from various space-bound missions. This review discusses existing models of CMEs, characterizing them by scientific aim and scope, CME initiation method, and physical effects included, thereby stressing the importance of fully 3-D ('4pi') spatial coverage.

Timelines as a tool for learning about space weather storms

Delores J. **Knipp**^{1,2*}, Valerie Bernstein¹, Kaiya Wahl³ and Hisashi Hayakawa^{4,5,6}

J. Space Weather Space Clim. 2021, 11, 29

<https://www.swsc-journal.org/articles/swsc/pdf/2021/01/swsc200106.pdf>

<https://doi.org/10.1051/swsc/2021011>

Space weather storms typically have solar, interplanetary, geophysical and societal-effect components that overlap in time, making it hard for students and novices to determine cause-and-effect relationships and relative timing. To address this issue, we use timelines to provide context for space weather storms of different intensities. First, we present a timeline and tabular description for the great auroral storms of the last 500 years as an example for space climate. The graphical summary for these 14 events suggests that they occur about every 40–60 years, although the distribution of such events is far from even. One outstanding event in **1770** may qualify as a one-in-500-year auroral event, based on duration. Additionally, we present two examples that describe space weather storms using solar, geospace and effects categories. The first of these is for the prolonged storm sequence of late **January 1938** that produced low-latitude auroras and space weather impacts on mature technology (telegraphs) and on high frequency radio communication for aviation, which was a developing technology. To illustrate storm effects in the space-age, we produce a detailed timeline for the strong **December 2006** geomagnetic storm that impacted numerous space-based technologies for monitoring space weather and for communication and navigation. During this event there were numerous navigation system disturbances and hardware disruptions. We adopt terminology developed in many previous space weather studies and blend it with historical accounts to create graphical timelines to help organize and disentangle the events presented herein.

The May 1967 Great Storm and Radio Disruption Event:

Extreme Space Weather and Extraordinary Responses

Space Weather 2016 doi: 10.1002/2016SW001423 **File**

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1002/2016SW001423>

Although listed as one of the most significant events of the last 80 years, the space weather storm of late May 1967 has been of mostly fading academic interest. The storm made its initial mark with a colossal solar radio burst causing radio

interference at frequencies between 0.01-9.0 GHz and near-simultaneous disruptions of dayside radio communication by intense fluxes of ionizing solar X-rays. Aspects of military control and communication were immediately challenged. Within hours a solar energetic particle event disrupted high frequency communication in the polar cap. Subsequently record-setting geomagnetic and ionospheric storms compounded the disruptions. We explain how the May 1967 storm was nearly one with ultimate societal impact, were it not for the nascent efforts of the United States Air Force in expanding its terrestrial weather monitoring-analysis-warning-prediction efforts into the realm of space weather forecasting. An important and long-lasting outcome of this storm was more formal Department of Defense support for current-day space weather forecasting. This story develops during the rapid rise of solar cycle 20 and the intense Cold War in the latter half of the 20th Century. We detail the events of late May 1967 in the intersecting categories of solar-terrestrial interactions and the political-military backdrop of the Cold War. This was one of the —Great Storms|| of the 20th century, despite the lack of large geomagnetically-induced currents. Radio disruptions like those discussed here warrant the attention of today's radio-reliant, cellular-phone and satellite-navigation enabled world. **May 23 1967**

Advances in Space Weather Ensemble Forecasting

Knipp, Delores J.

Space Weather, Volume 14, Issue 2, pp. 52-53, **2016** DOI: 10.1002/2016SW001366

At many space weather-related meetings I hear that space weather (SW) forecasting is several decades behind terrestrial weather forecasting. Some attribute the lag to the dearth of space environment observations. Occasionally, the relative youth of our science and the corresponding lack of sophistication in forecasting methodologies are mentioned. Ours will always be the “younger science.” Nonetheless, our community is making significant progress in the latter category, especially with respect to “ensemble forecasting.”

Waves and Magnetism in the Solar Atmosphere (WAMIS)

Yuan-Kuen **Ko**^{1*}, John D. Moses², John M. Laming¹, 1, Samuel Tun Beltran¹, Steven Tomczyk³, et al.

Front. Astron. Space Sci., **3**, 1. **2016**

sci-hub.se/10.3389/fspas.2016.00001

Comprehensive measurements of magnetic fields in the solar corona have a long history as an important scientific goal. Besides being crucial to understanding coronal structures and the Sun's generation of space weather, direct measurements of their strength and direction are also crucial steps in understanding observed wave motions. In this regard, the remote sensing instrumentation used to make coronal magnetic field measurements is well suited to measuring the Doppler signature of waves in the solar structures. In this paper, we describe the design and scientific values of the Waves and Magnetism in the Solar Atmosphere (WAMIS) investigation. WAMIS, taking advantage of greatly improved infrared filters and detectors, forward models, advanced diagnostic tools and inversion codes, is a long-duration high-altitude balloon payload designed to obtain a breakthrough in the measurement of coronal magnetic fields and in advancing the understanding of the interaction of these fields with space plasmas. It consists of a 20 cm aperture coronagraph with a visible-IR spectro-polarimeter focal plane assembly. The balloon altitude would provide minimum sky background and atmospheric scattering at the wavelengths in which these observations are made. It would also enable continuous measurements of the strength and direction of coronal magnetic fields without interruptions from the day-night cycle and weather. These measurements will be made over a large field-of-view allowing one to distinguish the magnetic signatures of different coronal structures, and at the spatial and temporal resolutions required to address outstanding problems in coronal physics. Additionally, WAMIS could obtain near simultaneous observations of the electron scattered K-corona for context and to obtain the electron density. These comprehensive observations are not provided by any current single ground-based or space observatory. The fundamental advancements achieved by the near-space observations of WAMIS on coronal field would point the way for future ground based and orbital instrumentation.

ANATOMY OF DEPLETED INTERPLANETARY CORONAL MASS EJECTIONS

M. **Kocher**, S. T. Lepri, E. Landi, L. Zhao, and W. B. Manchester IV

2017 ApJ 834 147

We report a subset of interplanetary coronal mass ejections (ICMEs) containing distinct periods of anomalous heavy-ion charge state composition and peculiar ion thermal properties measured by ACE/SWICS from 1998 to 2011. We label them “depleted ICMEs,” identified by the presence of intervals where C6+/C5+ and O7+/O6+ depart from the direct correlation expected after their freeze-in heights. These anomalous intervals within the depleted ICMEs are referred to

as "Depletion Regions." We find that a depleted ICME would be indistinguishable from all other ICMEs in the absence of the Depletion Region, which has the defining property of significantly low abundances of fully charged species of helium, carbon, oxygen, and nitrogen. Similar anomalies in the slow solar wind were discussed by Zhao et al. We explore two possibilities for the source of the Depletion Region associated with magnetic reconnection in the tail of a CME, using CME simulations of the evolution of two Earth-bound CMEs described by Manchester et al.

Successive interacting coronal mass ejections: How to create a perfect storm?

Gordon J. **Koehn**, [Ravindra T. Desai](#), [Emma E. Davies](#), [Robert J. Forsyth](#), [Jonathan P. Eastwood](#), [Stefaan Poedts](#)

ApJ **941** 139 **2022**

<https://arxiv.org/pdf/2211.05899.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/aca28c/pdf>

Coronal mass ejections (CMEs) are the largest type of eruptions on the Sun and the main driver of severe space weather at the Earth. In this study, we implement a force-free spheromak CME description within 3-D magnetohydrodynamic simulations to parametrically evaluate successive interacting CMEs within a representative heliosphere. We explore CME-CME interactions for a range of orientations, launch time variations and CME handedness and quantify their geoeffectiveness via the primary solar wind variables and empirical measures of the disturbance storm time index and subsolar magnetopause standoff distance. We show how the interaction of two moderate CMEs between the Sun and the Earth can translate into extreme conditions at the Earth and how CME-CME interactions at different radial distances can maximise different solar wind variables that induce different geophysical impacts. In particular, we demonstrate how the orientation and handedness of a given CME can have a significant impact on the conservation and loss of magnetic flux, and consequently Bz, due to magnetic reconnection with the interplanetary magnetic field. This study thus implicates identification of CME chirality in the solar corona as an early diagnostic for forecasting geomagnetic storms involving multiple CMEs. **13-14 July 2012.**

PUNCH: Polarimeter to UNify the Corona and Heliosphere

Kolinski, Don ; [Deforest, Craig](#) ; [Gibson, Sarah](#) ; [Morrow, Cherilynn](#) ; [Colaninno, Robin](#) ; et al.

The Third Triennial Earth-Sun Summit (TESS), held 8-11 August, **2022** in Bellevue/Seattle, WA. Bulletin of the AAS, Volume 54, Issue 7, article id. 2022n7i125p22

<https://baas.aas.org/pub/2022n7i125p22/release/1>

PUNCH is a NASA Small Explorer mission to better understand how the mass and energy of the Sun's corona become the solar wind that fills the solar system. The mission consists of a constellation of four small satellites in Sun-synchronous, low Earth orbit that together will produce deep-field, continuous, 3D images of the solar corona as it makes a transition to the young solar wind from the outermost solar atmosphere to the inner heliosphere. PUNCH's science goal is to comprehend cross-scale physical processes of heliophysics, from micro scale turbulence to the evolution of global scale structures. There are six science objectives that span the quiescent and dynamic young solar wind, which will be achieved by activities of six working groups. Through a series of workshops, PUNCH has been engaging the broader solar and heliospheric community to develop tools in anticipation of the data and to grow a broad community of PUNCH users to realize its maximum benefit. An undergraduate student collaboration to search for X-ray signatures of coronal heating mechanisms includes development of another instrument, the Student Thermal Energetic Activity Module (STEAM). Moreover, PUNCH engages interested heliophysicists in a mission-embedded outreach program with an Ancient & Modern Sun Watching theme that is collaborating with underserved and underrepresented populations and connecting to the broader public in the US Southwest and beyond. PUNCH is scheduled to launch in April of 2025. See our website (<https://punch.spaceops.swri.org>) for more information.

Magnetosheath jet occurrence rate in relation to CMEs and SIRs

Florian **Koller**, Manuela Temmer, Luis Preisser, Ferdinand Plaschke, Paul Geyer, Lan K Jian, Owen Wyn Roberts, Heli Hietala, Adrian T. LaMoury

JGR **Volume127, Issue4** e2021JA030124 **2022**

<https://www.essoar.org/doi/abs/10.1002/essoar.10508761.2>

<https://doi.org/10.1029/2021JA030124>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2021JA030124>

Magnetosheath jets constitute a significant coupling effect between the solar wind (SW) and the magnetosphere of the Earth. In order to investigate the effects and forecasting of these jets, we present the first-ever statistical study of the jet production during large-scale SW structures like coronal mass ejections (CMEs), stream interaction regions (SIRs) and high speed streams (HSSs). Magnetosheath data from Time History of Events and Macroscale Interactions during

Substorms (THEMIS) spacecraft between January 2008 to December 2020 serve as measurement source for jet detection. Two different jet definitions were used to rule out statistical biases induced by our jet detection method. For the CME and SIR+HSS lists, we used lists provided by literature and expanded on incomplete lists using OMNI data to cover the time range of May 1996 to December 2020. We find that the number and total time of observed jets decrease when CME-sheaths hit the Earth. The number of jets is lower throughout the passing of the CME-magnetic ejecta (ME) and recovers quickly afterwards. On the other hand, the number of jets increases during SIR and HSS phases. We discuss a few possibilities to explain these statistical results. **6 Feb 2013, 15 Feb 2013, 19-31 Jul 2016**

Suprathermal Electron Acceleration by a Quasi-perpendicular Shock: Simulations and Observations

F.-J. Kong and G. Qin

2020 ApJ 896 20

<https://sci-hub.tw/https://iopscience.iop.org/article/10.3847/1538-4357/ab8e32>

The acceleration of suprathermal electrons in the solar wind is mainly associated with shocks driven by interplanetary coronal mass ejections (ICMEs). It is well known that the acceleration of electrons is much more efficient at quasi-perpendicular shocks than at quasi-parallel ones. Yang et al. studied the acceleration of suprathermal electrons with observations at a quasi-perpendicular ICME-driven shock event to claim the important role of shock-drift acceleration (SDA). Here, we perform test-particle simulations to study the acceleration of electrons in this event, by calculating the downstream electron intensity distribution for all energy channels assuming an initial distribution based on the average upstream intensities. Using simulations, we obtain the results similar to the observations from Yang et al. as follows. It is shown that the ratio of downstream to upstream intensities peaks at about 90° pitch angle. In addition, in each pitch angle direction the downstream electron energy spectral index is much larger than the theoretical index of diffusive shock acceleration. Furthermore, the estimated drift length is proportional to the electron energy but the drift time is almost energy independent. Finally, we use a theoretical model based on SDA to describe the drift length and drift time especially, to explain their energy dependence. These results indicate the importance of SDA in the acceleration of electrons by quasi-perpendicular shocks.

An Anisotropic Density Turbulence Model from the Sun to 1 au Derived From Radio Observations

Eduard P. Kontar, A. Gordon Emslie, Daniel L. Clarkson, Xingyao Chen, Nicolina Chrysaphi, Francesco Azzollini, Natasha L. S. Jeffrey, Mykola Gordovskyy

ApJ 2023

<https://arxiv.org/pdf/2308.05839.pdf>

Solar radio bursts are strongly affected by radio-wave scattering on density inhomogeneities, changing their observed time characteristics, sizes, and positions. The same turbulence causes angular broadening and scintillation of galactic and extra-galactic compact radio sources observed through the solar atmosphere. Using large-scale simulations of radio-wave transport, the characteristics of anisotropic density turbulence from $0.1R_\odot$ to 1 au are explored. For the first time, a profile of heliospheric density fluctuations is deduced that accounts for the properties of extra-solar radio sources, solar radio bursts, and in-situ density fluctuation measurements in the solar wind at 1 au. The radial profile of the spectrum-weighted mean wavenumber of density fluctuations (a quantity proportional to the scattering rate of radio-waves) is found to have a broad maximum at around $(4-7)R_\odot$, where the slow solar wind becomes supersonic. The level of density fluctuations at the inner scale (which is consistent with the proton resonance scale) decreases with heliocentric distance as $\langle \delta n^2 \rangle(r) \approx 2 \times 10^7 (r/R_\odot - 1)^{-3.7} \text{ cm}^{-6}$. Due to scattering, the apparent positions of solar burst sources observed at frequencies between 0.1 and 300 MHz are computed to be essentially co-spatial and to have comparable sizes, for both fundamental and harmonic emission. Anisotropic scattering is found to account for the shortest solar radio burst decay times observed, and the required wavenumber anisotropy is $q_{\parallel}/q_{\perp} = 0.25-0.4$, depending on whether fundamental or harmonic emission is involved. The deduced radio-wave scattering rate paves the way to quantify intrinsic solar radio burst characteristics.

Modern Faraday Rotation Studies to Probe the Solar Wind

Jason Kooi, David Wexler, Elizabeth Jensen, Megan Kenny, Teresa Nieves-Chinchilla, Lynn Wilson III, Brian Wood, Lan Jian, Shing Fung, Alexei Pevtsov, Nat Gopalswamy, and Ward Manchester

<https://www.frontiersin.org/articles/10.3389/fspas.2022.841866/full>
<https://www.frontiersin.org/articles/10.3389/fspas.2022.841866/pdf>

For decades, observations of Faraday rotation have provided unique insights into the plasma density and magnetic field structure of the solar wind. Faraday rotation (FR) is the rotation of the plane of polarization when linearly polarized radiation propagates through a magnetized plasma, such as the solar corona, coronal mass ejection (CME), or stream interaction region. FR measurements are very versatile: they provide a deeper understanding of the large-scale coronal magnetic field over a range of heliocentric distances (especially $\approx 1.5 \approx 1.5$ to $20 R_{\odot}$) not typically accessible to in situ spacecraft observations; detection of small-timescale variations in FR can provide information on magnetic field fluctuations and magnetohydrodynamic wave activity; and measurement of differential FR can be used to detect electric currents. FR depends on the integrated product of the plasma density and the magnetic field component along the line of sight to the observer; historically, models have been used to distinguish between their contributions to FR. In the last two decades, though, new methods have been developed to complement FR observations with independent measurements of the plasma density based on the choice of background radio source: calculation of the dispersion measure (pulsars), measurement of Thomson scattering brightness (radio galaxies), and application of radio ranging and apparent-Doppler tracking (spacecraft). New methods and new technology now make it possible for FR observations of solar wind structures to return not only the magnitude of the magnetic field, but also the full vector orientation. In the case of a CME, discerning the internal magnetic flux rope structure is critical for space weather applications. **2003 October 28 , 2011 August 17 , 2012 August 2, 2013 May 10, 2015 July 31, 2015 August 21,**

Cosmic-Ray Transport in Heliospheric Magnetic Structures. III. Implications of Solar Magnetograms for the Drifts of Cosmic Rays

Andreas **Kopp**^{1,2}, Jan Louis Raath², Horst Fichtner^{1,3}, Marius S. Potgieter⁴, Stefan E. S. Ferreira², and Bernd Heber⁴

2021 ApJ 922 124

<https://doi.org/10.3847/1538-4357/ac23e0>

The transport of energetic particles in the heliosphere is reviewed regarding the treatment of their drifts over an entire solar cycle including the periods around solar maximum, when the tilt angles of the heliospheric current sheet increase to large values and the sign of the magnetic polarity changes. While gradient and curvature drifts are well-established elements of the propagation of cosmic rays in the heliospheric magnetic field, their perturbation by the solar-activity-induced large-scale distortions of dipole-like field configurations and by magnetic turbulence is an open problem. Various empirical or phenomenological approaches have been suggested, but either lack a theory-based motivation or have been shown to be incompatible with measurements. We propose a new approach of more closely investigating solar magnetograms obtained from GONG maps, leading to a new definition of (i) tilt angles that may exceed those provided by the Wilcox Solar Observatory during high activity and of (ii) a "noninteger sign" that can be used to reduce the drifts during these periods as well as to provide a refinement of the magnetic field polarity. The change of sign from $A < 0$ to $A > 0$ of solar cycle 24 can be in this way localized to occur between Carrington Rotations 2139 and 2140 in mid 2013. This treatment is fully consistent in the sense that the transport modeling uses the same input data to formulate the boundary conditions at the heliobase as do the magnetohydrodynamic models of the solar wind and the embedded heliospheric magnetic field that exploit solar magnetograms as inner boundary conditions.

Source and Propagation of a Streamer Blowout Coronal Mass Ejection Observed by the Parker Solar Probe

Kelly E. **Korreck**, Adam Szabo, Teresa Nieves Chinchilla, Benoit Lavraud, Janet Luhmann, Tatiana Niembro,

2020 ApJS 246 69

<https://sci-hub.si/https://iopscience.iop.org/article/10.3847/1538-4365/ab6ff9>

In the first orbit of the Parker Solar Probe (PSP), in situ thermal plasma and magnetic field measurements were collected as close as 35 R Sun from the Sun, an environment that had not been previously explored. During the first orbit of PSP, the spacecraft flew through a streamer blowout coronal mass ejection (SBO-CME) on **2018 November 11** at 23:50 UT as it exited the science encounter. The SBO-CME on November 11 was directed away from the Earth and was not visible by L1 or Earth-based telescopes due to this geometric configuration. However, PSP and the STEREO - A spacecraft were able to make observations of this slow ($v \approx 380 \text{ km s}^{-1}$) SBO-CME. Using the PSP data, STEREO - A images, and Wang–Sheeley–Arge model, the source region of the CME is found to be a helmet streamer formed between the northern polar coronal hole and a mid-latitude coronal hole. Using the YGUAZU-A model, the propagation of the CME is traced from the source at the Sun to PSP. This model predicts the travel time of the flux rope to the PSP spacecraft as 30 hr, which is within 0.33 hr of the actual measured arrival time. The in situ Solar Wind Electrons

Alphas and Protons data were examined to determine that no shock was associated with this SBO-CME. Modeling of the SBO-CME shows that no shock was present at PSP; however, at other positions along the SBO-CME front, a shock could have formed. The geometry of the event requires in situ and remote sensing observations to characterize the SBO-CME and further understand its role in space weather.

Physics of Space Storms: From the Solar Surface to the Earth

Hannu **Koskinen**

Read online:

<http://www.springerlink.com/content/978-3-642-00310-3/#section=845487&page=1&locus=49>

This **book** can be interpreted to consist of three parts. The long Chapter 1 forms the first part. It contains a phenomenological introduction to the scene, from the Sun to the Earth, where space weather plays are performed. A reader familiar with basic physics of the Sun, solar wind, magnetosphere and ionosphere can jump over this chapter and only return to it when there is a need to check definitions or concepts introduced there. The second part of the book consists of several chapters on fundamental space plasma physics. While this part is written in a self-consistent way, it is aimed at readers who already have been exposed to basic plasma physics. Chapter 2 briefly introduces the fundamental concepts and tools of plasma physics inherited from both electrodynamics and statistical physics. Chapter 3 reviews the classical guiding center approach to single particle motion and adiabatic invariants, including motion in the dipole field, near a current sheet, and in a time-dependent electric field.

GEOEFFECTIVITY OF CORONAL MASS EJECTIONS

H. E. J. **KOSKINEN**^{1,*} and K. E. J. **HUTTUNEN**[†]

Space Science Reviews (2006) 124: 169–181, **File**

Coronal mass ejections and post-shock streams driven by them are the most efficient drivers of strong magnetospheric activity, magnetic storms. For this reason there is considerable interest in trying to make reliable forecasts for the effects of CMEs as much in advance as possible. To succeed this requires understanding of all aspects related to CMEs, starting from their emergence on the Sun to their propagation to the vicinity of the Earth and to effects within the magnetosphere. In this article we discuss some recent results on the geoeffectivity of different types of CME/shock structures. A particularly intriguing observation is that smoothly rotating magnetic fields within CMEs are most efficient in driving storm activity seen in the inner magnetosphere due to enhanced ring current, whereas the sheath regions between the shock and the ejecta tend to favour high-latitude activity.

Behaviour of 27-Day and 13.5-Day Periodicities in Galactic Cosmic Particles as Observed by Spacecraft and Neutron Monitors During Different Solar Polarity Cycles

Pieter **Kotzé**

Solar Physics 298, Article number: 107 (2023)

<https://link.springer.com/content/pdf/10.1007/s11207-023-02203-9.pdf>

An analysis has been made of the behaviour of the 27-day and 13.5-day periodicities in proton, C, and O galactic-cosmic-ray (GCR) particles at different energies as observed by the Advanced Composition Explorer (ACE) and SOHO (Solar and Heliospheric Observatory) spacecraft during both Solar Cycles 23 and 24. In addition, the behaviour of the 27-day and 13.5-day periods in the solar-wind-modulation parameter $\zeta = \text{BIMF} \times \text{VSW}$ has been investigated during the same time interval to determine the existence of a possible solar-polarity dependence. Ground-based neutron-monitor (NM) observations, corresponding to different rigidity cutoff [RC] parameters, were also studied to determine the temporal behaviour of both the 27-day and 13.5-day periods during Cycles 23 and 24, revealing a statistically significant solar-polarity correlation. The Lomb–Scargle periodogram technique has been employed to extract spectral information from the above-mentioned observations for each individual year from 2001 – 2009 (Cycle 23) and 2010 – 2019 (Cycle 24). Daily mean energetic ACE and SOHO particle measurements are used to identify how both the 27-day and 13.5-day periodicities vary during each individual year during these cycles as a function of particle mean energy. This spectral analysis of proton, C, and O galactic-cosmic-particle data at different energies revealed that both the 27-day and 13.5-day periods are stronger during the minimum of Solar Cycle 24/25 when $A > 0$ (solar dipole pointing North) in comparison to the minimum of Cycle 23/24 when $A < 0$ (solar dipole pointing South) at certain energy levels. This showed a particularly strong energy-dependent behaviour for both periodicities. This article reports for the first time an annual time- and energy-dependent behaviour of both the 27-day and 13.5-day periodicities in daily-mean galactic cosmic particles observed by spacecraft and ground-based neutron monitors during consecutive Solar Cycles 23 and 24,

corresponding to opposite solar-magnetic-field orientations. Periodicity behaviour in heliospheric solar-wind data corroborate these results in general.

Spectral Analysis of Rieger Periodicity Behaviour in O and Fe Galactic Cosmic Particles Observed by ACE in Solar Cycles 23 and 24

Pieter **Kotzé**

[Solar Physics](#) volume 296, Article number: 177 (2021)

<https://link.springer.com/content/pdf/10.1007/s11207-021-01925-y.pdf>

<https://doi.org/10.1007/s11207-021-01925-y>

The behaviour of the Rieger periodicity at 152 – 156 days in O and Fe galactic cosmic ray (GCR) particles, at different energies as observed by the Advanced Composition Explorer (ACE) satellite, has been studied. Energetic particle data between 2000 and 2019 have been analysed using the Lomb-Scargle periodogram and Morlet wavelet spectral analysis techniques. Daily mean energetic particle measurements are used to identify how the Rieger periodicity varies in each individual year as a function of the mean particle energy. In particular, spectral analysis of galactic cosmic particle data at different energies revealed that the Rieger period occurs exceptionally strong during Solar Cycle 23 when $A < 0$ (solar dipole pointing south) compared to Cycle 24 when $A > 0$ (solar dipole pointing north). This article reports for the first time the time-dependence of the Rieger (152 – 156 days) periodicity in O and Fe GCR particles at various energies ranging from ≈ 70 MeV/n to ≈ 471 MeV/n.

Variation Spectra and Anisotropy of Cosmic Rays during Forbush Effects in March 2023

Kovalev, II ; Kravtsova, MV ; Olemskoy, SV ; Sdobnov, VE

COSMIC RESEARCH Volume 62 Issue 6 Page 533-539 2024

DOI 10.1134/S001095252460032X

Based on ground-based observations of cosmic rays (CRs) on the global network of neutron monitors, the Yakutsk complex of muon telescopes, and the URAGAN muon hodoscope (Moscow), the spectra of CR variations and anisotropy during the Forbush effects of **March 15 and 23, 2023** were calculated using the spectrographic global survey method. It is shown that the spectrum of CR variations during these periods is not described by a power function in a wide range of rigidities. It was found that the Earth was in a loop-shaped structure of the interplanetary magnetic field on March 15 and that it entered a magnetic cloud with closed field lines on March 23.

Spectra and Anisotropy of Cosmic Rays during GLE64.

Kovalev, I.I., Kravtsova, M.V., Olemskoy, S.V. et al.

Geomagn. Aeron. 64, 44–48 (2024).

<https://doi.org/10.1134/S0016793223600893>

Ground-based observations of cosmic rays by the spectrographic global survey method were used to study the ground-level enhancement in cosmic ray intensity on **August 24, 2002**. Spectra of variations of primary cosmic rays and their anisotropy were obtained. Based on measurements from the GOES spacecraft and global network of cosmic ray stations, the differential rigidity spectra of accelerated particles in the vicinity of the Sun were calculated. The maximum rigidity to which solar particles were accelerated was estimated.

Assessment of the near-Sun magnetic field of the 10 March 2022 coronal mass ejection observed by Solar Orbiter

Shifana **Koya**, [Spiros Patsourakos](#), [Manolis K. Georgoulis](#), [Alexander Nindos](#)

A&A 2024

<https://arxiv.org/pdf/2408.01142>

Aims. We estimate the near-Sun axial magnetic field of a coronal mass ejection (CME) on **10 March 2022**. Solar Orbiter's in situ measurements, 7.8 degrees east of the Sun-Earth line at 0.43 AU, provided a unique vantage point, along with the WIND measurements at 0.99 AU. We determine a single power-law index from near-Sun to L1, including in situ measurements from both vantage points. **Methods.** We tracked the temporal evolution of the instantaneous relative magnetic helicity of the source active region (AR), NOAA AR 12962. By estimating the helicity budget of the pre-and post-eruption AR, we estimated the helicity transported to the CME. Assuming a Lundquist flux-rope model and geometrical parameters obtained through the graduated cylindrical shell (GCS) CME forward modelling, we determined the CME axial magnetic field at a GCS-fitted height. Assuming a power-law variation of the axial magnetic field with heliocentric distance, we extrapolated the estimated near-Sun axial magnetic field to in situ measurements at 0.43 AU and 0.99 AU. **Results.** The net helicity difference between the post-and pre-eruption AR is

$(-7.1 \pm 1.2) \times 1041 \text{ Mx}^2$, which is assumed to be bodily transported to the CME. The estimated CME axial magnetic field at a near-Sun heliocentric distance of 0.03 AU is 2067 ± 405 nT. From 0.03 AU to L1, a single power-law falloff, including both vantage points at 0.43 AU and 0.99 AU, gives an index -1.23 ± 0.18 . Conclusions. We observed a significant decrease in the pre-eruptive AR helicity budget. Extending previous studies on innerheliospheric intervals from 0.3 AU to ~ 1 AU, referring to estimates from 0.03 AU to measurements at ~ 1 AU. Our findings indicate a less steep decline in the magnetic field strength with distance compared to previous studies, but they align with studies that include near-Sun in situ magnetic field measurements, such as from Parker Solar Probe.

Cosmic ray north-south anisotropy: rigidity spectrum and solar cycle variations observed by ground-based muon detectors

M. Kozai, Y. Hayashi, K. Fujii, K. Munakata, C. Kato, N. Miyashita, A. Kadokura, R. Kataoka, S. Miyake, M.L. Duldig, J.E. Humble, K. Iwai

ApJ 977 160 2024

<https://arxiv.org/pdf/2409.03182>

<https://iopscience.iop.org/article/10.3847/1538-4357/ad8577/pdf>

The north-south (NS) anisotropy of galactic cosmic rays (GCRs) is dominated by a diamagnetic drift flow of GCRs in the interplanetary magnetic field (IMF), allowing us to derive key parameters of cosmic-ray propagation, such as the density gradient and diffusion coefficient. We propose a new method to analyze the rigidity spectrum of GCR anisotropy and reveal a solar cycle variation of the NS anisotropy's spectrum using ground-based muon detectors in Nagoya, Japan, and Hobart, Australia. The physics-based correction method for the atmospheric temperature effect on muons is used to combine the different-site detectors free from local atmospheric effects. NS channel pairs in the multi-directional muon detectors are formed to enhance sensitivity to the NS anisotropy, and in this process, general graph matching in graph theory is introduced to survey optimized pairs. Moreover, Bayesian estimation with the Gaussian process allows us to unfold the rigidity spectrum without supposing any analytical function for the spectral shape. Thanks to these novel approaches, it has been discovered that the rigidity spectrum of the NS anisotropy is dynamically varying with solar activity every year. It is attributed to a rigidity-dependent variation of the radial density gradient of GCRs based on the nature of the diamagnetic drift in the IMF. The diffusion coefficient and mean-free-path length of GCRs as functions of the rigidity are also derived from the diffusion-convection flow balance. This analysis expands the estimation limit of the mean-free-path length into ≤ 200 GV rigidity region from < 10 GV region achieved by solar energetic particle observations.

Average spatial distribution of cosmic rays behind the interplanetary shock -Global Muon Detector Network observations-

M. Kozai, K. Munakata, C. Kato, T. Kuwabara, M. Rockenbach, A. Dal Lago, N. J. Schuch, C. R. Braga, R. R. S. Mendonça, H. K. Al Jassar, M. M. Sharma, M. L. Duldig, J. E. Humble, P. Evenson, I. Sabbah, M. Tokumaru

ApJ 825 100 2016

<http://arxiv.org/pdf/1605.06591v1.pdf>

We analyze the galactic cosmic ray (GCR) density and its spatial gradient in Forbush Decreases (FDs) observed with the Global Muon Detector Network (GMDN) and neutron monitors (NMs). By superposing the GCR density and density gradient observed in FDs following 45 interplanetary shocks (IP-shocks), each associated with an identified eruption on the sun, we infer the average spatial distribution of GCRs behind IP-shocks. We find two distinct modulations of GCR density in FDs, one in the magnetic sheath and the other in the coronal mass ejection (CME) behind the sheath. The density modulation in the sheath is dominant in the western flank of the shock, while the modulation in the CME ejecta stands out in the eastern flank. This east-west asymmetry is more prominent in GMDN data responding to ~ 60 GV GCRs than in NM data responding to ~ 10 GV GCRs, because of softer rigidity spectrum of the modulation in the CME ejecta than in the sheath. The GSE-y component of the density gradient, G_y shows a negative (positive) enhancement in FDs caused by the eastern (western) eruptions, while G_z shows a negative (positive) enhancement in FDs by the northern (southern) eruptions. This implies the GCR density minimum being located behind the central flank of IP-shock and propagating radially outward from location of the solar eruption. We also confirmed the average G_z changing its sign above and below the heliospheric current sheet, in accord with the prediction of the drift model for the large-scale GCR transport in the heliosphere. **2006 Dec 14, 2012 Jun 16, 2013 Apr 13**

JGR, Volume 119, Issue 7, pages 5401–5448, July 2014

On **21 January 2005**, a moderate magnetic storm produced a number of anomalous features, some seen more typically during superstorms. The aim of this study is to establish the differences in the space environment from what we expect (and normally observe) for a storm of this intensity, which make it behave in some ways like a superstorm. The storm was driven by one of the fastest interplanetary coronal mass ejections in solar cycle 23, containing a piece of the dense erupting solar filament material. The momentum of the massive solar filament caused it to push its way through the flux rope as the interplanetary coronal mass ejection decelerated moving toward 1 AU creating the appearance of an eroded flux rope (see companion paper by Manchester et al. (2014)) and, in this case, limiting the intensity of the resulting geomagnetic storm. On impact, the solar filament further disrupted the partial ring current shielding in existence at the time, creating a brief superfountain in the equatorial ionosphere—an unusual occurrence for a moderate storm. Within 1 h after impact, a cold dense plasma sheet (CDPS) formed out of the filament material. As the interplanetary magnetic field (IMF) rotated from obliquely to more purely northward, the magnetotail transformed from an open to a closed configuration and the CDPS evolved from warmer to cooler temperatures. Plasma sheet densities reached tens per cubic centimeter along the flanks—high enough to inflate the magnetotail in the simulation under northward IMF conditions despite the cool temperatures. Observational evidence for this stretching was provided by a corresponding expansion and intensification of both the auroral oval and ring current precipitation zones linked to magnetotail stretching by field line curvature scattering. Strong Joule heating in the cusps, a by-product of the CDPS formation process, contributed to an equatorward neutral wind surge that reached low latitudes within 1–2 h and intensified the equatorial ionization anomaly. Understanding the geospace consequences of extremes in density and pressure is important because some of the largest and most damaging space weather events ever observed contained similar intervals of dense solar material.

Earth's collision with a solar filament on 21 January 2005: Overview†

J. U. [Kozyra](#)^{1,*}, W. B. Manchester IV, ¹, C. P. Escoubet², S. T. Lepri, ¹, M. W. Liemohn, ¹, W. D. Gonzalez³, M. W. Thomsen, ⁴, B. T. Tsurutani

JGR, 2013

On **21 January 2005**, one of the fastest interplanetary coronal mass ejections (ICME) of solar cycle 23, containing exceptionally dense plasma directly behind the sheath, hit the magnetosphere. We show from charge-state analysis that this material was a piece of the erupting solar filament, and further, based on comparisons to the simulation of a fast CME, that the unusual location of the filament material was a consequence of three processes. As the ICME decelerated, the momentum of the dense filament material caused it to push through the flux rope towards the nose. Diverging non-radial flows in front of the filament moved magnetic flux to the sides of the ICME. At the same time reconnection between the leading edge of the ICME and the sheath magnetic fields worked to peel away the outer layers of the flux rope creating a remnant flux rope and a trailing region of newly opened magnetic field lines. These processes combined to move the filament material into direct contact with the ICME sheath region. Within one hour after impact and under northward IMF conditions, a cold dense plasma sheet formed within the magnetosphere from the filament material. Dense plasma sheet material continued to move through the magnetosphere for more than 6 hours as the filament passed by the Earth. Densities were high enough to produce strong diamagnetic stretching of the magnetotail despite the northward IMF conditions and low levels of magnetic activity. The disruptions from the filament collision are linked to an array of unusual features throughout the magnetosphere, ionosphere and atmosphere. These results raise questions about whether rare collisions with solar filaments may, under the right conditions, be a factor in producing even more extreme events.

Flux Rope Model of the 2003 October 28-30 Coronal Mass Ejection and Interplanetary Coronal Mass Ejection

[Krall](#), J.; Yurchyshyn, V. B.; Slinker, S.; Skoug, R. M.; Chen, J.

Astrophysical Journal, 642:541–553, 2006

the erupting flux rope (EFR) model (Chen and Garren 1993; Chen 1996; Krall,

Chen, and Santoro 2000) was able to reproduce many details of the CME/ICME event on October 28-30, 2003.

Ion kinetics of plasma interchange reconnection in the lower solar corona

<https://arxiv.org/pdf/2310.12093.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ad046b/pdf>

The exploration of the inner heliosphere by Parker Solar Probe has revealed a highly structured solar wind with ubiquitous deflections from the Parker spiral, known as switchbacks. Interchange reconnection (IR) may play an important role in generating these switchbacks by forming unstable particle distributions that generate wave activity that in turn may evolve to such structures. IR occurs in very low beta plasmas and in the presence of strong guiding fields. Although IR is unlikely to release enough energy to provide an important contribution to the heating and acceleration of the solar wind, it affects the way the solar wind is connected to its sources, connecting open field lines to regions of closed fields. This "switching on" provides a mechanism by which plasma near coronal hole boundaries can mix with that trapped inside the closed loops. This mixing can lead to a new energy balance. It may significantly change the characteristics of the solar wind because this plasma is already pre-heated and can potentially have quite different density and particle distributions. It not only replenishes the solar wind, but also affects the electric field, which in turn affects the energy balance. This interpenetration is manifested by the formation of a bimodal ion distribution, with a core and a beam-like population. Such distributions are indeed frequently observed by the Parker Solar Probe. Here we provide a first step towards assessing the role of such processes in accelerating and heating the solar wind.

Localized magnetic field structures and their boundaries in the near-Sun solar wind from Parker Solar Probe measurements

<https://doi.org/10.3847/1538-4357/ab7f2d>

One of the discoveries made by Parker Solar Probe during first encounters with the Sun is the ubiquitous presence of relatively small-scale structures standing out as sudden deflections of the magnetic field. They were called switchbacks as some of them show up the full reversal of the radial component of the magnetic field and then return to regular conditions. Analyzing the magnetic field and plasma perturbations associated with switchbacks we identify three types of structures with slightly different characteristics: 1. Alfvénic structures, where the variations of the magnetic field components take place while the magnitude of the field remains constant; 2. Compressional, the field magnitude varies together with changes of the components; 3. Structures manifesting full reversal of the magnetic field (extremal class of Alfvénic structures). Processing of structures boundaries and plasma bulk velocity perturbations lead to the conclusion that they represent localized magnetic field tubes with enhanced parallel plasma velocity and ion beta moving together with respect to surrounding plasma. The magnetic field deflections before and after the switchbacks reveal the existence of total axial current. The electric currents are concentrated on the relatively narrow boundary layers on the surface of the tubes and determine the magnetic field perturbations inside the tube. These currents are closed on the structure surface, and typically have comparable azimuthal and the axial components. The surface of the structure may also accommodate an electromagnetic wave, that assists to particles in carrying currents. We suggest that the two types of structures we analyzed here may represent the local manifestations of the tube deformations corresponding to a saturated stage of the Firehose instability development.

Thermosphere and geomagnetic response to interplanetary coronal mass ejections observed by ACE and GRACE: Statistical results

S. [Krauss](#), M. Temmer, A.M. Veronig, O. Baur, H. Lammer

JGR **2015**

<http://arxiv.org/pdf/1510.03549v1.pdf>

For the period July 2003 to August 2010, the interplanetary coronal mass ejection (ICME) catalogue maintained by Richardson and Cane lists 106 Earth-directed events, which have been measured in-situ by plasma and field instruments onboard the ACE satellite. We present a statistical investigation of the Earth's thermospheric neutral density response by

means of accelerometer measurements collected by the GRACE satellites, which are available for 104 ICMEs in the data set, and its relation to various geomagnetic indices and characteristic ICME parameters such as the impact speed, southward magnetic field strength (B_z). The majority of ICMEs causes a distinct density enhancement in the thermosphere, with up to a factor of eight compared to the pre-event level. We find high correlations between ICME B_z and thermospheric density enhancements (~ 0.9), while the correlation with the ICME impact speed is somewhat smaller (~ 0.7). The geomagnetic indices revealing the highest correlations are Dst and SYM-H (~ 0.9), the lowest correlations are obtained for k_p and AE (~ 0.7), which show a nonlinear relation with the thermospheric density enhancements. Separating the response for the shock sheath region and the magnetic structure of the ICME, we find that the Dst and SYM-H reveal a tighter relation to the B_z minimum in the magnetic structure of the ICME, whereas the polar cap indices show higher correlations with the B_z minimum in the shock sheath region. Since the strength of the B_z component - either in the sheath or the magnetic structure of the ICME - is highly correlated (~ 0.9) with the neutral density enhancement, we discuss the possibility of satellite orbital decay estimates based on magnetic field measurements at L1, i.e. before the ICME hits the Earth's magnetosphere. This will further stimulate progress in space weather understanding and applications regarding satellite operations.

Solar energetic particle cutoff variations during the 29-31 October 2003 geomagnetic storm

Kress, B. T.; Mertens, C. J.; Wiltberger, M.
Space Weather, Vol. 8, No. 5, S05001, 2010

<http://dx.doi.org/10.1029/2009SW000488>

At low latitudes to midlatitudes the Earth's magnetic field usually shields the upper atmosphere and spacecraft in low Earth orbit from solar energetic particles (SEPs). During severe geomagnetic storms, distortion of the Earth's field suppresses geomagnetic shielding, allowing SEPs access to the midlatitudes. A case study of the 26–31 October 2003 solar-geomagnetic event is used to examine how a severe geomagnetic storm affects SEP access to the Earth. Geomagnetic cutoffs are numerically determined in model geomagnetic fields using code developed by the Center for Integrated Space Weather Modeling (CISM) at Dartmouth College. The CISM-Dartmouth geomagnetic cutoff model is being used in conjunction with the High Energy and Charge Transport code (HZETRN) at the NASA Langley Research Center to develop a real-time data-driven prediction of radiation exposure at commercial airline altitudes. In this work, cutoff rigidities are computed on global grids and along several high-latitude flight routes before and during the geomagnetic storm. It is found that significant variations in SEP access to the midlatitudes and high latitudes can occur on time scales of an hour or less in response to changes in the solar wind dynamic pressure and interplanetary magnetic field. The maximum suppression of the cutoff is ~ 1 GV occurring in the midlatitudes during the main phase of the storm. The cutoff is also significantly suppressed by the arrival of an interplanetary shock. The maximum suppression of the cutoff due to the shock is approximately one half of the maximum suppression during the main phase of the storm.

Density Fluctuations in the Solar Wind Based on Type III Radio Bursts Observed by Parker Solar Probe

ApJS 2020

<https://arxiv.org/pdf/2001.03476.pdf>

Radio waves are strongly scattered in the solar wind, so that their apparent sources seem to be considerably larger and shifted than the actual ones. Since the scattering depends on the spectrum of density turbulence, better understanding of the radio wave propagation provides indirect information on the relative density fluctuations $\epsilon = \langle \delta n \rangle / \langle n \rangle$ at the effective turbulence scale length. Here, we have analyzed 30 type III bursts detected by Parker Solar Probe (PSP). For the first time, we have retrieved type III burst decay times τ_d between 1 MHz and 10 MHz thanks to an unparalleled temporal resolution of PSP. We observed a significant deviation in a power-law slope for frequencies above 1 MHz when compared to previous measurements below 1 MHz by the twin-spacecraft Solar TERrestrial RELations Observatory (STEREO) mission. We note that altitudes of radio bursts generated at 1 MHz roughly coincide with an expected location of the Alfvén point, where the solar wind becomes super-Alfvénic. By comparing PSP observations and Monte Carlo simulations, we predict relative density fluctuations ϵ at the effective turbulence scale length at radial distances between $2.5R_\odot$ and $14R_\odot$ to range from 0.22 and 0.09. Finally, we calculated relative density fluctuations ϵ measured

in situ by PSP at a radial distance from the Sun of $35.7 \sim R_{\odot}$ during the perihelion \#1, and the perihelion \#2 to be 0.07 and 0.06, respectively. It is in a very good agreement with previous STEREO predictions ($\epsilon=0.06-0.07$) obtained by remote measurements of radio sources generated at this radial distance. **2019 April 1–10; 2019-04-03 Table 1.** The list of type III burst time-frequency intervals

Statistical Survey of Coronal Mass Ejections and Interplanetary Type II Bursts

V. **Krupar**^{1,2,3}, J. Magdalenic⁴, J. P. Eastwood⁵, N. Gopalswamy², O. Kruparova³, A. Szabo², and F. Neme^c

<https://iopscience.iop.org/article/10.3847/1538-4357/ab3345/pdf>

Coronal mass ejections (CMEs) are responsible for most severe space weather events, such as solar energetic particle events and geomagnetic storms at Earth. Type II radio bursts are slow drifting emissions produced by beams of suprathermal electrons accelerated at CME-driven shock waves propagating through the corona and interplanetary medium. Here, we report a statistical study of 153 interplanetary type II radio bursts observed by the two STEREO spacecraft between 2008 March and 2014 August. The shock associated radio emission was compared with CME parameters included in the Heliospheric Cataloguing, Analysis and Techniques Service catalog. We found that faster CMEs are statistically more likely to be associated with the interplanetary type II radio bursts. We correlate frequency drifts of interplanetary type II bursts with white-light observations to localize radio sources with respect to CMEs. Our results suggest that interplanetary type II bursts are more likely to have a source region situated closer to CME flanks than CME leading edge regions. **2012 October 22**

AN ANALYSIS OF INTERPLANETARY SOLAR RADIO EMISSIONS ASSOCIATED WITH A CORONAL MASS EJECTION

V. **Krupar**^{1,2}, J. P. Eastwood¹, O. Kruparova², O. Santolik^{2,3}, J. Soucek², J. Magdalenic⁴, A. Vourlidas⁵, M. Maksimovic⁶, X. Bonnin⁶, V. Bothmer⁷, N. Mrotzek⁷, A. Pluta⁷, D. Barnes⁸, J. A. Davies⁸, J. C. Martínez Oliveros⁹, and S. D. Bale^{9,10}

2016 ApJ 823 L5

Coronal mass ejections (CMEs) are large-scale eruptions of magnetized plasma that may cause severe geomagnetic storms if Earth directed. Here, we report a rare instance with comprehensive in situ and remote sensing observations of a CME combining white-light, radio, and plasma measurements from four different vantage points. For the first time, we have successfully applied a radio direction-finding technique to an interplanetary type II burst detected by two identical widely separated radio receivers. The derived locations of the type II and type III bursts are in general agreement with the white-light CME reconstruction. We find that the radio emission arises from the flanks of the CME and are most likely associated with the CME-driven shock. Our work demonstrates the complementarity between radio triangulation and 3D reconstruction techniques for space weather applications.

Quasi-thermal Noise Spectroscopy Analysis of Parker Solar Probe Data: Improved Electron Density Model for Solar Wind

Oksana **Kruparova**^{1,2}, Vratislav Krupar^{1,2}, Adam Szabo², Marc Pulupa³, and Stuart D. Bale^{3,4}

2023 ApJ 957 13

<https://iopscience.iop.org/article/10.3847/1538-4357/acf572/pdf>

We present a comprehensive analysis of electron density measurements in the solar wind using quasi-thermal noise (QTN) spectroscopy applied to data from the first 15 encounters of the Parker Solar Probe mission (2018 November–2023 March). Our methodology involves the identification of the plasma line frequency and the calculation of plasma density based on in situ measurements. By analyzing over 2.1 million data points, we derive a power-law model for electron density as a function of radial distance from the Sun in the range of 13 to $50 R_{\odot}$: $n_e(r) = (343,466 \pm 19921) \times r^{(-1.87 \pm 0.11)}$. This model provides improved estimates for localizing interplanetary solar radio bursts. Moreover, obtained electron densities can be used for calibrating particle instruments on board the Parker Solar Probe. We discuss its limitations and potential for further refinement with additional Parker Solar Probe encounters.

Average characteristics of high-energy magnetospheric electron flux enhancements and the parameters of near-Earth and interplanetary medium in 1987–2021

O N Kryakunova, A V Belov, A F Yakovets, A A Abunin, I L Tsepakina, B B Seifullina, M A Abunina, N F Nikolayevskiy, N S Shlyk, A B Andreyev

MNRAS Volume 516, Issue 4, November 2022, Pages 4782–4791,

<https://doi.org/10.1093/mnras/stac2382>

Based on the data of 35-yr (1987–2021) measurements of magnetospheric electron fluxes with energy >2 MeV in geostationary orbits, solar wind speed, and geomagnetic activity, a catalogue of electron flux enhancements was compiled in which the electron fluence exceeds $108 \text{ cm}^{-2} \text{ sr}^{-1} \text{ d}^{-1}$. The epoch superposition method performed using the GOES-13 spacecraft data shows that large electron flux enhancements are preceded by a significant increase in the solar wind velocity and the Ap index of geomagnetic activity, and immediately before the increase the relativistic electron flux decreases. For the events of the catalogue, the average characteristics of electron flux enhancements and parameters of the interplanetary and near-Earth medium were calculated: the mean values of the diurnal and total fluxes during an event and the average duration of electron enhancements. The average duration of the electron flux enhancement is 5 d, and the maximum duration is 24 d. Based on the calculated mean values of the electron fluxes, solar wind velocity, and Ap-index of geomagnetic activity on the day of electron enhancement and on previous days, a typical behaviour of these parameters during and before an electron flux enhancement was obtained. The average characteristics of electron flux enhancements and the parameters of interplanetary and near-Earth medium are calculated before large electron flux enhancements, when the fluence exceeds 3×10^8 , 5×10^8 , and 10^9 particles $\text{cm}^{-2} \text{ sr}^{-1} \text{ d}^{-1}$, respectively. It is shown that the greater the increase in solar wind velocity and geomagnetic activity the larger the subsequent electron flux enhancement.

Recurrent and sporadic Forbush-effects in deep solar minimum

O Kryakunova¹, A Belov², A Abunin², M Abunina², E Eroshenko², A Malimbayev¹, I Tsepakina¹, V Yanke

Journal of Physics: Conference Series 632 (2015) 012062

<http://spaceweather.izmiran.ru/papers/kryakunova2015.pdf>

The effects of high-speed solar wind streams from low-latitude coronal holes and coronal mass ejections (CMEs) on cosmic ray intensity in 2007 are studied. The database on Forbush effects created at IZMIRAN, with cosmic ray density and anisotropy calculated by the Global Survey Method (GSM) on the basis of Neutron Monitor network data has been used. The behaviour of the mean characteristics by all the Forbush-effects in 2007 caused by coronal holes (interplanetary magnetic field intensity and solar wind velocity, 10 GV cosmic ray density and equatorial component of the cosmic ray anisotropy) is calculated by the epoch method. Features of the Forbush-effects caused by high-speed solar wind streams from lowlatitude coronal holes and coronal mass ejections are described.

Influence of high-speed streams from coronal holes on cosmic ray intensity in 2007

O Kryakunova, I Tsepakina, N Nikolayevskiy, A Malimbayev, A Belov, A Abunin, M Abunina, E Eroshenko, V Oleneva, V Yanke

ECRS-2012, sh_526.

In this work we study the effect of high-speed solar wind streams from low-latitude coronal holes on cosmic ray intensity. We used Forbush effect database created at IZMIRAN with calculations of the cosmic ray density and anisotropy performed by the Global Survey Method (GSM) using Neutron Monitor network data for the entire 2007. The essential growths of the solar wind plasma density and interplanetary magnetic field intensity are observed before arrival of high-speed solar wind streams from low-latitude coronal holes. From the analysis of events in 2007 we found that relationship of the Forbush effect magnitude and solar wind speed is much weaker than with the magnitude of the interplanetary magnetic field. One of the typical signs of the impact of high-speed streams from coronal holes on cosmic ray intensity is a gradual onset of the Forbush effect. As a rule, the direction of the equatorial vector component of anisotropy changed before the Forbush effect.

Prediction of Geomagnetic Storm Strength from Inner Heliospheric In Situ Observations

M. Kubicka, C. Möstl, T. Amerstorfer, P. D. Boakes, L. Feng, J. P. Eastwood, O. Tormanen

2016 ApJ 833 255

<https://arxiv.org/pdf/1610.06713v1.pdf>

Prediction of the effects of coronal mass ejections (CMEs) on Earth strongly depends on knowledge of the interplanetary magnetic field southward component, Bz. Predicting the strength and duration of Bz inside a CME with sufficient

accuracy is currently impossible, which forms the so-called Bz problem. Here, we provide a proof-of-concept of a new method for predicting the CME arrival time, speed, Bz and the resulting Dst index at Earth based only on magnetic field data, measured in situ in the inner heliosphere (< 1AU). On **2012 June 12-16**, three approximately Earthward-directed and interacting CMEs were observed by the STEREO imagers, and by Venus Express (VEX) in situ at 0.72 AU, 6 degree away from the Sun Earth line. The CME kinematics are calculated using the drag-based and WSA-Enlil models, constrained by the arrival time at VEX, resulting in the CME arrival time and speed at Earth. The CME magnetic field strength is scaled with a power law from VEX to Wind. Our investigation shows promising results for the Dst forecast (predicted: -96 and -114 nT (from 2 Dst models), observed: -71 nT), for the arrival speed (predicted: 531 +- 23 km s⁻¹, observed: 488 +- 30 km s⁻¹) and timing (6 +- 1 hours after actual arrival time). The prediction lead time is 21 hours. The method may be applied to vector magnetic field data from a spacecraft at an artificial Lagrange point between the Sun and Earth, or to data taken by any spacecraft temporarily crossing the Sun--Earth line.

Observations of a comet tail disruption induced by the passage of a CME

Kuchar, T. A.; Buffington, A.; Arge, C. N.; Hick, P. P.; Howard, T. A.; Jackson, B. V.; Johnston, J. C.; Mizuno, D. R.; Tappin, S. J.; Webb, D. F.

Journal of Geophysical Research: Space Physics, Volume 113, Issue A4, CiteID A04101, **2008**

The Solar Mass Ejection Imager observed an extremely faint interplanetary coronal mass ejection (ICME) as it passed Comet C/2001 Q4 (NEAT) on 5 May 2004, apparently causing a disruption of its plasma tail. This is the first time that an ICME has been directly observed interacting with a comet. SMEI's nearly all-sky coverage and image cadence afforded unprecedented coverage of this rarely observed event. The onset first appeared as a "kink" moving antisunward that eventually developed knots within the disturbed tail. These knots appeared to be swept up in the solar wind flow. We present the SMEI observations as well as identify a likely SOHO/LASCO progenitor of the CME. SMEI observed two other comets (C/2002 T7 [LINEAR] and C/2004 F4 [Bradfield]) and at least five similar events during a 35-d period encompassing this observation. Although these had similar morphologies to the 5 May NEAT event, SMEI did not observe any ICMEs in these cases. Three of these were observed close to the heliospheric current sheet indicating that a magnetic boundary crossing may have contributed to the disruptions. However, there are no discernable causes in the SMEI observations for the remaining two events.

Variability of Low Energy Cosmic Rays Near Earth

A Review

On The Influence Of The Solar Wind On The Propagation Of Earth-impacting Coronal Mass Ejections

Sandeep **Kumar**, [Nandita Srivastava](#), [Nat Gopalswamy](#), [Ashutosh Dash](#)

ApJ **977** 57 **2024**

<https://arxiv.org/pdf/2411.01165>

<https://iopscience.iop.org/article/10.3847/1538-4357/ad8e63/pdf>

Coronal Mass Ejections (CMEs) are subject to changes in their direction of propagation, tilt, and other properties as they interact with the variable solar wind. We investigated the heliospheric propagation of 15 Earth-impacting CMEs observed during April 2010 to August 2018 in the field of view (FOV) of the Heliospheric Imager (HI) onboard the STEREO. About half of the 15 events followed self-similar expansion up to 40 R_☉. The remaining events showed deflection either in latitude, longitude, or a tilt change. Only two events showed significant rotation in the HI1 FOV. We also use toroidal and cylindrical flux rope fitting on the in situ observations of interplanetary magnetic field (IMF) and solar wind parameters to estimate the tilt at L1 for these two events. Although the sample size is small, this study suggests that CME rotation is not very common in the heliosphere. We attributed the observed deflections and rotations of CMEs to a combination of factors, including their interaction with the ambient solar wind and the influence of the ambient magnetic field. These findings contribute to our understanding of the complex dynamics involved in CME propagation and highlight the need for comprehensive modeling and observational studies to improve space weather prediction. In particular, HI observations help us to connect observations near the Sun and near Earth, improving our understanding of how CMEs move through the heliosphere. **May 23, 2010, September 7, 2011, May 23-27, 2017, Table 1.** List of 15 Earth-impacting events selected for our study 2010-2018

Rotation of a Stealth CME on 2012 October 5 Observed in the Inner Heliosphere

Sandeep Kumar, [Dinesha V. Hegde](#), [Nandita Srivastava](#), [Nikolai V. Pogorelov](#), [Nat Gopalswamy](#), [Seiji Yashiro](#)

ApJ **958** 103 **2023**

<https://arxiv.org/pdf/2310.04023.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ad011f/pdf>

Coronal Mass Ejections (CMEs) are subject to changes in their direction of propagation, tilt, and other properties. This is because CMEs interact with the ambient solar wind and other large-scale magnetic field structures. In this work, we report on the observations of the **2012 October 5** stealth CME using coronagraphic and heliospheric images. We find clear evidence of a continuous rotation of the CME, i.e., an increase in the tilt angle, estimated using the Graduated Cylindrical Shell (GCS) reconstruction at different heliocentric distances, up to 58 solar radii. We find a further increase in the tilt at L1 estimated from the toroidal and cylindrical flux rope fitting on the in situ observations of IMF and solar wind parameters. This study highlights the importance of observations of Heliospheric Imager (HI), onboard the Solar TERrestrial RELations Observatory (STEREO). In particular, the GCS reconstruction of CMEs in HI field-of-view promises to bridge the gap between the near-Sun and in-situ observations at the L1. The changes in the CME tilt has significant implications for the space weather impact of stealth CMEs.

New Evidence on the Origin of Solar Wind Microstreams/Switchbacks

Pankaj Kumar, [Judith T. Karpen](#), [Vadim M. Uritsky](#), [Craig E. Deforest](#), [Nour E. Raouafi](#), [C. Richard DeVore](#), [Spiro K. Antiochos](#)

ApJL **951** L15 **2023**

<https://arxiv.org/pdf/2305.06914.pdf>

<https://iopscience.iop.org/article/10.3847/2041-8213/acd54e/pdf>

Microstreams are fluctuations in the solar wind speed and density associated with polarity-reversing folds in the magnetic field (also denoted switchbacks). Despite their long heritage, the origin of these microstreams/switchbacks remains poorly understood. For the first time, we investigated periodicities in microstreams during Parker Solar Probe (PSP) Encounter 10 to understand their origin. Our analysis was focused on the inbound corotation interval on **2021 November 19-21**, while the spacecraft dove toward a small area within a coronal hole (CH). Solar Dynamics Observatory remote-sensing observations provide rich context for understanding the PSP in-situ data. Extreme ultraviolet images from the Atmospheric Imaging Assembly reveal numerous recurrent jets occurring within the region that was magnetically connected to PSP during intervals that contained microstreams. The periods derived from the fluctuating radial velocities in the microstreams (approximately 3, 5, 10, and 20 minutes) are consistent with the periods measured in the emission intensity of the jetlets at the base of the CH plumes, as well as in larger coronal jets and in the plume fine structures. Helioseismic and Magnetic Imager magnetograms reveal the presence of myriad embedded bipoles, which are known sources of reconnection-driven jets on all scales. Simultaneous enhancements in the PSP proton flux and ionic (3He, 4He, Fe, O) composition during the microstreams further support the connection with jetlets and jets. In keeping with prior observational and numerical studies of impulsive coronal activity, we conclude that quasiperiodic jets generated by interchange/breakout reconnection at CH bright points and plume bases are the most likely sources of the microstreams/switchbacks observed in the solar wind.

A parametric study of performance of two solar wind velocity forecasting models during 2006 to 2011

Sandeep Kumar, [Nandita Srivastava](#)

Space Weather e2022SW003069 [Volume20, Issue9](#) **2022**

<https://doi.org/10.1029/2022SW003069>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2022SW003069>

There is an increasing need for the development of a robust space weather forecasting framework. State-of-the-art MHD space weather forecasting frameworks are based upon the Potential Field Source Surface and Schatten Current Sheet extrapolation models for the magnetic field using synoptic magnetograms. These models create a solar wind background for the simulations using empirical relations of Wang, Sheeley and Arge, at the inner boundary of heliosphere and have been used to simulate CMEs for specific cases in previous studies. Besides these MHD frameworks, the Heliospheric Upwind eXtrapolation technique can extrapolate solar wind from inner heliospheric boundaries to L1 and can give a reliable estimate of the solar wind velocity at L1 comparable to MHD models but in a short computational time. We carried out an extensive parametric study of the performance of the Model1 and Model2 for solar wind velocity prediction at L1. We implemented this framework on 60 Carrington Rotations from CR2047 to CR2107 during 2006 to 2011, covering the descending and deep minimum phase of solar cycle (SC) 23, and the ascending phase of SC 24. Our results show an unexpected decrease in the performance of the framework during the deep minimum phase of cycle 23,

which is attributed to the decrease in the observed coronal hole area. As SC 24 began, this decreasing trend vanished due to an increase in the coronal hole area at the low and mid-latitudes, suggesting a correlation between the performance of the framework and the variation in the coronal hole area.

A comparison study of extrapolation models and empirical relations in forecasting solar wind

Frontiers Astron. Space Sci. Volume 7, id.92 2020

<https://arxiv.org/pdf/2010.13793.pdf>

<https://www.frontiersin.org/articles/10.3389/fspas.2020.572084/full>

<https://doi.org/10.3389/fspas.2020.572084>

Coronal mass ejections (CMEs) and high speed solar streams serve as perturbations to the background solar wind that have major implications in space weather dynamics. Therefore, a robust framework for accurate predictions of the background wind properties is a fundamental step towards the development of any space weather prediction toolbox. In this pilot study, we focus on the implementation and comparison of various models that are critical for a steady state, solar wind forecasting framework. Specifically, we perform case studies on Carrington rotations 2053, 2082 and 2104, and compare the performance of magnetic field extrapolation models in conjunction with velocity empirical formulations to predict solar wind properties at Lagrangian point L1. Two different models to extrapolate the solar wind from the coronal domain to the inner-heliospheric domain are presented, namely, (a) Kinematics based (Heliospheric Upwind eXtrapolation [HUX]) model and (b) Physics based model. The physics based model solves a set of conservative equations of hydrodynamics using the PLUTO code and can additionally predict the thermal properties of solar wind. The assessment in predicting solar wind parameters of the different models is quantified through statistical measures. We further extend this developed framework to also assess the polarity of inter-planetary magnetic field at L1. Our best models for the case of CR2053 gives a very high correlation coefficient ($\sim 0.73-0.81$) and has an root mean square error of ($\sim 75-90$ kms $^{-1}$). Additionally, the physics based model has a standard deviation comparable with that obtained from the hourly OMNI solar wind data and also produces a considerable match with observed solar wind proton temperatures measured at L1 from the same database.

Passage of ICMEs, Their Associated Shock Structure, and Transient Modulation of Galactic Cosmic Rays

Anand Kumar, Badruddin, Moncef Derouich

Solar Physics November 2017, 292:166

<https://link.springer.com/content/pdf/10.1007%2Fs11207-017-1190-4.pdf>

Coronal mass ejections (CMEs) from the Sun propagate into interplanetary space and evolve to form a structure. When this structure is observed in near-Earth space, it consists in many cases of the CME ejecta and an extended shock region. Thus, while passing a point of observation (Earth/spacecraft), the interplanetary CME (ICME) structure may cross it from its near-central, intermediate, or near-end location. Therefore, galactic cosmic rays (GCRs) arriving at the Earth-based/space-borne detector may encounter solar plasma and field regimes of different strength, topology, and duration. We analyse the GCR intensity and the solar plasma/field parameters in three different situations when the ICME structure passes the detector from the central, intermediate, and the near-end portions of its extended structure. We study the behaviour of transient depressions in the GCR intensity in these three situations. Simultaneous changes in the solar plasma and field parameters are also studied. The differences in the amplitudes of the depression and the recovery characteristics during the passage of three groups of ICMEs are analysed and discussed.

Study of solar transients causing GMSs with Dst ≤ -100 nT during the period 1999-2010

Rajiv Kumar, N.K. Pandey, Gajendra Singh

Proc. of 35th International Cosmic Ray Conference - ICRC2017 10-20 July, 2017 Bexco, Busan, Korea

<https://pos.sissa.it/301/069/pdf>

The effect of solar features on geospheric conditions leading to geomagnetic storms(GMSs)with Dst index $Dst \leq -100$ nT has been investigated using interplanetary magnetic field(IMF),solar wind data(SWP) and solar geophysical data with CMEs that erupted between 1999 and 2010, we considered all 51 events .The study investigated *the relationship coronal mass ejection (CME) and their influence on Earth's geomagnetic field*, i.e. storms and sub storms .The study is performed mainly considering intense geomagnetic storms that occurred during Solar Cycle 23 and ascending phase of 24 Solar Cycle . It has been analysed and estimated by cross correlation method that there is a delay of 17 to 96 hours in happening GMSs on the Earth after the happening of the CME on the sun.

Estimation of interplanetary electric field conditions for historical geomagnetic storms

Sandeep **Kumar**, B. Veenadhari, S. Tulasi Ram, R. Selvakumaran, Shyamoli Mukherjee, Rajesh Singh, B. D. Kadam

JGR Volume 120, Issue 9 September 2015 Pages 7307–7317

Ground magnetic measurements provide a unique database in understanding space weather. The continuous geomagnetic records from Colaba-Alibag observatories in India contain historically longest and continuous observations from 1847 to present date. Some of the super intense geomagnetic storms that occurred prior to 1900 have been revisited and investigated in order to understand the probable interplanetary conditions associated with intense storms. Following Burton et al. (1975), an empirical relationship is derived for estimation of interplanetary electric field (IEFy) from the variations of *Dst* index and ΔH at Colaba-Alibag observatories. The estimated IEFy values using *Dst* and ΔH_{ABG} variations agree well with the observed IEFy, calculated using Advanced Composition Explorer (ACE) satellite observations for intense geomagnetic storms in solar cycle 23. This study will provide the uniqueness of each event and provide important insights into possible interplanetary conditions for intense geomagnetic storms and probable frequency of their occurrence.

Cosmic-Ray Modulation due to High-Speed Solar-Wind Streams of Different Sources, Speed, and Duration

Anand **Kumar**, Badruddin

Solar Physics, Volume 289, Issue 11, pp 4267-4296 2014

We study the modulation of galactic cosmic rays (GCR) due to high-speed streams (HSS) identified in the solar wind. We compare the GCR modulation due to i) streams with different speed, ii) streams of different duration, and iii) streams from different solar sources. We apply the method of superposed-epoch analysis to analyze the interplanetary plasma and field parameters during the passage of streams with distinct plasma and field characteristics. We use the plasma/field characteristics to distinguish various features of solar sources and interplanetary structures, and discuss the observed differences in the cosmic-ray response. We study the influence of speed, duration, and solar sources of the streams on the GCR modulation. We discuss the relative importance of different solar-wind parameters in the modulation process.

Interplanetary Coronal Mass Ejections, Associated Features, and Transient Modulation of Galactic Cosmic Rays

Review

Anand **Kumar**, Badruddin

Solar Phys., Volume 289, Issue 6, pp 2177-2205, 2014, **File**

Interplanetary structures such as shocks, sheaths, interplanetary counterparts of coronal mass ejections (ICMEs), magnetic clouds, and corotating interaction regions (CIRs) are of special interest for the study of the transient modulation of galactic cosmic rays (GCRs). These structures modulate the GCR intensity with varying amplitudes and recovery-time profiles. It is known that ICMEs are mainly responsible for Forbush decreases in the GCR intensity. However, not all of the ICMEs produce such decreases in GCR intensity. We utilize GCR intensity data recorded by neutron monitors and solar-wind plasma/field data during the passage of ICMEs with different features and structures, and we perform a superposed-epoch analysis of the data. We also adopt the best-fit approach with suitable functions to interpret the observed similarities and differences in various parameters. Using the GCR-effectiveness as a measure of the cosmic-ray response to the passage of ICMEs, about half of the ICMEs identified during 1996–2009 are found to produce moderate to very large intensity depressions in GCR intensity. The ICMEs associated with halo CMEs, magnetic-cloud (MC) structures, bidirectional superthermal electron (BDE) signatures, and those driving shocks are 1.5 to 4 times more GCR effective than the ICMEs not associated with these structures/features. Further, the characteristic recovery time of GCR intensity due to shock/BDE/MC/halo-CME-associated ICMEs is larger than those due to ICMEs not associated with these structures/features.

Solar Wind: Origin, Properties and Impact on Earth

Multiwavelength Study on Solar and Interplanetary Origins of the Strongest Geomagnetic Storm of Solar Cycle 23

Pankaj [Kumar](#), P. K. Manoharan and Wahab Uddin

Solar Physics, Volume 271, Numbers 1-2, 149-167, **2011**, [File](#)

We study the solar sources of an intense geomagnetic storm of solar cycle 23 that occurred on **20 November 2003**, based on ground- and space-based multiwavelength observations. The coronal mass ejections (CMEs) responsible for the above geomagnetic storm originated from the super-active region NOAA 10501. We investigate the H α observations of the flare events made with a 15 cm solar tower telescope at ARIES, Nainital, India. The propagation characteristics of the CMEs have been derived from the three-dimensional images of the solar wind (i.e., density and speed) obtained from the interplanetary scintillation data, supplemented with other ground- and space-based measurements. The TRACE, SXI and H α observations revealed two successive ejections (of speeds ≈ 350 and ≈ 100 km s $^{-1}$), originating from the same filament channel, which were associated with two high speed CMEs (≈ 1223 and ≈ 1660 km s $^{-1}$, respectively). These two ejections generated propagating fast shock waves (i.e., fast-drifting type II radio bursts) in the corona. The interaction of these CMEs along the Sun–Earth line has led to the severity of the storm. According to our investigation, the interplanetary medium consisted of two merging magnetic clouds (MCs) that preserved their identity during their propagation. These magnetic clouds made the interplanetary magnetic field (IMF) southward for a long time, which reconnected with the geomagnetic field, resulting the super-storm (Dst peak = -472 nT) on the Earth.

Observation of Kinetic Alfvén Waves inside an Interplanetary Coronal Mass Ejection Magnetic Cloud at 1 au

Recent advancements have significantly enhanced our grasp of interplanetary coronal mass ejections (ICMEs) in the heliosphere. These observations have uncovered complex kinematics and structural deformations in ICMEs, hinting at the possible generation of magnetohydrodynamic (MHD) and kinetic-scale waves. While MHD-scale waves in magnetic clouds have been explored, understanding the dynamics of kinetic-scale mode waves remains challenging. This article demonstrates the first in situ observation of kinetic Alfvén waves (KAWs) within an ICME's magnetic cloud, notably near the heliospheric current sheet–ICME interaction region, close to the reconnection exhaust. Analysis indicates a distinctive negative bump in the estimated normalized magnetic helicity ($\sigma_m = -0.38$) around the gyrofrequency spread, indicating a right-handed polarization of the wave. Furthermore, examination across flow angle (θ_{VB}) within the frequency domain reveals a specific zone (90° – 135°) showcasing negative helicity fluctuations, confirming the presence of KAWs. Moreover, we noted a significant rise in temperature anisotropy in the vicinity, indicating the role of KAWs in plasma heating. Identifying KAW challenges established notions about ordered magnetic clouds and raises questions about energy transfer processes within these structures. This finding opens the door to a deeper understanding of energy transfer mechanisms within traditionally nondissipative regions and invites further exploration of low-beta plasma heating and the interactions between waves and particles in magnetic clouds.

EVOLUTION OF A CORONAL MASS EJECTION AND ITS MAGNETIC FIELD IN INTERPLANETARY SPACE

V. [Kunkell](#)^{1,2} and J. Chen³

Astrophysical Journal Letters, 715:L80–L83, **2010** June

This Letter presents the first theoretical study of the dynamics of a coronal mass ejection (CME) observed by *STEREO-A/B*. The CME was continuously tracked by SECCHI-A, providing position-time data from eruption to 1 AU. The ejecta was intersected by *STEREO-B* at 1 AU, where the magnetic field and plasma parameters were measured. The observed CME trajectory and the evolution of the CME magnetic field are modeled using the semianalytic erupting flux-rope model. It is shown that the best-fit theoretical solution is in good agreement—within 1% of the measured CME trajectory in the 1 AU field of view—and is consistent with the in situ magnetic field and plasma data at 1 AU. **2007** December 24

Determination of interplanetary coronal mass ejection geometry and orientation from ground-based observations of galactic cosmic rays

Kuwabara, T.; Bieber, J. W.; Evenson, P.; Munakata, K.; Yasue, S.; Kato, C.; Fushishita, A.; Tokumaru, M.; Duldig, M. L.; Humble, J. E.; Silva, M. R.; Dal Lago, A.; Schuch, N. J.

J. Geophys. Res., Vol. 114, No. A5, A05109, 2009 **File**

<http://dx.doi.org/10.1029/2008JA013717>

We have developed a method for determining interplanetary coronal mass ejection (ICME) geometry from galactic cosmic ray data recorded by the ground-based muon detector network. The cosmic ray density depression inside the ICME, which is associated with a Forbush decrease, is represented by an expanding cylinder that is based on a theoretical model of the cosmic ray particle diffusion. ICME geometry and orientation are deduced from observed time variations of cosmic ray density and density gradient and are compared with those deduced from a magnetic flux rope model. From March 2001 to May 2005, 11 ICME events that produced Forbush decreases >2% were observed, and clear variations of the density gradient due to ICME passage were observed in 8 of 11 events. In five of the eight events, signatures of magnetic flux rope structure (large, smooth rotation of magnetic field) were also seen, and the ICME geometry and orientation deduced from the two methods were very similar in three events. This suggests that the cosmic ray-based method can be used as a complementary method for deducing ICME geometry especially for events where a large Forbush decrease is observed.

Study of Forbush Decrease Recovery Times by the Payload for Antimatter Matter Exploration and Light-Nuclei Astrophysics (PAMELA) Experiment

A Forbush decrease (FD) is a sudden drop of cosmic-ray intensity arising as an effect of coronal mass ejection (CME) propagation in interplanetary space. The different physical properties of each CME cause variability in the FDs observed by scientific instruments. A comprehensive study of both phenomena is required to properly understand the processes involved in FDs. Most of the current studies in this field use experimental data obtained by ground-based apparatus that measure the flux of cosmic rays via their interaction with Earth's atmosphere. Direct measurements in space of FDs are rather rare. In this work, we present the results obtained by the spacecraft-borne experiment Payload for Antimatter Matter Exploration and Light-nuclei Astrophysics (PAMELA). The experiment took data from 15 June 2006 until January 2016. A series of FDs during the period 2006 – 2013 were studied. Only significant events with amplitude $\geq 10\%$ for the proton flux $R=1.1 - 2.9$ GV were taken into account. The dependencies of the recovery times on the particle rigidity were obtained for FD events generated by halo-type CMEs.

Interplanetary Consequences of a Large CME

To appear in "Magnetic Coupling between the Interior and the Atmosphere of the Sun", eds. S.S. Hasan and R.J. Rutten, Astrophysics and Space Science Proceedings, Springer-Verlag, Heidelberg, Berlin, 2009, **File**

We analyze a coronal mass ejection (CME) which resulted from an intense flare in active region AR486 on **November 4, 2003**. The CME propagation and speed are studied with interplanetary scintillation images, near-Earth space mission data, and Ulysses measurements. Together, these diverse diagnostics suggest that the internal magnetic energy of the CME determines its interplanetary consequences.

The Radial Variation of Interplanetary Shocks in the Inner Heliosphere: Observations by Helios, MESSENGER, and STEREO

H. R. **Lai**, C. T. Russell, L. K. Jian, X. Blanco-Cano, B. J. Anderson, J. G. Luhmann and A. Wennmacher
[Solar Physics](#), Volume 278, Number 2 (2012), 421-433

The two major sources of collisionless shocks in the solar wind are interplanetary coronal mass ejections (ICMEs) and stream interaction regions (SIRs). Previous studies show that some SIR-associated shocks form between Venus and

Earth while most form beyond 1 AU. Here we examine the high-resolution magnetometer records from Helios 1 and 2 obtained between 0.28 and 1 AU and from MESSENGER obtained between 0.3 and 0.7 AU to further refine our understanding as to where, and in what context, shocks are formed in the inner solar system. From Helios data (Helios 1 from 1974 to 1981 and Helios 2 from 1976 to 1980), we find there were only a few shocks observed inside the orbit of Venus with the closest shock to the Sun at 0.29 AU. We find that there is a strong correlation between shock occurrence and solar activity as measured by the sunspot number. Most of the shocks inside of the orbit of Venus appear to be associated with ICMEs. Even the ICME-associated shocks are quite weak inside the orbit of Venus. By comparing MESSENGER and STEREO results, from 2007 to 2009, we find that in the deep solar minimum, SIR-driven shocks began to form at about 0.4 AU and increased in number with heliocentric distance.

Access of Energetic Particles to a Magnetic Flux Rope from External Magnetic Field Lines

T. Laitinen and S. Dalla

2021 ApJ 906 9

<https://doi.org/10.3847/1538-4357/abc622>

Cosmic-ray (CR) fluxes in the heliosphere are affected by the transient interplanetary coronal mass ejections (ICMEs), causing so-called Forbush decreases (FDs), characterized by a decline of up to 25% in the neutron monitor counts at the Earth's surface, lasting up to over a week. FDs are thought to be caused by the ICME shock wave or the magnetic flux rope embedded in the ICME inhibiting CR propagation through the ICME structure. FDs are typically modeled as enhanced diffusion within the ICME structure. However, so far modeling has not considered the access of the CRs from the interplanetary field lines into the isolated magnetic field lines of the ICME flux rope. We study the effect of an ICME flux rope on particle propagation by using full-orbit particle simulations, with the interface between the external interplanetary magnetic field and the isolated flux rope field lines modeled analytically. We find that the particles can access the flux rope through the x-point region, where the external magnetic fields cancel the azimuthal component of the rope field. The transport through this region is fast compared to diffusive radial propagation within the rope. As a result, the propagation of CRs into the flux rope can be modeled as diffusion into a cylinder. The density cavity within the rope is asymmetric, and limited to the magnetic field lines isolated from the external field. Thus, in order to evaluate the role of the flux rope in FDs, one must analyze the extent of the region where the flux rope magnetic field lines are separated from the interplanetary magnetic fields.

Using Solar Orbiter as an Upstream Solar Wind Monitor for Real Time Space Weather Predictions

Coronal mass ejections (CMEs) can create significant disruption to human activities and systems on Earth, much of which can be mitigated with prior warning of the upstream solar wind conditions. However, it is currently extremely challenging to accurately predict the arrival time and internal structure of a CME from coronagraph images alone. In this study, we take advantage of a rare opportunity to use Solar Orbiter, at 0.5 au upstream of Earth, as an upstream solar wind monitor. In combination with low-latency images from STEREO-A, we successfully predicted the arrival time of two CME events before they reached Earth. Measurements at Solar Orbiter were used to constrain an ensemble of simulation runs from the ELEvoHI model, reducing the uncertainty in arrival time from 10.4 to 2.5 hr in the first case study. There was also an excellent agreement in the Bz profile between Solar Orbiter and Wind spacecraft for the second case study, despite being separated by 0.5 au and 10° longitude. The opportunity to use Solar Orbiter as an upstream solar wind monitor will repeat once a year, which should further help assess the efficacy upstream in-situ measurements in real time space weather forecasting. Coronal mass ejections (CMEs) can create significant disruption to human activities and systems on Earth, much of which can be mitigated with prior warning of the upstream solar wind conditions. Switchback deflections beyond the early parker solar probe encounters

R **Laker**, [T S Horbury](#), [L Matteini](#), [S D Bale](#), [J E Stawarz](#), [L D Woodham](#), [T Woolley](#)

MNRAS, Volume 517, Issue 1, November **2022**, Pages 1001–1005,

<https://doi.org/10.1093/mnras/stac2477>

Switchbacks are Alfvénic fluctuations in the solar wind, which exhibit large rotations in the magnetic field direction. Observations from Parker Solar Probe’s (PSP’s) first two solar encounters have formed the basis for many of the described switchback properties and generation mechanisms. However, this early data may not be representative of the typical near-Sun solar wind, biasing our current understanding of these phenomena. One defining switchback property is the magnetic deflection direction. During the first solar encounter, this was primarily in the tangential direction for the longest switchbacks, which has since been discussed as evidence, and a testable prediction, of several switchback generation methods. In this study, we re-examine the deflection direction of switchbacks during the first eight PSP encounters to confirm the existence of a systematic deflection direction. We first identify switchbacks exceeding a threshold deflection in the magnetic field and confirm a previous finding that they are arc-polarized. In agreement with earlier results from PSP’s first encounter, we find that groups of longer switchbacks tend to deflect in the same direction for several hours. However, in contrast to earlier studies, we find that there is no unique direction for these deflections, although several solar encounters showed a non-uniform distribution in deflection direction with a slight preference for the tangential direction. This result suggests a systematic magnetic configuration for switchback generation, which is consistent with interchange reconnection as a source mechanism, although this new evidence does not rule out other mechanisms, such as the expansion of wave modes.

Multi-spacecraft study of the solar wind at solar minimum: Dependence on latitude and transient outflows

<https://doi.org/10.1051/0004-6361/202140679>

Context. The recent launches of Parker Solar Probe, Solar Orbiter (SO), and BepiColombo, along with several older spacecraft, have provided the opportunity to study the solar wind at multiple latitudes and distances from the Sun simultaneously.

Aims. We take advantage of this unique spacecraft constellation, along with low solar activity across two solar rotations between May and July 2020, to investigate how the solar wind structure, including the heliospheric current sheet (HCS), varies with latitude.

Methods. We visualise the sector structure of the inner heliosphere by ballistically mapping the polarity and solar wind speed from several spacecraft onto the Sun’s source surface. We then assess the HCS morphology and orientation with the in situ data and compare this with a predicted HCS shape.

Results. We resolve ripples in the HCS on scales of a few degrees in longitude and latitude, finding that the local orientations of sector boundaries were broadly consistent with the shape of the HCS but were steepened with respect to a modelled HCS at the Sun. We investigate how several CIRs varied with latitude, finding evidence for the compression region affecting slow solar wind outside the latitude extent of the faster stream. We also identified several transient structures associated with HCS crossings and speculate that one such transient may have disrupted the local HCS orientation up to five days after its passage.

Conclusions. We have shown that the solar wind structure varies significantly with latitude, with this constellation providing context for solar wind measurements that would not be possible with a single spacecraft. These measurements provide an accurate representation of the solar wind within $\pm 10^\circ$ latitude, which could be used as a more rigorous constraint on solar wind models and space weather predictions. In the future, this range of latitudes will increase as SO’s orbit becomes more inclined.

Statistical analysis of orientation, shape, and size of solar wind switchbacks

One of the main discoveries from the first two orbits of Parker Solar Probe (PSP) was the presence of magnetic switchbacks, whose deflections dominated the magnetic field measurements. Determining their shape and size could provide evidence of their origin, which is still unclear. Previous work with a single solar wind stream has indicated that these are long, thin structures although the direction of their major axis could not be determined. We investigate if this long, thin nature extends to other solar wind streams, while determining the direction along which the switchbacks within a stream were aligned. We try to understand how the size and orientation of the switchbacks, along with the flow velocity and spacecraft trajectory, combine to produce the observed structure durations for past and future orbits. We searched for the alignment direction that produced a combination of a spacecraft cutting direction and switchback duration that was most consistent with long, thin structures. The expected form of a long, thin structure was fitted to the results of the best alignment direction, which determined the width and aspect ratio of the switchbacks for that stream. The switchbacks had a mean width of 50,000km, with an aspect ratio of the order of 10. We find that switchbacks are not aligned along the background flow direction, but instead aligned along the local Parker spiral, perhaps suggesting that they propagate along the magnetic field. Since the observed switchback duration depends on how the spacecraft cuts through the structure, the duration alone cannot be used to determine the size or influence of an individual event. For future PSP orbits, a larger spacecraft transverse component combined with more radially aligned switchbacks will lead to long duration switchbacks becoming less common.

Chapter 7 - Supergeomagnetic Storms: Past, Present, and Future

Review

Gurbax S. [Lakhina](#) [Bruce T. Tsurutani](#)

In: Extreme Events in Geospace

Origins, Predictability, and Consequences

Book

Editor: Natalia [Buzulukova](#), Elsevier, 2018, 798 p. **File**

Pages 157-185 **File**

<http://sci-hub.se/10.1016/B978-0-12-812700-1.00007-8>

Geomagnetic storms are large-scale disturbances in the Earth's magnetic field due to orders of magnitude increases in trapped energetic $\sim 10\text{--}300$ keV particle fluxes in the magnetosphere. During geomagnetic storms, the horizontal component of the low-latitude magnetic fields is significantly depressed over a time span of one to a few hours from the diamagnetic effect from the enhanced ring current fluxes. This is known as the main phase of the storm, and is followed by the recovery phase where the particles are lost. This latter phase may extend over several days. The strength of magnetic storms is measured by the Disturbance Storm Time (Dst) index. Superintense magnetic storms (defined here as those with $\text{Dst} < -500$ nT), although relatively rare in occurrence, have the largest societal and technological impacts. Such storms can cause life-threatening power outages, satellite damage, satellite communication failures, navigational problems, and loss of satellites in low Earth orbit (LEO). In this chapter, we shall first review the present knowledge about supermagnetic storms. Then, we discuss the superstorms that have occurred in the past, and consider the case history of the Carrington storm as a representative example. This will be followed by the consideration of supermagnetic storms of present (the space-age era). Next, we explore supermagnetic storms that can occur in the future with an emphasis on the maximum possible intensity of an event. The occurrence probability of superstorms having intensities equal to the Carrington storm or higher will be discussed. Finally, we discuss the status of nowcasting (~ 1 h) and short-time scale forecasting (\sim a few hours to a few days) of supermagnetic storms. **September 1–2, 1859, March 13–16, 1989**

Table 1 A List of Intense and Superintense Magnetic Storms From Colaba and Alibag Magnetic Observatories (1847-2005)

Coronal mass ejections and solar wind mass fluxes over the heliosphere during solar cycles 23 and 24 (1996–2014)†

P. [Lamy](#), O. Floyd, E. Quémerais, B. Boclet, S. Ferron Ferro

JGR Volume 122, Issue 1 January 2017 Pages 50–62

doi: 10.1002/2016ja022970

Coronal mass ejections (CMEs) play a major role in the heliosphere and their contribution to the solar wind mass flux, already considered in the Skylab and Solwind eras with conflicting results, is re-examined in the light of 19 years (1996-

2014) of SOHO observations with the Large Angle and Spectroscopic Coronagraph “LASCO-C2” for the CMEs and extended for the first time to all latitudes thanks to the whole-heliosphere data from the Solar Wind ANisotropies “SWAN” instrument supplemented by in-situ data aggregated in the OMNI database. First, several mass estimates reported in the ARTEMIS catalog of LASCO CMEs are compared with determinations based on the combined observations with the twin STEREO/SECCHI coronagraphs in order to ascertain their validity. A simple geometric model of the CMEs is introduced to generate Carrington maps of their mass flux and then to produce annualized synoptic maps. The Lyman- α SWAN data are inverted to similarly produce synoptic maps to be compared with those of the CME flux. The ratio of the annualized CME to solar wind mass flux is found to closely track the solar cycle over the heliosphere. In the near-ecliptic region and at latitudes up to $\sim 55^\circ$, this ratio was negligibly small during the solar minima of cycles 22/23 and 23/24 and rose to 6% and 5% respectively at the maximum of solar cycles 23 and 24. These maximum ratios increased at higher latitudes but this result is likely biased by the inherent limitation of determining the true latitude of CMEs.

A robust estimation of the twist distribution in magnetic clouds

A&A 668, A160 2022

<https://arxiv.org/pdf/2211.08758.pdf>

<https://www.aanda.org/articles/aa/pdf/2022/12/aa45062-22.pdf>

Magnetic clouds (MCs) are observed in situ by spacecraft. The rotation of their magnetic field is typically interpreted as the crossing of a twisted magnetic flux tube, or flux rope, which was launched from the solar corona. The detailed magnetic measurements across MCs permit us to infer the flux rope characteristics. Still, the precise spatial distribution of the magnetic twist is challenging, and thus is debated. In order to improve the robustness of the results, we performed a superposed epoch analysis (SEA) of a set of well observed MCs at 1 au. While previous work was done using the MC central time, we here used the result of a fitted flux rope model to select the time of the closest approach to the flux rope axis. This implies a precise separation of the in- and outbound regions to coherently phase the observed signals. We also searched for and minimised the possible biases such as magnetic asymmetry and a finite impact parameter. We applied the SEA to derive the median profiles both for the flux rope remaining when crossed by the spacecraft and to recover the one present before erosion. In particular, the median azimuthal B component is nearly a linear function of the radius. More generally, the results confirm our previous results realised without such a deep analysis. The twist profile is nearly uniform in the flux rope core, with a steep increase at the border of the flux rope and with similar profiles in the in- and outbound regions. The main difference with our previous study is a larger twist by $\sim 20\%$. **22 August 1995, 24 July 2004**

Magnetic twist profile inside magnetic clouds derived with a superposed epoch analysis

https://lesia.obspm.fr/perso/pascal-demoulin/20/Lanabere20_twist_profile_SEA.pdf

Context. Magnetic clouds (MCs) are large-scale interplanetary transient structures in the heliosphere that travel from the Sun into the interplanetary medium. The internal magnetic field lines inside the MCs are twisted, forming a flux rope (FR). This magnetic field structuring is determined by its initial solar configuration, by the processes involved during its eruption from the Sun, and by the dynamical evolution during its interaction with the ambient solar wind.

Aims. One of the most important properties of the magnetic structure inside MCs is the twist of the field lines forming the FR (the number of turns per unit length). The detailed internal distribution of twist is under debate mainly because the magnetic field (B) in MCs is observed only along the spacecraft trajectory, and thus it is necessary to complete observations with theoretical assumptions. Estimating the twist from the study of a single event is difficult because the field fluctuations significantly increase the noise of the observed B time series and thus the bias of the deduced twist.

Methods. The superposed epoch applied to MCs has proven to be a powerful technique, permitting the extraction of their common features, and removing the peculiarity of individual cases. We apply a superposed epoch technique to analyse the magnetic components in the local FR frame of a significant sample of moderately asymmetric MCs observed at 1 au. **Results.** From the superposed profile of B components in the FR frame, we determine the typical twist distribution in MCs. The twist is nearly uniform in the FR core (central half part), and it increases moderately, up to a factor two, towards the MC boundaries. This profile is close to the Lundquist field model limited to the FR core where the axial field component is above about one-third of its central value.

Improving solar wind forecasting using Data Assimilation

Matthew **Lang**, [Jake Witherington](#), [Harriet Turner](#), [Matt Owens](#), [Pete Riley](#)
Space Weather **Volume19, Issue7** e2020SW002698 2021

Data Assimilation (DA) has enabled huge improvements in the skill of terrestrial operational weather forecasting. In this study, we use a variational DA scheme with a computationally efficient solar wind model and in situ observations from STEREO A, STEREO B and ACE. This scheme enables solar-wind observations far from the Sun, such as at 1 AU, to update and improve the inner boundary conditions of the solar wind model (at 30 solar radii). In this way, observational information can be used to improve estimates of the near-Earth solar wind, even when the observations are not directly downstream of the Earth. This allows improved initial conditions of the solar wind to be passed into forecasting models. To this effect we employ the HUXt solar wind model to produce 27-day forecasts of the solar wind during the operational time of STEREO B (01/11/2007–30/09/2014). At ACE, we compare these DA forecasts to the corotation of STEREO B observations and find that 27-day RMSE for STEREO-B corotation and DA forecasts are comparable. However, the DA forecast is shown to improve solar wind forecasts when STEREO-B's latitude is offset from Earth. And the DA scheme enables the representation of the solar wind in the whole model domain between the Sun and the Earth to be improved, which will enable improved forecasting of CME arrival time and speed.

A Variational Approach to Data Assimilation in the Solar Wind

Matthew **Lang** [Mathew J. Owens](#)
Space Weather 17(1) Pages: 59-83 2019
sci-hub.se/10.1029/2018SW001857

Variational data assimilation (DA) has enabled huge improvements in the skill of operational weather forecasting. In this study, we use a simple solar-wind propagation model to develop the first solar-wind variational DA scheme. This scheme enables solar-wind observations far from the Sun, such as at 1 AU, to update and improve the inner-boundary conditions of the solar wind model (at 30 solar radii). In this way, observational information can be used to improve estimates of the near-Earth solar wind, even when the observations are not directly downstream of the Earth. Using controlled experiments with synthetic observations, we demonstrate this method's potential to improve solar wind forecasts, though the best results are achieved in conjunction with accurate initial estimates of the solar wind. The variational DA scheme is also applied to Solar-Terrestrial Relations Observatory (STEREO) in situ observations using initial solar wind conditions supplied by a coronal model of the observed photospheric magnetic field. We consider the period October 2010 to October 2011, when the STEREO spacecraft were approximately 80° ahead/behind Earth in its orbit. For 12 of 13 Carrington Rotations, assimilation of STEREO data improves the near-Earth solar wind estimate over the nonassimilated state, with a 18.4% reduction in the root mean square error. The largest gains are made by the DA during times when the steady-state assumption of the coronal models breaks down. While applying this pure variational approach to complex solar-wind models is technically challenging, we discuss hybrid DA approaches which are simpler to implement and may retain many of the advantages demonstrated here.

Dynamic Time Warping as a New Evaluation for Dst Forecast With Machine Learning

Brecht **Laperre***, Jorge Amaya and Giovanni Lapenta
Front. Astron. Space Sci. 7:39. 2020
<https://www.frontiersin.org/articles/10.3389/fspas.2020.00039/full>
<https://doi.org/10.3389/fspas.2020.00039>

Models based on neural networks and machine learning are seeing a rise in popularity in space physics. In particular, the forecasting of geomagnetic indices with neural network models is becoming a popular field of study. These models are evaluated with metrics such as the root-mean-square error (RMSE) and Pearson correlation coefficient. However, these classical metrics sometimes fail to capture crucial behavior. To show where the classical metrics are lacking, we trained a neural network, using a long short-term memory network, to make a forecast of the disturbance storm time index at origin time t with a forecasting horizon of 1 up to 6 h, trained on OMNIWeb data. Inspection of the model's results with the correlation coefficient and RMSE indicated a performance comparable to the latest publications. However, visual inspection showed that the predictions made by the neural network were behaving similarly to the persistence model. In this work, a new method is proposed to measure whether two time series are shifted in time with respect to each other, such as the persistence model output versus the observation. The new measure, based on Dynamical Time Warping, is capable of identifying results made by the persistence model and shows promising results in confirming the visual observations of the neural network's output. Finally, different methodologies for training the neural network are explored in order to remove the persistence behavior from the results.

<https://doi.org/10.1029/2024JA032478>

The heliosphere is full of galactic cosmic rays (GCR), high-energy charged particles coming isotropically from the galaxy. The GCR interact with the solar wind blown by the Sun carrying out plasma, magnetic fields and transient structures such as interplanetary coronal mass ejections (ICMEs) and their associated magnetic flux ropes (MFR). The GCR interaction with ICMEs has been extensively studied particularly the GCR flux attenuation (known as Forbush decreases) as a result of interacting with the ICME sheath and magnetic field. In this work, we investigate the opposite effect: the MFR's ability to generate GCR anisotropies which an observer may detect as an increase in the GCR flux. To achieve this, we simulated a flux of protons with energies in the 10–160 GeV range arriving from all directions to a cylindrical MFR (with and without sheath) with plasma, magnetic field, and spatial dimensions found in average ICMEs observed at 1 au. By following the individual trajectories of the injected particles we found that the MFR deviates the charged particles preferentially in one direction parallel to the MFR-axis. We also found that the peak of this anisotropic GCR flux depends on: the angle between the MFR and ambient magnetic fields; the presence or not of the sheath region; the energy of the incident particles and the observer location inside the MFR.

Galactic Cosmic Ray Sun Shadow during the declining phase of cycle 24 observed by HAWC

Alejandro [Lara](#), [Paulina Colin](#), [K.P. Arunbabu](#), [James Ryan](#)

PoS(ICRC2019)1104 **2019**

<https://arxiv.org/pdf/1908.07509.pdf>

The High Altitude Water Cherenkov (HAWC) array is sensitive to high energy Cosmic Rays (CR) in the ~ 10 to ~ 200 TeV energy range, making it possible to construct maps of the so called "Sun Shadow" (SS), i. e. of the deficit of CR coming from the direction of the Sun. In this work, we present the variation of the Relative Intensity of the deficit (SSRI) for three years of HAWC observations from 2016 to 2018 in which we found a clear decreasing trend of the (SSRI) over the studied period, corresponding to the declining phase of the solar cycle 24. By comparing the SSRI with the photospheric magnetic field evolution, we show that there is a linear relationship between the SSRI and the median photospheric magnetic field of the Active Region belt ($-40^\circ \leq \text{lat} \leq 40^\circ$) and an inverse linear relationship with the polar photospheric magnetic field ($\text{lat} \geq \pm 60^\circ$). The former relationship is due to the magnetic field causing a deviation of the CR, whereas the latter reflects the change of the heliospheric field topology from multipolar to dipolar configurations. These relationships are valid only when the median magnetic field is lower than 8 G, during the declining and minimum phases of the solar cycle 24. Finally, we show that relativistic charged particles, in the 10 to 200 TeV energy range, are deflected a few degrees.

Velocity profile of interplanetary coronal mass ejections beyond 1 AU

[Lara](#), A.; [Flandes](#), A.; [Borgazzi](#), A.; [Subramanian](#), P.

J. Geophys. Res., Vol. 116, No. A12, A12102, 2011

<http://onlinelibrary.wiley.com/doi/10.1029/2011JA016807/pdf>

We analyze the dynamics of interplanetary coronal mass ejections (ICMEs) through the interplanetary medium from the lower solar corona to ~ 5.3 AU. Our analysis uses a one-dimensional hydrodynamical model derived from the fluid equation of motion that considers an effective drag force under both the laminar and turbulent hypotheses (low and high Reynolds number, respectively). The model has three sets of input parameters. The first set is related to the ICME itself, i. e., initial speed and mass; the second set of parameters is related to the ambient solar wind: density and velocity; and the final set corresponds to the ambient solar wind-ICME interaction: an ICME expansion factor and a viscosity or drag parameter. We use this model to explain the radial dynamics of a particular ICME detected at three different locations:

close to the Sun, where the ICME was ejected on **20 January 2004**, and detected by the SOHO/LASCO coronagraphs; two days later, at Earth's L1 by the ACE spacecraft (~ 1.0 AU), and finally, ~ 14 days later, at ~ 5.3 AU by the Ulysses spacecraft near Jupiter's orbit. The model is then compared to a general set of ICMEs data from Ulysses that cover distances from ~ 1.3 AU to ~ 5.3 AU. Our model successfully reproduces the dynamical behavior of ICMEs at distances near Earth's orbit and works reasonably well at larger distances ≈ 5.3 AU. Therefore, our analysis shows that the ICME - solar wind interaction may be treated as a drag interaction with the appropriate drag factors, not only at distances ≤ 1 AU, but at larger distances. Finally, we show that our model is useful in identifying ICMEs at different heliocentric distances.

Dynamics of interplanetary CMEs and associated type II bursts

Alejandro **Lara** and Andrea I. Borgazzi

Proceedings of the International Astronomical Union / Volume 4 / Symposium S257, pp 287 – 290,

Published online: 16 Март **2009**, **File**

Coronal mass ejections (CMEs) are large scale structures of plasma ($\sim 10^{16}$ g) and magnetic field expelled from the solar corona to the interplanetary medium. During their travel in the inner heliosphere, these “interplanetary CMEs” (ICMEs), suffer acceleration due to the interaction with the ambient solar wind. Based on hydrodynamic theory, we have developed an analytical model for the ICME transport which reproduce well the observed deceleration of fast ICMEs. In this work we present the results of the model and its application to the CME observed on **May 13, 2005** and the associated interplanetary type II burst.

The Extended Field-aligned Suprathermal Proton Beam and Long-lasting Trapped Energetic Particle Population Observed Upstream of a Transient Interplanetary Shock

2022 ApJ 925 198

<https://iopscience.iop.org/article/10.3847/1538-4357/ac3c47/pdf>

The properties of the suprathermal particle distributions observed upstream of interplanetary shocks depend not only on the properties of the shocks but also on the transport conditions encountered by the particles as they propagate away from the shocks. The confinement of particles in close proximity to the shocks, as well as particle scattering processes during propagation to the spacecraft, lead to the common observation of upstream diffuse particle distributions. We present observations of a rare extended anisotropic low-energy ($\lesssim 30$ keV) proton beam together with a trapped $\gtrsim 500$ keV proton population observed in association with the arrival of an oblique interplanetary shock at the Advanced Composition Explorer, the Interplanetary Monitoring Platform-8, and the Wind spacecraft on **2001 January 31**. Continuous injection of particles by the traveling shock into a smooth radial magnetic field region formed in the tail of a modest high-speed solar wind stream produced an extended foreshock region of energetic particles. The absence of enhanced magnetic field fluctuations upstream of the shock results in the observation of a prolonged anisotropic field-aligned beam of $\lesssim 30$ keV protons as well as a population of higher-energy ($\gtrsim 500$ keV) protons with small pitch-angle cosine ($\mu \sim 0$) extending far from the shock.

The Streamer Blowout Origin of a Flux Rope and Energetic Particle Event Observed by Parker Solar Probe at 0.5 au

2020 ApJ 897 134

<https://doi.org/10.3847/1538-4357/ab9942>

The distribution of spacecraft in the inner heliosphere during 2019 March enabled comprehensive observations of an interplanetary coronal mass ejection (ICME) that encountered Parker Solar Probe (PSP) at 0.547 au from the Sun. This ICME originated as a slow (~ 311 km s⁻¹) streamer blowout (SBO) on the Sun as measured by the white-light coronagraphs on board the Solar TERrestrial RELations Observatory-A and the Solar and Heliospheric Observatory.

Despite its low initial speed, the passage of the ICME at PSP was preceded by an anisotropic, energetic (≈ 100 keV/n) ion enhancement and by two interplanetary shocks. The ICME was embedded between slow (~ 300 km s⁻¹) solar wind and a following, relatively high-speed (~ 500 km s⁻¹), stream that most likely was responsible for the unexpectedly short (based on the SBO speed) ICME transit time of less than ~ 56 hr between the Sun and PSP, and for the formation of the preceding shocks. By assuming a graduated cylindrical shell (GCS) model for the SBO that expands self-similarly with time, we estimate the propagation direction and morphology of the SBO near the Sun. We reconstruct the flux-rope structure of the in situ ICME assuming an elliptic-cylindrical topology and compare it with the portion of the 3D flux-

rope GCS morphology intercepted by PSP. ADAPT-WSA-ENLIL-Cone magnetohydrodynamic simulations are used to illustrate the ICME propagation in a structured background solar wind and estimate the time when PSP established magnetic connection with the compressed region that formed in front of the ICME. This time is consistent with the arrival at PSP of energetic particles accelerated upstream of the ICME.

Evolution of the magnetic field rotation distributions in the inner heliosphere

A&A, 686, A238 (2024)

<https://www.aanda.org/articles/aa/pdf/2024/06/aa50030-24.pdf>

Context. The nature and evolution of the solar wind magnetic field rotations is studied in data from the Parker Solar Probe.

Aims. We investigated the magnetic field deflections in the inner heliosphere below 0.5 au in a distance- and scale-dependent manner to shed some light on the mechanism behind their evolution.

Methods. We used the magnetic field data from the FIELDS instrument suite to study the evolution of the magnetic field vector increment and rotation distributions that contain switchbacks.

Results. We find that the rotation distributions evolve in a scale-dependent fashion. They have the same shape at small scales regardless of the radial distance, in contrast to larger scales, where the shape evolves with distance. The increments are shown to evolve towards a log-normal shape with increasing radial distance, even though the log-normal fit works quite well at all distances, especially at small scales. The rotation distributions are shown to evolve towards a previously developed rotation model moving away from the Sun.

Conclusions. Our results suggest a scenario in which the evolution of the rotation distributions is primarily the result of the expansion-driven growth of the fluctuations, which are reshaped into a log-normal distribution by the solar wind turbulence.

Switchbacks: statistical properties and deviations from alfvénicity

A. [Larosa](#), [V. Krasnoselskikh](#), [T. Dudok de Wit](#)^{1,2},

A&A 2020

<https://arxiv.org/pdf/2012.10420.pdf>

{Parker Solar Probe's first solar encounter has revealed the presence of sudden magnetic field deflections that are called switchbacks and are associated with proton velocity enhancements in the slow alfvénic solar wind.} {We study their statistical properties with a special focus on their boundaries.} {Using data from SWEAP and FIELDS we investigate particle and wavefield properties. The magnetic boundaries are analyzed with the minimum variance technique.} {Switchbacks are found to be alfvénic in 73% of the cases and compressible in 27%. The correlations between magnetic field magnitude and density fluctuations reveal the existence of both positive and negative correlations, and the absence of perturbations of the magnetic field magnitude. Switchbacks do not lead to a magnetic shear in the ambient field. Their boundaries can be interpreted in terms of rotational or tangential discontinuities. The former are more frequent.} {Our findings provide constraints on the possible generation mechanisms of switchbacks, which has to be able to account also for structures that are not purely alfvénic. One of the possible candidates, among others, manifesting the described characteristics is the firehose instability.} 4-8 Nov 2018

Evolution of coronal mass ejections with and without sheaths from the inner to the outer heliosphere: Statistical investigation for 1975 to 2022

C. [Larrodera](#)^{1,2} and M. Temmer²

A&A, 685, A89 (2024)

<https://arxiv.org/pdf/2402.16653.pdf>

<https://www.aanda.org/articles/aa/pdf/2024/05/aa48641-23.pdf>

Aims. This study covers a thorough statistical investigation of the evolution of interplanetary coronal mass ejections (ICMEs) with and without sheaths through a broad heliocentric distance and temporal range. The analysis treats the sheath and magnetic obstacle (MO) separately in order to gain more insight on their physical properties. In detail, we aim to unravel different characteristics of these structures occurring over the inner and outer heliosphere.

Methods. The method is based on a large statistical sample of ICMEs probed over different distances in the heliosphere. For this, information about detection times for the sheath and MO from 13 individual ICME catalogs was collected and crosschecked. The time information was then combined into a main catalog that was used as the basis for the statistical investigation. The data analysis based on this catalog covers a large number of spacecraft missions, enabling in situ solar wind measurements from 1975 to 2022. This allowed us to study the differences between solar cycles.

Results. All the structures under study (sheath, MO with and without sheath) show the biggest increase in size together with the largest decrease in density at a distance of ~ 0.75 AU. At 1 AU, we found different sizes for MOs with and without a sheath, with the former being larger. Up to 1 AU, the upstream solar wind shows the strongest pileup close to the interface with the sheath. For larger distances, the pileup region seems to shift, and it recedes from that interface further into the upstream solar wind. This might refer to a change in the sheath formation mechanism (driven versus non-driven) with heliocentric distance, suggesting the relevance of the CME propagation and the expansion behavior in the outer heliosphere. A comparison to previous studies showed inconsistencies over the solar cycle, which makes more detailed studies necessary in order to fully understand the evolution of ICME structures.

Appendix A: Description of catalogs Table A.1. References of the individual catalogs used.

Estimation of the solar wind extreme events

C. Larrodera, L. Nikitina, C. Cid

Space Weather. **Volume19, Issue12** e2021SW002902 2021

<https://arxiv.org/pdf/2112.00005.pdf>

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2021SW002902>

<https://doi.org/10.1029/2021SW002902>

This research provides an analysis of extreme events in the solar wind and in the magnetosphere due to disturbances of the solar wind. Extreme value theory has been applied to a 20 year data set from the Advanced Composition Explorer (ACE) spacecraft for the period 1998-2017. The solar proton speed, solar proton temperature, solar proton density and magnetic field have been analyzed to characterize extreme events in the solar wind. The solar wind electric field, vB_z has been analyzed to characterize the impact from extreme disturbances in the solar wind to the magnetosphere. These extreme values were estimated for one-in-40 and one-in-80 years events, which represent two and four times the range of the original data set. The estimated values were verified by comparison with measured values of extreme events recorded in previous years. Finally, our research also suggests the presence of an upper boundary in the magnitudes under study.

The distribution function of the average iron charge state at 1 AU: from a bimodal wind to ICME identification

C. Larrodera, C. Cid

Solar Phys. **295**, Article number: 156 2020

<https://arxiv.org/pdf/2009.07596.pdf>

<https://link.springer.com/content/pdf/10.1007/s11207-020-01727-8.pdf>

We aim to investigate the distribution function of $\langle Q_{Fe} \rangle$ at 1AU to check if it corresponds to a bimodal wind. We use data from SWICS instrument on board the ACE spacecraft along 20 years. We propose the bi-Gaussian function as the probability distribution function that fits the $\langle Q_{Fe} \rangle$ distribution. We study the evolution of the parameters of the bimodal distribution with the solar cycle. We compare the outliers of the sample with the existing catalogues of ICMEs and identify new ICMEs. The $\langle Q_{Fe} \rangle$ at 1 AU shows a bimodal distribution related to the solar cycle. Our results confirm that $\langle Q_{Fe} \rangle > 12$ is a trustworthy proxy for ICME identification and a reliable signature in the ICME boundary definition.

26 April-2 May 2003 , 16-23 February 2011

Universal Heliophysical Processes Proceedings IAU Symposium No. 257, 2008, N. Gopalswamy & D.F. Webb, eds., 2009

<http://journals.cambridge.org/action/displayIssue?iid=4866212>

We study the geoeffectiveness of a sample of complex events; each includes a coronal type II burst, accompanied by a GOES SXR flare and LASCO CME. The radio bursts were recorded by the ARTEMIS-IV radio spectrograph, in the 100-650 MHz range; the GOES SXR flares and SOHO/LASCO CMEs, were obtained from the Solar Geophysical Data (SGD) and the LASCO catalogue respectively. These are compared with changes of solar wind parameters and geomagnetic indices in order to establish a relationship between solar energetic events and their effects on geomagnetic activity.

Magnetic reconnection as a mechanism to produce multiple proton populations and beams locally in the solar wind

B. Lavraud, R. Kieokaew, N. Fargette, P. Louarn, A. Fedorov, N. André, G. Fruit, V. Génot, V. Réville, A. P. Rouillard, I. Plotnikov, E. Penou, A. Barthe, L. Prech, C. J. Owen, R. Bruno, F. Allegrini, M. Berthomier, D. Kataria, S. Livi, J. M. Raines, R. D'Amicis, J. P. Eastwood, C. Froment, R. Laker, M. Maksimovic, F. Marcucci, S. Perri, D. Perrone, T. D. Phan, D. Stansby, J. Stawarz, S. Toledo Redondo, A. Vaivads, D. Verscharen, I. Zouganelis, V. Angelini, V. Evans, T. S. Horbury, H. O'Brien

A&A 2021

<https://arxiv.org/pdf/2109.11232.pdf>

Context. Spacecraft observations early revealed frequent multiple proton populations in the solar wind. Decades of research on their origin have focused on processes such as magnetic reconnection in the low corona and wave-particle interactions in the corona and locally in the solar wind.

Aims. This study aims to highlight that multiple proton populations and beams are also produced by magnetic reconnection occurring locally in the solar wind.

Methods. We use high resolution **Solar Orbiter** proton velocity distribution function measurements, complemented by electron and magnetic field data, to analyze the association of multiple proton populations and beams with magnetic reconnection during a period of slow Alfvénic solar wind on **16 July 2020**.

Results. At least 6 reconnecting current sheets with associated multiple proton populations and beams, including a case of magnetic reconnection at a switchback boundary, are found during this day. This represents 2% of the measured distribution functions. We discuss how this proportion may be underestimated, and how it may depend on solar wind type and distance from the Sun. Conclusions. Although suggesting a likely small contribution, but which remains to be quantitatively assessed, Solar Orbiter observations show that magnetic reconnection must be considered as one of the mechanisms that produce multiple proton populations and beams locally in the solar wind.

The Heliospheric Current Sheet and Plasma Sheet during Parker Solar Probe's First Orbit

B. Lavraud¹, N. Fargette¹, V. Réville¹, A. Szabo², J. Huang ...

2020 ApJL 894 L19

<https://doi.org/10.3847/2041-8213/ab8d2d>

We present heliospheric current sheet (HCS) and plasma sheet (HPS) observations during Parker Solar Probe's (PSP) first orbit around the Sun. We focus on the eight intervals that display a true sector boundary (TSB; based on suprathermal electron pitch angle distributions) with one or several associated current sheets. The analysis shows that (1) the main density enhancements in the vicinity of the TSB and HCS are typically associated with electron strahl dropouts, implying magnetic disconnection from the Sun, (2) the density enhancements are just about twice that in the surrounding regions, suggesting mixing of plasmas from each side of the HCS, (3) the velocity changes at the main boundaries are either correlated or anticorrelated with magnetic field changes, consistent with magnetic reconnection, (4) there often exists a layer of disconnected magnetic field just outside the high-density regions, in agreement with a reconnected topology, (5) while a few cases consist of short-lived density and velocity changes, compatible with short-duration reconnection exhausts, most events are much longer and show the presence of flux ropes interleaved with higher- β regions. These findings are consistent with the transient release of density blobs and flux ropes through sequential magnetic reconnection at the tip of the helmet streamer. The data also demonstrate that, at least during PSP's first orbit, the only structure that may be defined as the HPS is the density structure that results from magnetic reconnection, and its byproducts, likely released near the tip of the helmet streamer.

Geo-effectiveness and radial dependence of magnetic cloud erosion by magnetic reconnection

Benoit Lavraud, Alexis Ruffenach, Alexis P. Rouillard, Primoz Kajdic, Ward B. Manchester and Noé Lugaz
JGR, Volume 119, Issue 1, pages 26–35, January 2014

<http://onlinelibrary.wiley.com/doi/10.1002/2013JA019154/pdf>

Magnetic flux erosion by magnetic reconnection occurs at the front of at least some magnetic clouds (MCs). We first investigate how erosion influences the geo-effectiveness of MCs in a general sense and using a south-north magnetic polarity MC observed on **18–20 October 1995**. Although the magnetic shear at its front may not be known during propagation, measurements at 1 AU show signatures of local reconnection. Using a standard MC model, an empirical model of the geomagnetic response (Dst), and an observational estimate of the magnetic flux erosion, we find that the strength of the observed ensuing storm was ~30% lower than if no erosion had occurred. We then discuss the interplay between adiabatic compression and magnetic erosion at the front of MCs. We conclude that the most geo-effective configuration for a south-north polarity MC is to be preceded by a solar wind with southward IMF. This stems not only from the formation of a geo-effective sheath ahead of it but also from the adiabatic compression and reduced (or lack

thereof) magnetic erosion which constructively conspire for the structure to be more geo-effective. Finally, assuming simple semiempirical and theoretical Alfvén speed profiles expected from expansion to 1 AU, we provide first-order estimates of the erosion process radial evolution. We find that the expected reconnection rates during propagation allow for significant erosion, on the order of those reported. Calculations also suggest that most of the erosion should occur in the inner heliosphere, and up to ~50% may yet occur beyond Mercury's orbit.

Statistics of counter-streaming solar wind suprathermal electrons at solar minimum: STEREO observations

B. [Lavraud](#), A. Opitz, J. Gosling, A. Rouillard, K. Meziane, J. Sauvaud, A. Fedorov, I. Dandouras, V. Genot, C. Jacquy, P. Louarn, C. Mazelle, E. Penou, D. Larson, J. Luhmann, P. Schroeder, L. Jian, C. Russell, C. Foullon, R. Skoug, J. Steinberg, K. Simunac, and A. Galvin
Ann. Geophys., 28, 233-246, 2010

Previous work has shown that solar wind suprathermal electrons can display a number of features in terms of their anisotropy. Of importance is the occurrence of counter-streaming electron patterns, i.e., with "beams" both parallel and anti-parallel to the local magnetic field, which is believed to shed light on the heliospheric magnetic field topology. In the present study, we use STEREO data to obtain the statistical properties of counter-streaming suprathermal electrons (CSEs) in the vicinity of corotating interaction regions (CIRs) during the period March–December 2007. Because this period corresponds to a minimum of solar activity, the results are unrelated to the sampling of large-scale coronal mass ejections, which can lead to CSE owing to their closed magnetic field topology. The present study statistically confirms that CSEs are primarily the result of suprathermal electron leakage from the compressed CIR into the upstream regions with the combined occurrence of halo depletion at 90° pitch angle. The occurrence rate of CSE is found to be about 15–20% on average during the period analyzed (depending on the criteria used), but superposed epoch analysis demonstrates that CSEs are preferentially observed both before and after the passage of the stream interface (with peak occurrence rate >35% in the trailing high speed stream), as well as both inside and outside CIRs. The results quantitatively show that CSEs are common in the solar wind during solar minimum, but yet they suggest that such distributions would be much more common if pitch angle scattering were absent. We further argue that (1) the formation of shocks contributes to the occurrence of enhanced counter-streaming sunward-directed fluxes, but does not appear to be a necessary condition, and (2) that the presence of small-scale transients with closed-field topologies likely also contributes to the occurrence of counter-streaming patterns, but only in the slow solar wind prior to CIRs.

Relationships between Interplanetary Coronal Mass Ejection Characteristics and Geoeffectiveness in the Declining Phase of Solar Cycles 23 and 24

M. Benedict [Lawrance](#), [Y.-J. Moon](#) & [A. Shanmugaraju](#)

[Solar Physics](#) volume 295, Article number: 62 (2020)

<https://link.springer.com/content/pdf/10.1007%2Fs11207-020-01623-1.pdf>

In this paper, we have examined the relationships between the characteristics of interplanetary coronal mass ejections (ICMEs) and geoeffectiveness in the declining phase of Solar Cycles 23 and 24. We discuss the results in comparison with those of the rising phase. Major results of this study are as follows: The ICMEs in the declining phase of Cycle 23 have generated higher storm strength than those in Cycle 24. The mean storm strength of the sheath and ICME for each cycle in the declining phase is greater than in the rising phase. This indicates that the declining phase is more geoeffective than the rising phase. Cycle 24 events seem to be slightly more geoeffective towards the second half of the cycle even though the cycle is weak in the rising phase. The mean radial size of ICMEs is ~ 0.36 AU in Cycle 23 and ~0.32 AU in Cycle 24. Around 25% of the ICMEs in Cycle 23 and 15% in Cycle 24 exceed ~0.5 AU in size at 1 AU. The correlation between the southward magnetic component (BsBs) and the storm strength they cause is decisive in both cycles. This substantiates that the storm strength of the ICMEs strongly relies on the ICME BsBs in both cycles. The correlation between the storm strength/BsBs and the size of sheath/ICME seems insignificant, which suggests that the storm strength is independent of the size of the ICMEs. Almost 80% of geomagnetic storm peaks occurred in the ICME duration of the declining phase of Cycles 23 and 24, which is substantially identical to the rising phase. Summing up, this sort of study will be eminent to emphasize the variations in the rising and declining phases of solar cycles. The ICMEs are dominant in generating storms both in the rising and declining phases of a solar although in the declining phase they seem to generate more geoeffectiveness than in the rising phase.

Table 1 List of ICME and sheath parameters for the declining phase of Cycle 23 (2002 – 2008).

Table 2 List of ICME and sheath parameters for the declining phase of Cycle 24 (2014 – 2018).

Relationships Between Interplanetary Coronal Mass Ejection Characteristics and Geoeffectiveness in the Rising Phase of Solar Cycles 23 and 24

M. Benedict [Lawrance](#), A. Shanmugaraju, Y.-J. Moon, M. Syed Ibrahim, S. Umapathy
Solar Physics, Volume 291, Issue 5, pp 1547-1560 2016

The characteristics and geoeffectiveness of interplanetary coronal mass ejections (ICMEs) are derived and their relationships are investigated. The results are compared for a set of events in the rising phase of Solar Cycles 23 and 24. These events are considered from the reported list of Cane and Richardson (Geophys. Res. Lett. 27, 3591, [2000](#)). The geoeffectiveness is studied independently for ICME and sheath. The results obtained are that i) CMEs of Cycle 23 have generated a higher Dst index than Cycle 24 CMEs and that ii) the southward magnetic component (BsBs) and the Dst index of ICMEs correlate well for both Cycles 23 and 24 in their rising phase. These findings agree with the literature, which has described Cycle 24 to be weaker than Cycle 23 and where the ICME/sheath regions of Cycle 23 are found to have a greater BsBs that results in stronger storms. In addition, other results obtained are as follows: i) The relation between ICME size and the related Dst index gives a weak correlation for the rising phases of both Cycles 23 and 24. ii) The correlation between sheath size and Dst index is higher in the rising phase of Cycle 24 than in the rising phase of Cycle 23. iii) The average ICME size of the rising phase of Cycle 23 (84 R_☉) is greater than that of the rising phase of Cycle 24 (58 R_☉). However, the average sheath size is 24 R_☉, which is nearly equal to that of Cycle 24 (26 R_☉). Thus the differences between the properties of ICME and sheath in both the cycles are demonstrated. Nearly 75 % of geomagnetic storm peaks occurred in the ICME duration in the rising phase of Cycles 23 and 24. This shows that the ICMEs are more important in generating the storms than the sheaths in the rising phase of a solar cycle.

Solar Wind Electron Strahls Associated with a High-Latitude CME: **\emph{Ulysses}** Observations

M. [Lazar](#), J. Pomoell, S. Poedts, C. Dumitrache, N.A. Popescu
Solar Phys., Volume 289, Issue 11, pp 4239-4266 2014

<http://arxiv.org/pdf/1405.5690v1.pdf>

Counterstreaming beams of electrons are ubiquitous in coronal mass ejections (CMEs) - although their existence is not unanimously accepted as a necessary and/or sufficient signature of these events. We continue the investigations of a high-latitude CME registered by the **\emph{Ulysses}** spacecraft on **January 18--19, 2002** (Dumitrache, Popescu, and Oncica, Solar Phys. **{\bf 272}**, 137, 2011), by surveying the solar wind electron distributions associated with this event. The temporal-evolution of the pitch-angle distributions reveal populations of electrons distinguishable through their anisotropy, with clear signatures of i) electron strahls, ii) counter-streaming in the magnetic clouds and their precursors, and iii) unidirectional in the fast wind preceding the CME. The analysis of the counter-streams inside the CME allows us to elucidate the complexity of the magnetic-cloud structures embedded in the CME and to refine the borders of the event. Identifying such strahls in CMEs, which preserve properties of the low $\beta < 1$ coronal plasma, gives more support to the hypothesis that these populations are remnants of the hot coronal electrons that escape from the electrostatic potential of the Sun into the heliosphere.

Dst index forecast based on ground-level data aided by bio-inspired algorithms

J. A. [Lazzús](#) , [P. Vega-Jorquera](#) , [L. Palma-Chilla](#) , [M. V. Stepanova](#),

<https://agupubs.onlinelibrary.wiley.com/doi/epdf/10.1029/2019SW002215>

In this study, different hybridized techniques that combine an artificial neural network (ANN) with bio-inspired optimization algorithms such as particle swarm optimization (PSO), genetic algorithm (GA), and a hybridized PSO+GA were applied to update the ANN connection weights and so forecast the disturbance storm time (Dst) index. The past values of Dst index time series were used as input parameters to forecast its variation from 1 to 6 hours ahead. The database collected considers 233,760 hourly data from 01 January 1990 to 31 August 2016, containing storms and quiet period, grouped into three data sets: learning set (116,880 hourly data points), validation set (58,440 data points), and testing set (58,440 data points). Several ANN configurations were studied and optimized during the training process by evaluating the root mean square error (RMSE) and the correlation coefficient (R). An analysis of the predictive capability of each method was made year per year, and according to the levels of the geomagnetic storm. Also, an additional test was applied to the proposed method using 17 intense geomagnetic storms reported during solar cycle 24, including the St. Patrick's Day storm of 2015. Results show that the hybridized ANN+PSO method can forecast the Dst index quite accurately from 1 to 3 h in advance (with $RMSE \leq 5$ nT and $R \geq 0.9$), while the ANN+PSO+GA method can forecast the Dst index quite accurately from 4 to 6 h ahead ($RMSE \leq 7$ nT and $R \geq 0.8$)

Source Locations and Solar-Cycle Distribution of the Major Geomagnetic Storms ($Dst \leq -100$ nT) from 1932 to 2018

Gui-Ming Le, [Ming-Xian Zhao](#), [Wen-Tao Zhang](#) & [Gui-Ang Liu](#)

[Solar Physics](#) volume 296, Article number: 187 (2021)

<https://link.springer.com/content/pdf/10.1007/s11207-021-01927-w.pdf>

<https://doi.org/10.1007/s11207-021-01927-w>

We studied the source locations and solar-cycle (SC) distribution of the major geomagnetic storms (MGSs) that occurred from 1932 to 2018. We divided the MGSs into two groups: the intense geomagnetic storms (IGSs) ($-200 \text{ nT} < Dst \leq -100 \text{ nT}$) and the great geomagnetic storms (GGSs) ($Dst \leq -200 \text{ nT}$). The GGSs were split into three subgroups: GGSs-I ($-300 \text{ nT} < Dst \leq -200 \text{ nT}$), GGSs-II ($-400 \text{ nT} < Dst \leq -300 \text{ nT}$) and GGSs-III ($-600 \text{ nT} < Dst \leq -400 \text{ nT}$). The source locations of the GGSs-I and GGSs-II were distributed in the longitudinal range of [E84, W73], while the GGSs-III were distributed in the range of [E22, W14]. 90% of the GGSs were distributed in the longitudinal area of [E45, W45]. The statistical results show that 38.6%, 61.4% and 86% of the GGSs occurred in the ascending phase, the descending phase, and the period from two years before to three years after the solar maximum, respectively. 33.3%, 66.7% and 76% of the IGSs appeared in the ascending phase, the descending phase, and the period from two years to three years after the solar maximum, respectively. The number of MGSs in a SC has a good correlation with the SC size. However, the largest storm intensity in a SC has almost no relationship with the SC size, implying that the number of MGSs in a weak SC will be small. However, we cannot rule out the possibility that a weak SC may have a very strong extreme geomagnetic storm.

Table 1 The largest storm intensity for each SC from 1932 to 2016

Table 4 The GGSs during SCs 17 – 24 ($Dst \leq -200$ nT).

Dependence of Major Geomagnetic Storm Intensity ($Dst \leq -100$ nT) on Associated Solar Wind Parameters

Gui-Ming Le, [Gui-Ang Liu](#) & [Ming-Xian Zhao](#)

[Solar Physics](#) volume 295, Article number: 108 (2020)

<https://link.springer.com/content/pdf/10.1007/s11207-020-01675-3.pdf>

We investigate the influence of various solar wind parameters on the intensity of the associated major geomagnetic storm. SYM-Hmin was used to indicate the intensity of major geomagnetic storms, while $I(B_s)$, $I(E_y)$ and $I(Q)$ were used to indicate the time integrals of the southward interplanetary magnetic field component (B_s), the solar wind electric field (E_y), and Q , which is the combination of E_y and the solar wind dynamic pressure, during the main phase of a major geomagnetic storm, respectively. We have found that the correlation coefficient (CC) between the time integral of solar wind parameters and the intensity of an associated major geomagnetic storm has a physical meaning, while the CC between the peak value of a given solar wind parameter and the intensity of an associated major geomagnetic storm has no physical meaning. We used 67 major geomagnetic storms that occurred between 1998 and 2006 to calculate the CC between SYM-Hmin and $I(B_s)$, the CC between SYM-Hmin and $I(E_y)$, and the CC between SYM-Hmin and $I(Q)$. The derived CC between $I(B_s)$ and SYM-Hmin is 0.33, while the CC between $I(E_y)$ and SYM-Hmin is 0.57, and the CC between $I(Q)$ and SYM-Hmin is 0.86, respectively. These values indicate that $I(B_s)$, $I(E_y)$ and $I(Q)$ contribute in a small, moderate, and crucial way to the intensity of a major geomagnetic storm, respectively. For the solar wind to have a strong geoeffectiveness B_s plays a role, together the solar wind speed and density, but also the dynamic pressure > 3 nPa. Large and long duration B_s or E_y cannot ensure a major geomagnetic storm, if the solar wind dynamic pressure is much lower than 3 nPa. **18–19, October 1998**

Geoeffectiveness of the coronal mass ejections associated with solar proton events

Gui-Ming Le, Chuan Li, Yu-Hua Tang, Liu-Guan Ding, Zhi-Qiang Yin, Yu-Lin Chen, Yang-Ping Lu, Min-Hao Chen, Zhong-Yi Li

Research in Astronomy and Astrophysics (RAA) [Vol 16, No 1 \(2016\)](#) paper 14, **File**

The intensity-time profiles of solar proton events (SPEs) are grouped into three types in the present study. The Type-I means that the intensity-time profile of an SPE has one peak, which occurs shortly after the associated solar flare and coronal mass ejection (CME). The Type-II means that the SPE profile has two peaks: the first peak occurs shortly after the solar eruption, the second peak occurs at the time when the CME-driven shock reaches the Earth, and the intensity of the second peak is lower than the first one. If the intensity of the second peak is higher than the first one, or the SPE intensity increases continuously until the CME-driven shock reaches the Earth, this kind of intensity-time profile is defined as Type-III. It is found that most CMEs associated with Type-I SPEs have no geoeffectiveness and only a small part of CMEs associated with Type-I SPEs can produce minor ($-50 \text{ nT} \leq Dst \leq -30 \text{ nT}$) or moderate geomagnetic storms

($-100 \text{ nT} \leq \text{Dst} \leq -50 \text{ nT}$), but never an intense geomagnetic storm ($-200 \text{ nT} \leq \text{Dst} < -100 \text{ nT}$). However, most of the CMEs associated with Type-II and Type-III SPEs can produce intense or great geomagnetic storms ($\text{Dst} \leq -200 \text{ nT}$). The solar wind structures responsible for the geomagnetic storms associated with SPEs with different intensity-time profiles have also been investigated and discussed. **1998 May 2, 1998 May 6, 2001 January 28, 2003 October 28, 2004 July 25, 2006 December 13**

Modeling Energetic Particle Acceleration and Transport in a Solar Wind Region with Contracting and Reconnecting Small-scale Flux Ropes at Earth Orbit

J. A. **Le Roux**^{1,2}, G. M. Webb², O. V. Khabarova³, L.-L. Zhao², and L. Adhikari²

2019 ApJ 887 77

[sci-hub.se/10.3847/1538-4357/ab521f](https://doi.org/10.3847/1538-4357/ab521f)

New analytical steady-state and time-dependent solutions for the acceleration of energetic particles by contracting and reconnecting small-scale flux ropes (SMFRs) in the solar wind are presented. For this purpose, a telegrapher-type Parker transport equation was derived from the existing underlying focused transport equation. The solutions unify all SMFR acceleration mechanisms present in the transport equation, showing that SMFR acceleration by the reconnection electric field in the mixed-derivative transport term is constrained by and requires the presence of second-order Fermi SMFR acceleration. We explore the potential of these solutions in reproducing energetic proton flux enhancements and spectral evolution between $\sim 50 \text{ keV}$ and 5 MeV in dynamic SMFR regions near large-scale reconnecting current sheets in the solar wind at Earth orbit. It is shown that second-order Fermi SMFR acceleration involving the variance in SMFR compression and incompressible parallel shear flow and confirmed that first-order SMFR Fermi acceleration, due to mean SMFR compression (successfully used before in data fits), are both workable options in reproducing observed flux amplification factors when using reasonable SMFR parameters. However, the predicted substantial quantitative differences in the spatial evolution of the accelerated spectra through the SMFR region might provide a way to distinguish between first- and second-order Fermi SMFR acceleration in observations. It is concluded that more detailed data analysis of SMFR parameters in SMFR acceleration events is needed before the relative role of first- and second-order SMFR acceleration mechanisms can be determined.

HOW THE SOLAR WIND TIES TO ITS PHOTOSPHERIC ORIGINS

Robert J. Leamon¹ and Scott W. McIntosh²

2009 ApJ 697 L28-L32 doi: [10.1088/0004-637X/697/1/L28](https://doi.org/10.1088/0004-637X/697/1/L28)

We present a new method of visualizing the solar photospheric magnetic field based on the "Magnetic Range of Influence" (MRoI). The MRoI is a simple realization of the magnetic environment in the photosphere, reflecting the distance required to balance the integrated magnetic field contained in any magnetogram pixel. It provides a new perspective on where subterrestrial field lines in a Potential Field Source Surface (PFSS) model connect to the photosphere, and thus the source of Earth-directed solar wind (within the limitations of PFSS models), something that is not usually obvious from a regular synoptic magnetogram. In each of three sample solar rotations, at different phases of the solar cycle, the PFSS footpoint either jumps between isolated areas of high MRoI or moves slowly within one such area. Footpoint motions are consistent with Fisk's interchange reconnection model.

Helicity of magnetic clouds and their associated active regions

Leamon, R.J., Canfield, R.C., Jones, S.L., Lambkin, K., Lundberg, B.J., Pevtsov, A.A.:

2004, *J. Geophys. Res.* **109**, 5106. **File**

<http://onlinelibrary.wiley.com/doi/10.1029/2003JA010324/pdf>

In this work we relate the magnetic and topological parameters of twelve interplanetary magnetic clouds to associated solar active regions. We use a cylindrically symmetric constant- α force-free model to derive field line twist, total current, and total magnetic flux from in situ observations of magnetic clouds. We compare these properties with those of the associated solar active regions, which we infer from solar vector magnetograms. Our comparison of fluxes and currents reveals: (1) the total flux ratios $\Phi_{\text{MC}}/\Phi_{\text{AR}}$ tend to be of order unity, (2) the total current ratios $I_{\text{MC}}/I_{\text{AR}}$ are orders of magnitude smaller, and (3) there is a statistically significant proportionality between them. Our key findings in comparing total twists αL are that (1) the values of $(\alpha L)_{\text{MC}}$ are typically an order of magnitude greater than those of $(\alpha L)_{\text{AR}}$ and (2) **there is no statistically significant sign or amplitude relationship between them. These findings compel us to believe that magnetic clouds associated with active region eruptions are formed by magnetic**

reconnection between these regions and their larger-scale surroundings, rather than simple eruption of preexisting structures in the corona or chromosphere.

Leamon *et al.* (2004) performed such fits to 12 MCs and found that their inferred axial fluxes roughly matched the flux of the entire active region (AR) whose CME had ejected it.

We note that the solar observations are ambiguous, and that in an active region a left-handed flux rope in the low corona may also be associated with a right-handed MC, as in some cases reported by Leamon *et al.* (2004).

Modeling CME encounters at Parker Solar Probe with OSPREI: Dependence on photospheric and coronal conditions*

Vincent E. **Ledvina**^{1,★★}, Erika Palmerio¹, Christina Kay^{2,3}, Nada Al-Haddad⁴ and Pete Riley¹
A&A 673, A96 (2023)

<https://doi.org/10.1051/0004-6361/202245445>

<https://www.aanda.org/articles/aa/pdf/2023/05/aa45445-22.pdf>

Context. Coronal mass ejections (CMEs) are eruptions of plasma from the Sun that travel through interplanetary space and may encounter Earth. CMEs often enclose a magnetic flux rope (MFR), the orientation of which largely determines the CMEs' geoeffectiveness. Current operational CME models do not model MFRs, but a number of research ones do, including the Open Solar Physics Rapid Ensemble Information (OSPREI) model.

Aims. We report the sensitivity of OSPREI to a range of user-selected photospheric and coronal conditions.

Methods. We modeled four separate CMEs observed in situ by Parker Solar Probe (PSP). We varied the input photospheric conditions using four input magnetograms (HMI Synchronic, HMI Synoptic, GONG Synoptic Zero-Point Corrected, and GONG ADAPT). To vary the coronal field reconstruction, we employed the Potential Field Source Surface (PFSS) model and varied its source-surface height in the range 1.5–3.0 R_{\odot} with 0.1 R_{\odot} increments.

Results. We find that both the input magnetogram and PFSS source surface often affect the evolution of the CME as it propagates through the Sun's corona into interplanetary space, and therefore the accuracy of the MFR prediction compared to in situ data at PSP. There is no obvious best combination of input magnetogram and PFSS source surface height.

Conclusions. The OSPREI model is moderately sensitive to the input photospheric and coronal conditions. Based on where the source region of the CME is located on the Sun, there may be best practices when selecting an input magnetogram to use. **21 Jun 2020, 9 Jun 2021, 7 Nov 2021, 26 Jan 2022**

Solar Chromospheric Network as a Source for Solar Wind Switchbacks

Jeongwoo **Lee**, Vasyli Yurchyshyn, Haimin Wang, Xu Yang, Wenda Cao, Juan Carlos Martínez Oliveros
ApJL , 935:L27 2022

<https://iopscience.iop.org/article/10.3847/2041-8213/ac86bf/pdf>

Recent studies suggest that the magnetic switchbacks (SBs) detected by the Parker Solar Probe carry information on the scales of solar supergranulation (large scale) and granulation (medium scale). We test this claim using high-resolution $H\alpha$ images obtained with the visible spectropolarimeters of the Goode Solar Telescope in Big Bear Solar Observatory. As possible solar sources, we count all the spicule-like features standing along the chromospheric networks near the coronal hole boundary visible in the $H\alpha$ blue-wing but absent in the red-wing images and measure the geometric parameters of dense sections of individual flux tubes. Intervals between adjacent spicules located along the chromospheric networks are found in the range of 0.4–1.5 Mm ($0^{\circ}.03$ – $0^{\circ}.12$) tending to be smaller than the medium scale of SBs. Interdistances between all pairs of the flux tubes are also counted and they appear in a single peak distribution around 0.7 Mm ($0^{\circ}.06$) unlike the waiting-time distribution of SBs in a scale-free single power-law form. The length-to-diameter ratio of the dense section of flux tubes is as high as 6–40, similar to the aspect ratio of SBs. The number of spicules along a network can be as high as 40–100, consistent with numerous SBs within a patch. With these numbers, it is argued that the medium scale of SBs can be understood as an equilibrium distance resulting from a random walk within each diverging magnetic field funnel connected to the chromospheric networks. **2020 June 17**

Effects of Geometries and Substructures of ICMEs on Geomagnetic Storms

Jae-Ok **Lee**, Kyung-Suk Cho, Rok-Soon Kim, Soojeong Jang, Katsuhide Marubashi

Solar Physics September 2018, 293:129 **File**

<https://link.springer.com/content/pdf/10.1007%2Fs11207-018-1344-z.pdf>

To better understand geomagnetic storm generations by ICMEs, we consider the effect of substructures (magnetic cloud, MC, and sheath) and geometries (impact location of flux-rope at the Earth) of the ICMEs. We apply the toroidal magnetic flux-rope model to 59 CDAW CME–ICME pairs to identify their substructures and geometries, and select 20 MC-associated and five sheath-associated storm events. We investigate the relationship between the storm strength indicated by minimum Dst index (D_{stmin}) and solar wind conditions related to a southward magnetic field. We find that all slopes of linear regression lines for sheath-storm events are steeper (≥ 1.4) than those of the MC-storm events in the relationship between D_{stmin} and solar wind conditions, implying that the efficiency of sheath for the process of geomagnetic storm generations is higher than that of MC. These results suggest that different general solar wind conditions (sheaths have a higher density, dynamic and thermal pressures with a higher fluctuation of the parameters and higher magnetic fields than MCs) have different impact on storm generation. Regarding the geometric encounter of ICMEs, 100% (2/2) of major storms ($D_{stmin} \leq -100$ nT) occur in the regions at negative PYPY (relative position of the Earth trajectory from the ICME axis in the YY component of the GSE coordinate) when the eastern flanks of ICMEs encounter the Earth. We find similar statistical trends in solar wind conditions, suggesting that the dependence of geomagnetic storms on 3D ICME–Earth impact geometries is caused by asymmetric distributions of the geoeffective solar wind conditions. For western flank events, 80% (4/5) of the major storms occur in positive PYPY regions, while intense geoeffective solar wind conditions are not located in the positive PYPY. These results suggest that the strength of geomagnetic storms depends on ICME–Earth impact geometries as they determine the solar wind conditions at Earth. **10 December 1997, 22 January 2000, 11 – 13 April 2001, 18 – 20 May 2002**

Table 1 Observational solar wind conditions of 25 ICMEs and their associated geomagnetic storm (1997-2006)

Are 3-D coronal mass ejection parameters from single-view observations consistent with multiview ones?

Harim Lee, Y.-J. Moon, Hyeonock Na, Soojeong Jang, Jae-Ok Lee

JGR December 2015 Vol: 120, Pages: 10,237–10,249

<http://onlinelibrary.wiley.com/doi/10.1002/2015JA021118/pdf>

To prepare for when only single-view observations are available, we have made a test whether the 3-D parameters (radial velocity, angular width, and source location) of halo coronal mass ejections (HCMEs) from single-view observations are consistent with those from multiview observations. For this test, we select 44 HCMEs from December 2010 to June 2011 with the following conditions: partial and full HCMEs by SOHO and limb CMEs by twin STEREO spacecraft when they were approximately in quadrature. In this study, we compare the 3-D parameters of the HCMEs from three different methods: (1) a geometrical triangulation method, the STEREO CAT tool developed by NASA/CCMC, for multiview observations using STEREO/SECCHI and SOHO/LASCO data, (2) the graduated cylindrical shell (GCS) flux rope model for multiview observations using STEREO/SECCHI data, and (3) an ice cream cone model for single-view observations using SOHO/LASCO data. We find that the radial velocities and the source locations of the HCMEs from three methods are well consistent with one another with high correlation coefficients (≥ 0.9). However, the angular widths by the ice cream cone model are noticeably underestimated for broad CMEs larger than 100° and several partial HCMEs. A comparison between the 3-D CME parameters directly measured from twin STEREO spacecraft and the above 3-D parameters shows that the parameters from multiview are more consistent with the STEREO measurements than those from single view.

Ensemble Modeling of Successive Halo CMEs: A Case Study

C. O. Lee, C. N. Arge, D. Odstrcil, G. Millward, V. Pizzo, N. Lugaz

Solar Phys., **2015**

The Wang–Sheeley–Arge (WSA)–Enlil cone modeling system is used for making routine arrival-time forecasts of Earth-directed halo coronal mass ejections (CMEs), since they typically produce the most geoeffective events. A major objective of this work is to better understand the sensitivity of the WSA–Enlil modeling results to input model parameters and how these parameters contribute to the overall model uncertainty and performance. In this study, ensemble-modeling results for a succession of three halo CME events that occurred on **2 – 4 August 2011** are presented. We investigate the sensitivity of the modeled CME arrival times to small variations in the input-cone properties by creating ensemble sets of numerical simulations for each CME event, based on multiple sets of cone parameters. We find that the accuracy of the modeled CME arrival times not only depends on the small variations to the initial input geometry, but also on the reliable specification of the background solar wind, which is driven by the input maps of the photospheric magnetic field. The accuracy in the arrival-time predictions also depends on whether the cone parameters

for all three CMEs are specified in a single WSA–Enlil simulation. The inclusion or exclusion of one or two of the preceding CMEs affects the solar-wind conditions through which the succeeding CME propagates. Although the accuracy of the modeled arrival times is sensitive to the input maps that are used to drive the background solar wind, the spread in the modeling ensemble remains mostly unchanged when different input maps are used.

Dependence of Geomagnetic Storms on Their Associated Halo CME Parameters

Jae-Ok [Lee](#)¹, Y.-J. Moon^{1, 2}, Kyoung-Sun Lee³ and R.-S. Kim

Solar Phys, Volume 289, Issue 6, pp 2233-2245, **2014, File**

We compare the geoeffective parameters of halo coronal mass ejections (CMEs). We consider **50 front-side full-halo CMEs (FFH CMEs)**, which are from the list of Michalek, Gopalswamy, and Yashiro (Solar Phys. 246, 399, 2007), whose asymmetric-cone model parameters and earthward-direction parameter were available. For each CME we use its projected velocity [V p], radial velocity [V r], angle between cone axis and sky plane [γ] from the cone model, earthward-direction parameter [D], source longitude [L], and magnetic-field orientation [M] of its CME source region. We make a simple linear-regression analysis to find out the relationship between CME parameters and Dst index. The main results are as follows: i) The combined parameters [(V r D)^{1/2} and V r γ] have higher correlation coefficients [cc] with the Dst index than the other parameters [V p and V r]: cc=0.76 for (V r D)^{1/2}, cc=0.70 for V r γ , cc=0.55 for V r, and cc=0.17 for V p. ii) Correlation coefficients between V r γ and Dst index depend on L and M; cc=0.59 for 21 eastern events [E], cc=0.80 for 29 western events [W], cc=0.49 for 17 northward magnetic-field events [N], and cc=0.69 for 33 southward magnetic-field events [S]. iii) Super geomagnetic storms (Dst \leq -200 nT) only appear in the western and southward magnetic-field events. The mean absolute Dst values of geomagnetic storms (Dst \leq -50 nT) increase with an order of E+N, E+S, W+N, and W+S events; the mean absolute Dst value (169 nT) of W+S events is significantly larger than that (75 nT) of E+N events. Our results demonstrate that not only do the cone-model parameters together with the earthward-direction parameter improve the relationship between CME parameters and Dst index, but also the longitude and the magnetic-field orientation of a FFH CME source region play a significant role in predicting geomagnetic storms.

Ensemble Modeling of CME Propagation

C. O. [Lee](#)¹, C. N. Arge¹, D. Odstrčil², G. Millward³, V. Pizzo³, J. M. Quinn¹ and C. J. Henney

Solar Phys. July **2013**, Volume 285, Issue 1-2, pp 349-368; **File, 2012**,

The current progression toward solar maximum provides a unique opportunity to use multi-perspective spacecraft observations together with numerical models to better understand the evolution and propagation of coronal mass ejections (CMEs). Of interest to both the scientific and forecasting communities are the Earth-directed “halo” CMEs, since they typically produce the most geoeffective events. However, determining the actual initial geometries of halo CMEs is a challenge due to the plane-of-sky projection effects. Thus the recent **15 February 2011** halo CME event has been selected for this study. During this event the Solar TERrestrial Relations Observatory (STEREO) A and B spacecraft were fortuitously located $\sim 90^\circ$ away from the Sun–Earth line such that the CME was viewed as a limb event from these two spacecraft, thereby providing a more reliable constraint on the initial CME geometry. These multi-perspective observations were utilized to provide a simple geometrical description that assumes a cone shape for a CME to calculate its angular width and central position. The event was simulated using the coupled Wang–Sheeley–Arge (WSA)-Enlil 3D numerical solar corona-solar wind model. Daily updated global photospheric magnetic field maps were used to drive the background solar wind. To improve our modeling techniques, the sensitivity of the modeled CME arrival times to the initial input CME geometry was assessed by creating an ensemble of numerical simulations based on multiple sets of cone parameters for this event. It was found that the accuracy of the modeled arrival times not only depends on the initial input CME geometry, but also on the accuracy of the modeled solar wind background, which is driven by the input maps of the photospheric field. To improve the modeling of the background solar wind, the recently developed data-assimilated magnetic field synoptic maps produced by the Air Force Data Assimilative Photospheric flux Transport (ADAPT) model were used. The ADAPT maps provide a more instantaneous snapshot of the global photospheric field distribution than that provided by traditional daily updated synoptic maps. Using ADAPT to drive the background solar wind, an ensemble set of eight different CME arrival times was generated, where the spread in the predictions was ~ 13 hours and was nearly centered on the observed CME shock arrival time.

Simultaneity of Forbush decrease events observed at middle-latitude neutron monitors

Seongsuk [Lee](#), Suyeon Oh, Yu Yi

JGR, Volume 118, Issue 2, pages 608–614, February 2013

<http://onlinelibrary.wiley.com/doi/10.1002/jgra.50159/abstract>

Ground neutron monitors (NMs) sometimes observe a sudden reduction in galactic cosmic ray intensity—the so-called Forbush decrease (FD) event. Such events are mainly associated with interplanetary coronal mass ejections passing around the Earth and corotating interaction regions in the heliosphere. Some FD events are observed globally, either simultaneously or nonsimultaneously, at different NM stations in the case that the simultaneity is determined by the overlapping of the FD main phase, with the period of the cosmic ray intensity decreasing before returning to a steady state. Previous studies have identified two types of FD events with statistically significant differences in the distributions of the main phase onset time. It has been hypothesized that simultaneous FD events occur when a strong magnetic cloud passes by the Earth through the central part of the magnetic barrier, whereas nonsimultaneous events occur if a weaker magnetic cloud passes on the duskside of the magnetosphere. However, the previous statistical analyses were performed using only data from high geomagnetic latitude NM stations in the Northern Hemisphere. To address this shortcoming and to further test the above hypothesis, we repeated the analysis using data from NM stations located at middle latitudes (Jungfrauoch, Irkutsk, and Climax), employing cutoff rigidities 3–6 GV for the last solar maximum period (1998–2002), spanning the same time period as Oh et al. (2008) that employed high-latitude NM stations. The results of the present statistical analysis support the above hypothesis with high confidence levels. **Table (1998-2002).**

Organization of Energetic Particles by the SolarWind Structure During the Declining to Minimum Phase of Solar Cycle 23

C.O. Lee · J.G. Luhmann · I. de Pater · G.M. Mason · D. Haggerty · I.G. Richardson · H.V. Cane · L.K. Jian · C.T. Russell · M.I. Desai

Solar Phys (2010) 263: 239–261, DOI 10.1007/s11207-010-9556-x

We investigate the organization of the low energy energetic particles ($\leq 1\text{MeV}$) by solar wind structures, in particular corotating interaction regions (CIRs) and shocks driven by interplanetary coronal mass ejections, during the declining-to-minimum phase of Solar Cycle 23 from Carrington rotation 1999 to 2088 (January 2003 to October 2009). Because CIR-associated particles are very prominent during the solar minimum, the unusually long solar minimum period of this current cycle provides an opportunity to examine the overall organization of CIR energetic particles for a much longer period than during any other minimum since the dawn of the Space Age. We find that the particle enhancements associated with CIRs this minimum period recurred for many solar rotations, up to 30 at times, due to several high-speed solar wind streams that persisted. However, very few significant CIR-related energetic particle enhancements were observed towards the end of our study period, reflecting the overall weak high-speed streams that occurred at this time. We also contrast the solar minimum observations with the declining phase when a number of solar energetic particle events occurred, producing a mixed particle population. In addition, we compare the observations from this minimum period with those from the previous solar cycle. One of the main differences we find is the shorter recurrence rate of the high-speed solar wind streams (~ 10 solar rotations) and the related CIR energetic particle enhancements for the Solar Cycle 22 minimum period. Overall our study provides insight into the coexistence of different populations of energetic particles, as well as an overview of the large-scale organization of the energetic particle populations approaching the beginning of Solar Cycle 24.

Detailed Analysis of Solar Data Related to Historical Extreme Geomagnetic Storms: 1868 – 2010

Laure Lefèvre, Susanne Vennerstrøm, Mateja Dumbović, Bojan Vršnak, Davor Sudar, Rainer Arlt, Frédéric Clette, Norma Crosby

Solar Phys. Volume 291, Issue 5, pp 1483-1531 2016 File

An analysis of historical Sun–Earth connection events in the context of the most extreme space weather events of the last ~ 150 years is presented. To identify the key factors leading to these extreme events, a sample of the most important geomagnetic storms was selected based mainly on the well-known aa index and on geomagnetic parameters described in the accompanying paper (Vennerstrøm et al., Solar Phys. in this issue, 2016, hereafter Paper I). This part of the analysis

focuses on associating and characterizing the active regions (sunspot groups) that are most likely linked to these major geomagnetic storms.

For this purpose, we used detailed sunspot catalogs as well as solar images and drawings from 1868 to 2010. We have systematically collected the most pertinent sunspot parameters back to 1868, gathering and digitizing solar drawings from different sources such as the Greenwich archives, and extracting the missing sunspot parameters. We present a detailed statistical analysis of the active region parameters (sunspots, flares) relative to the geomagnetic parameters developed in Paper I.

In accordance with previous studies, but focusing on a much larger statistical sample, we find that the level of the geomagnetic storm is highly correlated to the size of the active regions at the time of the flare and correlated with the size of the flare itself. We also show that the origin at the Sun is most often a complex active region that is also most of the time close to the central meridian when the event is identified at the Sun. Because we are dealing with extremely severe storms, and not the usual severe storm sample, there is also a strong correlation between the size of the linked active region, the estimated transit speed, and the level of the geomagnetic event. In addition, we confirm that the geomagnetic events studied here and the associated events at the Sun present a low probability of occurring at low sunspot number value and are associated mainly with the maximum and descending part of the solar cycle.

Model Fitting of Wind Magnetic Clouds for the Period 2004 – 2006

R. P. [Lepping](#), [C.-C. Wu](#), [D. B. Berdichevsky](#) & [A. Szabo](#)

[Solar Physics](#) volume 295, Article number: 83 (2020)

<https://link.springer.com/content/pdf/10.1007/s11207-020-01630-2.pdf>

We give the results of parameter fitting of the magnetic clouds (MCs) observed by the Wind spacecraft for the three year period – 2004 to the end of 2006 (the “Present period”) using the force-free MC model of Lepping, Jones, and Burlaga (J. Geophys. Res.95, 11957, [1990](#)). There were 19 MCs identified in the Present period, which was mainly in the declining phase of the solar cycle. The long-term occurrence rate of MCs is 10.3/year (1995-2015), whereas the occurrence rate for the Present period is only 6.3/year, similar to that for the period 2007-2009. Hence, the MC occurrence rate has had an appreciable decrease for the six years 2004-2009. The MC modeling gives such basic MC quantities as size, axial orientation, field handedness, axial magnetic field strength, center time, and closest approach vector. A statistically based modification of the modeled field intensity is tested. Also calculated are derived quantities, such as axial magnetic flux, axial current density, and axial current. Quality (Q0Q0) estimates are assigned representing excellent (1), good/fair (2), and poor (3). We provide error estimates on the specific fit parameters for the individual MCs for the Q0=1,2,Q0=1,2 cases, and give a distribution of MC types (i.e. N ⇒ S, S ⇒ N, All N, All S, etc., ten categories in all). There is an inordinately large percentage of the N ⇒ S type in the Present period (32%). The Present period basic model fitting results are compared to the results of the full Wind mission and other 3-year periods. First, we notice that during the Present period the MCs are, on average, significantly faster (by 21%), distinctly stronger in axial magnetic field (by 37%), and smaller in diameter (by 5.5%), than those in the Long-term period. The quality of the MCs in the Present period is significantly better than that of the Long-term period, where the ratio $N(Q0=1,2)/N(Q0=1,2,3)N(Q0=1,2)/N(Q0=1,2,3)$ for each is 0.79 and 0.58, respectively. The Present period is quite different from the Long-term period (1995-2015), it is from the other three 3-year periods between 2006 and the end of 2015. In the Present period upstream shocks occur for the first 12 MCs of the 19 cases (63%); for comparison the Long-term rate is 56%.

Magnetic Field Magnitude Modification for a Force-free Magnetic Cloud Model

R. P. [Lepping](#), [C.-C. Wu](#), [D. B. Berdichevsky](#), [C. Kay](#)

[Solar Phys.](#) 293:162 2018

<https://arxiv.org/ftp/arxiv/papers/1811/1811.07978.pdf>

A scheme was developed by Lepping, Berdichevsky, and Wu (Solar Phys., doi.10. 1007/ s11207-016-1040-9, 2017) [called the LBW article here] to approximate the average magnetic field magnitude (B-) profile of a "typical" magnetic cloud (MC) at/near 1AU. It was based on actual Wind MC data, taken over 21 years, that was used to modify a time shifted Bessel function (force-free) magnetic field, where shifted refers to a field that was adjusted for typical MC self-similar expansion. This was developed in the context of the Lepping, Jones, and Burlaga (J. Geophys. Res. vol. 95, p.11957, 1990) [called LJB here] MC parameter fitting model and should provide more realistic future representations of the MC's B-profile in most cases. In the LBW article, through testing, it was shown that on average it can be expected that in about 80% of the MC cases (but it varies according to the spacecrafts' actual closest approach distances) the modified model's B-profile of the MC should be significantly improved by use of this scheme. We describe how this scheme can be

employed practically in modifying the LJB MC fitting model, and we test a new and slightly better (and less unwieldy) version of the scheme, the non-shifted (of Bessel functions) version, which is the one actually used in the LJB model modification. The new scheme is based on modification formulae that are slightly more accurate than the old scheme, and it is expected to improve the B-profile in approximately 83% of the cases on average. The schemes are applicable for use with data originating only at/near 1 AU, since the magnetic field and plasma data used in the development of the associated formulae were from only the Wind spacecraft, which was and is at 1 AU.

Wind Magnetic Clouds for the Period 2013–2015: Model Fitting, Types, Associated Shock Waves, and Comparisons to Other Periods

R. P. Lepping, C.-C. Wu, D. B. Berdichevsky, A. Szabo

Solar Physics April 2018, 293:65

<https://link.springer.com/content/pdf/10.1007%2Fs11207-018-1273-x.pdf>

We give the results of parameter fitting of the magnetic clouds (MCs) observed by the Wind spacecraft for the three-year period 2013 to the end of 2015 (called the “Present” period) using the MC model of Lepping, Jones, and Burlaga (J. Geophys. Res.95, 11957, 1990). The Present period is almost coincident with the solar maximum of the sunspot number, which has a broad peak starting in about 2012 and extending to almost 2015. There were 49 MCs identified in the Present period. The modeling gives MC quantities such as size, axial attitude, field handedness, axial magnetic-field strength, center time, and closest-approach vector. Derived quantities are also estimated, such as axial magnetic flux, axial current density, and total axial current. Quality estimates are assigned representing excellent, fair/good, and poor. We provide error estimates on the specific fit parameters for the individual MCs, where the poor cases are excluded. Model-fitting results that are based on the Present period are compared to the results of the full Wind mission from 1995 to the end of 2015 (Long-term period), and compared to the results of two other recent studies that encompassed the periods 2007–2009 and 2010–2012, inclusive. We see that during the Present period, the MCs are, on average, slightly slower, slightly weaker in axial magnetic field (by 8.7%), and larger in diameter (by 6.5%) than those in the Long-term period. However, in most respects, the MCs in the Present period are significantly closer in characteristics to those of the Long-term period than to those of the two recent three-year periods. However, the rate of occurrence of MCs for the Long-term period is 10.3 year⁻¹–110.3 year⁻¹, whereas this rate for the Present period is 16.3 year⁻¹–116.3 year⁻¹, similar to that of the period 2010–2012. Hence, the MC occurrence rate has increased appreciably in the last six years. MC Type (N–S, S–N, All N, All S, etc.) is assigned to each MC; there is an inordinately large percentage of All S, by about a factor of two compared to that of the Long-term period, indicating many strongly tipped MCs. In 2005, there was a distinct change in variability and average value (viewed at 1/21/2 year averages) of the duration, MC speed, axial magnetic field strength, axial magnetic flux, and total current to lower values. In the Present period, upstream shocks occur for 43% of the 49 cases; for comparison, the Long-term rate is 56%.

Table 49 MCs

Average Magnetic Field Magnitude Profiles of Wind Magnetic Clouds as a Function of Closest Approach to the Clouds’ Axes and Comparison to Model

R. P. Lepping, D. B. Berdichevsky, C.-C. Wu

Solar Physics February 2017, 292:27

We examine the average magnetic field magnitude ($|\mathbf{B}| \equiv B$) within magnetic clouds (MCs) observed by the Wind spacecraft from 1995 to July 2015 to understand the difference between this B and the ideal B -profiles expected from using the static, constant- α , force-free, cylindrically symmetric model for MCs of Lepping, Jones, and Burlaga (J. Geophys. Res.95, 11957, 1990, denoted here as the LJB model). We classify all MCs according to an assigned quality, Q_0 ($= 1, 2, 3$), for excellent, good, and poor). There are a total of 209 MCs and 124 when only $Q_0 = 1$, 2 cases are considered. The average normalized field with respect to the closest approach (CA) is stressed, where we separate cases into four CA sets centered at 12.5 %, 37.5 %, 62.5 %, and 87.5 % of the average radius; the averaging is done on a percentage-duration basis to treat all cases the same. Normalized B means that before averaging, the B for each MC at each point is divided by the LJB model-estimated B for the MC axis, B_0 . The actual averages for the 209 and 124 MC sets are compared to the LJB model, after an adjustment for MC expansion (e.g. Lepping et al. in Ann. Geophys.26, 1919, 2008). This provides four separate difference-relationships, each fitted with a quadratic (Quad) curve of very small σ . Interpreting these Quad formulae should provide a comprehensive view of the variation in normalized B throughout the average MC, where we expect external front and rear compression to be part of its explanation. These formulae are also being considered for modifying the LJB model. This modification will be used in a scheme for forecasting the timing and

magnitude of magnetic storms caused by MCs. Extensive testing of the Quad formulae shows that the formulae are quite useful in correcting individual MC B_z -profiles, especially for the first $\approx 1/3$ of these MCs. However, the use of this type of B_z correction constitutes a (slight) violation of the force-free assumption used in the original LJB MC model.

Table 3 Examples of magnetic clouds used for checking the B/B_0 -correction with expansion* considered.

Wind Magnetic Clouds for 2010 – 2012: Model Parameter Fittings, Associated Shock Waves, and Comparisons to Earlier Periods

R. P. [Lepping](#), C.-C. Wu, D. B. Berdichevsky, A. Szabo

Solar Phys. Volume 290, Issue 8, pp 2265-2290 **2015**

We fitted the parameters of magnetic clouds (MCs) as identified in the Wind spacecraft data from early 2010 to the end of 2012 using the model of Lepping, Jones, and Burlaga (J. Geophys. Res. 95, 1195, [1990](#)). The interval contains 48 MCs and 39 magnetic cloud-like (MCL) events. This work is a continuation of MC model fittings of the earlier Wind sets, including those in a recent publication, which covers 2007 to 2009. This period (2010 – 2012) mainly covers the maximum portion of Solar Cycle 24. Between the previous and current interval, we document 5.7 years of MCs observations. For this interval, the occurrence frequency of MCs markedly increased in the last third of the time. In addition, over approximately the last six years, the MC type (i.e. the profile of the magnetic-field direction within an MC, such as North-to-South, South-to-North, all South) dramatically evolved to mainly North-to-South types when compared to earlier years. Furthermore, this evolution of MC type is consistent with global solar magnetic-field changes predicted by Bothmer and Rust (Coronal Mass Ejections, 139, [1997](#)). Model fit parameters for the MCs are listed for 2010 – 2012. For the 5.7 year interval, the observed MCs are found to be slower, weaker in estimated axial magnetic-field intensity, and shorter in duration than those of the earlier 12.3 years, yielding much lower axial magnetic-field fluxes. For about the first half of this 5.7 year period, i.e. up to the end of 2009, there were very few associated MC-driven shock waves (distinctly fewer than the long-term average of about 50 % of MCs). But since 2010, such driven shocks have increased markedly, reflecting similar statistics as the long-term averages. We estimate that 56 % of the total observed MCs have upstream shocks when the full interval of 1995 – 2012 is considered. However, only 28 % of the total number of MCLs have driven shocks over the same period. Some interplanetary shocks during the 2010 – 2012 interval are seen to apparently occur without an obvious MC-driver, probably indicating an encounter with a distant flank of a MC-driven shock. Some of these may be driven by a different kind of structure, however.

Yearly Comparison of Magnetic Cloud Parameters, Sunspot Number, and Interplanetary Quantities for the First 18 Years of the Wind Mission

R. P. [Lepping](#), C.-C. Wu, D. B. Berdichevsky

Solar Phys., February **2015**, Volume 290, [Issue 2](#), pp 553-578

In the scalar part of this study, we determine various statistical relationships between estimated magnetic cloud (MC) model fit-parameters and sunspot number (SSN) for the interval defined by the Wind mission, i.e., early 1995 until the end of 2012, all in terms of yearly averages. The MC-fitting model used is that of Lepping, Jones, and Burlaga (J. Geophys. Res. 95, 11957 – 11965, 1990). We also statistically compare the MC fit-parameters and other derived MC quantities [e.g., axial magnetic flux (Φ_0) and total axial current density (J_{O})] with some associated ambient interplanetary quantities (including the interplanetary magnetic field (B IMF), proton number density (N P), and others). Some of the main findings are that the minimum SSN is nearly simultaneous with the minimum in the number of MCs per year (N MC), which occurs in 2008. There are various fluctuations in N MC and the MC model-fit quality (Q') throughout the mission, but the last four years (2009 – 2012) are markedly different from the others; Q' is low and N MC is large over these four years. N MC is especially large for 2012. The linear correlation coefficient (c.c. ≈ 0.75) between the SSN and each of the three quantities J_{O} , MC diameter ($2R_{\text{O}}$), and B IMF, is moderately high, but none of the MC parameters track the SSN well in the sense defined in this article. However, there is good statistical tracking among the following: MC axial field, B IMF, $2R_{\text{O}}$, average MC speed (V_{MC}), and yearly average solar wind speed (V_{SW}) with relatively high c.c.s among most of these. From the start of the mission until late 2005, J_{O} gradually increases, with a slight violation in 2003, but then a dramatic decrease (by more than a factor of five) occurs to an almost steady and low value of $\approx 3 \mu\text{A km}^{-2}$ until the end of the interval of interest, i.e., lasting for at least seven years. This tends to split the overall 18-year interval into two phases with a separator at the end of 2005. There is good tracking between $2R_{\text{O}}$ and the total axial current density, as expected. The MC duration is also correlated well with these two quantities. Φ_0 shows marked variations throughout the mission, but has no obvious trend. N P, B IMF, V_{MC} , Q' , and V_{SW} are all quite steady over the full 18 years and have markedly low relative variation. Concerning vector quantities, we examine the distribution of MC type for the 18 years, where type refers to the field directional change through a given MC starting at first encounter (i.e., North-to-South, or South-to-North, All South, All North, etc.). Combining all 18 years of MC types

shows that the occurrence rate varies strongly across the various MC types, with N-to-S being most prevalent, with a 27 % occurrence rate (of all MCs), and S-to-N being second, with a 23 % occurrence. Then All N and All S come next at 16 % and 10 % occurrence rate, respectively. All others are at 7 % or lower. For the variation of MC types with time, the southern types (i.e., those that start with a southern magnetic field, a negative B Z in geocentric-solar-ecliptic coordinates) decrease, as the northern types (i.e., those that start with a northern field) increase, apparently consistent with the specific timing of the polarity change of the solar magnetic field, as predicted by Bothmer and Rust (in Crooker, N., Joselyn, J., Feynman J. (eds), Geophys. Monogr., 139 – 146, 1997).

Selection effects in identifying magnetic clouds and the importance of the closest approach parameter,

Lepping, R. P. and Wu, C.-C.:

Ann. Geophys., 28, 1539-1552, doi:10.5194/angeo-28-1539-2010, **2010**.

This study is motivated by the unusually low number of magnetic clouds (MCs) that are strictly identified within interplanetary coronal mass ejections (ICMEs), as observed at 1 AU; this is usually estimated to be around 30% or lower. But a looser definition of MCs may significantly increase this percentage. Another motivation is the unexpected shape of the occurrence distribution of the observers' "closest approach distances" (measured from a MC's axis, and called CA) which drops off somewhat rapidly as |CA| (in % of MC radius) approaches 100%, based on earlier studies. We suggest, for various geometrical and physical reasons, that the |CA|-distribution should be somewhere between a uniform one and the one actually observed, and therefore the 30% estimate should be higher. So we ask, When there is a failure to identify a MC within an ICME, is it occasionally due to a large |CA| passage, making MC identification more difficult, i.e., is it due to an event selection effect? In attempting to answer this question we examine WIND data to obtain an accurate distribution of the number of MCs vs. |CA| distance, whether the event is ICME-related or not, where initially a large number of cases (N=98) are considered. This gives a frequency distribution that is far from uniform, confirming earlier studies. This along with the fact that there are many ICME identification-parameters that do not depend on |CA| suggest that, indeed an MC event selection effect may explain at least part of the low ratio of (No. MCs)/(No. ICMEs). We also show that there is an acceptable geometrical and physical consistency in the relationships for both average "normalized" magnetic field intensity change and field direction change vs. |CA| within a MC, suggesting that our estimates of |CA|, BO (magnetic field intensity on the axis), and choice of a proper "cloud coordinate" system (all needed in the analysis) are acceptably accurate. Therefore, the MC fitting model (Lepping et al., 1990) is adequate, on average, for our analysis. However, this selection effect is not likely to completely answer our original question, on the unexpected ratio of MCs to ICMEs, so we must look for other factors, such as peculiarities of CME birth conditions. As a by-product of this analysis, we determine that the first order structural effects within a MC due to its interaction with the solar wind, plus the MC's usual expansion at 1 AU (i.e., the non-force free components of the MC's field) are, on average, weakly dependent on radial distance from the MC's axis; that is, in the outer reaches of a typical MC the non-force free effects show up, but even there they are rather weak. Finally, we show that it is not likely that a MC's size distribution statistically controls the occurrence distribution of the estimated |CA|s.

Average Thickness of Magnetosheath Upstream of Magnetic Clouds at 1 AU versus Solar Longitude of Source

R.P. **Lepping** · C.-C.Wu · N. Gopalswamy · D.B. Berdichevsky

Solar Phys (2008) 248: 125–139

<http://www.springerlink.com/content/e01848h71hm75634/fulltext.pdf>

Starting with a large number ($N = 100$) of *Wind* magnetic clouds (MCs) and applying necessary restrictions, we find a proper set of $N = 29$ to investigate the average ecliptic plane projection of the upstream magnetosheath thickness as a function of the longitude of the solar source of the MCs, for those cases of MCs having upstream shock waves.

Table

On the variation of interplanetary magnetic cloud type through solar cycle 23: Wind events,

Lepping, R. P., and C. Wu (2007),

J. Geophys. Res., 112, A10103, <http://dx.doi.org/10.1029/2006JA012140>, 2007

This statistical study examines the change in interplanetary magnetic cloud (MC) type, based on Wind observations of 100 MCs, taken during solar cycle 23 and split into three intervals: the minimum and rising phase of the cycle (over the years 1995–1998), the maximum phase (1999–2001), and the declining phase (2002 to early 2006).

The Wind magnetic cloud and events of October 18–20, 1995: Interplanetary properties and as triggers for geomagnetic activity

<http://onlinelibrary.wiley.com/doi/10.1029/97JA00272/pdf>

Late on **October 18, 1995**, a magnetic cloud arrived at the Wind spacecraft ≈ 175 RE upstream of the Earth. The cloud had an intense interplanetary magnetic field that varied slowly in direction, from being strongly southward to strongly northward during its ≈ 30 hours duration, and a low proton temperature throughout. From a linear force free field model the cloud was shown to have a flux rope magnetic field line geometry, an estimated diameter of about 0.27 AU, and an axis that was aligned with the Y axis(GSE) within about 25° . A corotating stream, in which large amplitude Alfvén waves of about 0.5 hour period were observed, was overtaking the cloud and intensifying the fields in the rear of the cloud. The prolonged southward magnetic field observed in the early part of the cloud produced a geomagnetic storm of $K_p = 7$ and considerable auroral activity late on October 18. About 8 hours in front of the cloud an interplanetary shock occurred. About three-fourths the way into the cloud another apparent interplanetary shock was observed. It had an unusual propagation direction, differing by only 21° from alignment with the cloud axis. It may have been the result of the interaction with the postcloud stream, compressing the cloud, or was possibly due to an independent solar event. It is shown that the front and rear boundaries of the cloud and the upstream driven shock had surface normals in good agreement with the cloud axis in the ecliptic plane. The integrated Poynting flux into the magnetosphere, which correlated well with geomagnetic indices, jumped abruptly to a high value upon entry into the magnetic cloud, slowly decreased to zero near its middle, and again reached substantial but sporadic values in the cloud-stream interface region. This report aims to support a variety of ISTP studies ranging from the solar origins of these events to resulting magnetospheric responses.

Elemental Abundances of Prominence Material inside ICMEs

Susan T. **Lepri**¹ and Yeimy J. Rivera^{1,2}

2021 ApJ 912 51

<https://doi.org/10.3847/1538-4357/abea9f>

A small number of interplanetary coronal mass ejections (ICMEs) have been identified that contain measurable contributions from prominence plasma. In situ measurements from during these events are marked by the presence of unusually low-charge states of C, O, and Fe, representing ionization equilibrium formation temperatures of ~ 104 – 105 K, consistent with prominence material observed at the Sun. We present a thorough analysis of the elemental abundances of a wide variety of heavy ions, measured by Advanced Composition Explorer/SWICS, in prominence material observed in the solar wind. We find that prominence material observed in situ tends to be more enriched in heavy ions than the surrounding ICME plasma and the fast and slow solar wind. We also find that the material is on average moderately enhanced in low first ionization potential elements compared to photospheric abundances, with values that lie between fast and slow solar wind. In rare instances, where in situ prominence material is observed to have clear, persistent, low-charge states over longer periods of time, it exhibits elemental abundances that are photospheric in nature. However, in most prominence events we see indications that the associated material contains a mixture of prominence and adjacent ICME plasma. The anomalous behavior of the elemental and ionic composition in ICMEs with and without prominence material can be used to study physical processes that occur during CME initiation and release.

SPATIALLY DEPENDENT HEATING AND IONIZATION IN AN ICME OBSERVED BY BOTH ACE AND ULYSSES

Susan T. **Lepri**¹, J. Martin Laming², Cara E. Rakowski², and Rudolf von Steiger

2012 ApJ 760 105

The **2005 January 21** interplanetary coronal mass ejection (ICME) observed by multiple spacecraft at L1 was also observed from January 21–February 4 at Ulysses (5.3 AU). Previous studies of this ICME have found evidence suggesting that the flanks of a magnetic cloud like structure associated with this ICME were observed at L1 while a more central cut through the associated magnetic cloud was observed at Ulysses. This event allows us to study spatial variation across the ICME and relate it to the eruption at the Sun. In order to examine the spatial dependence of the heating in this ICME, we present an analysis and comparison of the heavy ion composition observed during the passage of the ICME at L1 and at Ulysses. Using SWICS, we compare the heavy ion composition across the two different observation cuts through the ICME and compare it with predictions for heating during the eruption based on models of the time-dependent ionization balance throughout the event.

DIRECT OBSERVATIONAL EVIDENCE OF FILAMENT MATERIAL WITHIN INTERPLANETARY CORONAL MASS EJECTIONS

S. T. [Lepri](#) and T. H. Zurbuchen

The Astrophysical Journal Letters, 723:L22–L27, 2010

Coronal mass ejections (CMEs) are explosive events that escape the Sun's corona carrying solar material and energy into the heliosphere. The classic picture of a CME observed in the corona presents a "three-part structure," including a bright front at the leading edge indicating dense plasma, a low-density cavity, the possible signature of an embedded magnetic flux rope, and the so-called core, a high-density region observed to be associated with an erupting filament. Although there are experimental analogs to the first two parts of the CME when observed in situ, there are only a handful of in situ observations of cold, filament-type plasma. This has been a source of major uncertainty and qualitative disagreement between remote and in situ observations of these ejecta. We present the first comprehensive and long-term survey of such low charge states observed by the *Advanced Composition Explorer* SolarWind Ion Composition Spectrometer, using a novel data analysis process developed to identify ions with low ionic charge states. Using a very stringent set of observational signatures, we find that more than 4% of detected interplanetary CMEs have significant contributions of ions with low charge states. These time periods of low-charge ions often occur concurrent with some of the hottest ions, previously interpreted to be affected by flare heating during the CME initiation.

Prediction of the Dst Index and Analysis of Its Dependence on Solar Wind Parameters Using Neural Network

Ahmed [Lethy](#), [Mohamed A. El-Eraki](#), [Aalaa Samy](#), [Hanafy A. Deebes](#)

Space Weather [Volume16, Issue9](#) Pages 1277-1290 2018

<http://sci-hub.tw/10.1029/2018SW001863>

In this work, we propose an artificial neural network (ANN) with seven input parameters for the prediction of disturbance storm time (Dst) index 1 to 12 hr ahead. The ANN uses past near-Earth solar wind parameter values to forecast the Dst. The input parameters are the solar wind interplanetary magnetic field, north-south component of interplanetary magnetic field, temperature, density, speed, pressure, and electric field. The ANN was trained on the data period from 1 January 2007 to 31 December 2015, which contains 78,888 hourly data samples. While the period from 1 January 2016 to 31 May 2017 was used to test the prediction capabilities of the ANN. Several ANN structures were tested and the best results were determined using the correlation coefficient (R) during the training and prediction phases. The results indicate an adequate accuracy of $R = 0.876$ for prediction 2 hr in advance and $R = 0.857$ for prediction 12 hr in advance. The power of the proposed ANN was illustrated using the strongest six storms recorded during the prediction period. Generally, the duration and number of the input parameters significantly affect the training and prediction performance of the applied ANN. The results are outstanding in term of accuracy when considering a medium-term prediction of 12 hr in advance and in terms of timing of the Dst minimum occurrence. In addition, the results show a strong dependence on the solar wind electric current.

Monitoring the daily variation of Sun-Earth magnetic fields using galactic cosmic rays

The [LHAASO Collaboration](#)

The Innovation 5(6): 100695, November 4, 2024

<https://arxiv.org/pdf/2410.09064>

The interplanetary magnetic field (IMF) between the Sun and Earth is an extension of the solar magnetic field carried by the solar wind into interplanetary space. Monitoring variations in the IMF upstream of the Earth would provide very important information for the prediction of space weather effects, such as effects of solar storms and the solar wind, on human activity. In this study, the IMF between the Sun and Earth was measured daily for the first time using a cosmic-ray observatory. Cosmic rays mainly consist of charged particles that are deflected as they pass through a magnetic [this http URL](#), the cosmic-ray Sun shadow, caused by high-energy charged cosmic rays blocked by the Sun and deflected by the magnetic field, can be used to explore the transverse IMF between the Sun and Earth. By employing the powerful kilometer-square array at the Large High Altitude Air Shower Observatory, the cosmic-ray Sun shadows were observed daily with high significance for the first time. The displacement of the Sun shadow measured in 2021 correlates well with the transverse IMF component measured in situ by spacecraft near the Earth, with a time lag of $3:31 \pm 0:12$ days. The displacement of the Sun shadow was also simulated using Parker's classic IMF model, yielding a time lag of $2:06 \pm 0:04$ days. This deviation may provide valuable insights into the magnetic field structure, which can improve space weather research.

CME Arrival Time Prediction Based on Coronagraph Observations and Machine-learning Techniques

Yucong Li^{1,2}, Yi Yang^{1,2}, Fang Shen^{1,2}, Bofeng Tang¹, and Rongpei Lin^{1,2}
2024 ApJ 976 141

<https://iopscience.iop.org/article/10.3847/1538-4357/ad82e5/pdf>

The timely and precise prediction of the arrival time of coronal mass ejections (CMEs) is crucial in mitigating their potential adverse effects. In this study, we present a novel prediction method utilizing a deep-learning framework coupled with physical characteristics of CMEs and background solar wind. Time series images from synchronized solar white-light and EUV observations of 156 geoeffective CME events during 2000–2020 are collected for this study, according to the Richardson and Cane interplanetary CME directory and the SOHO/LASCO CME catalog of NASA/CDAW. The CME parameters are obtained from the CDAW website and the solar wind parameters are from OMNI2 website. The observational images are first fed into a convolutional neural network (CNN) to train a regression model as Model A. The results generated by the original CNN are then integrated with 11 selected physical parameters in additional neural network layers of Model B to improve the predictions. Under optimal configurations, Model A achieves a minimum mean absolute error (MAE) of 7.87 hr, whereas Model B yields a minimum MAE of 5.12 hr. During model training, we employed tenfold cross validation to reduce the occasionality of biased data. The average MAE of Model B on 10 folds is 33% lower than that of model A. The results demonstrate that combining the imaging observations with the physical properties of CMEs and background solar wind to train a machine-learning model can benefit the forecasting of CME arrival times.

Predicting the Arrival Time of an Interplanetary Shock Based on DSRT Spectrum Observations for the Corresponding Type II Radio Burst and a Blast Wave Theory

Ran Li^{1,2}, Xinhua Zhao^{1,3}, Jingye Yan^{1,3}, Lin Wu^{1,3}, Yang Yang^{1,3}, +++
2024 ApJ 962 178

<https://iopscience.iop.org/article/10.3847/1538-4357/ad150f/pdf>

Since fast head-on coronal mass ejections and their associated shocks represent potential hazards to the space environment of the Earth and even other planets, forecasting the arrival time of the corresponding interplanetary shock is a priority in space weather research and prediction. Based on the radio spectrum observations of the 16-element array of the Daocheng Solar Radio Telescope (DSRT), the flagship instrument of the Meridian Project of China, during its construction, this study determines the initial shock speed of a type II solar radio burst on 2022 April 17 from its drifting speed in the spectrum. Assuming that the shock travels at a steady speed during the piston-driven phase (determined from the X-ray flux of the associated flare) and then propagates through interplanetary space as a blast wave, we estimate the propagation and arrival time of the corresponding shock at the orbit of the Solar Terrestrial Relations Observatory-A (STEREO-A). The prediction shows that the shock will reach STEREO-A at 14:31:57 UT on 2022 April 19. The STEREO-A satellite detected an interplanetary shock at 13:52:12 UT on the same day. The discrepancy between the predicted and observed arrival time of the shock is only 0.66 hr. The purpose of this paper is to establish a general method for predicting the shock's propagation and arrival time from this example, which will be utilized to predict more events in the future based on the observations of ground-based solar radio spectrometers or telescopes like DSRT. **2022-04-17-19**

Comparison of the Composition of ICMEs from Active Regions and Quiet-Sun Regions

Jinrong Li, Hongqiang Song, Qi Lv, Hui Fu, Leping Li, Ruisheng Zheng, Yao Chen

ApJ 945 163 2023

<https://arxiv.org/pdf/2302.03804.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/acba90/pdf>

The composition, including the ionic charge states and elemental abundances of heavy elements, within interplanetary coronal mass ejections (ICMEs) has tight correlations with their source regions and eruption processes. This can help analyze the eruption mechanisms and plasma origins of CMEs, and deepen our understanding of energetic solar activities. The active regions and quiet-Sun regions have different physical properties, thus from a statistical point of view, ICMEs originating from the two types of regions should exhibit different compositional characteristics. To demonstrate the differences comprehensively, we conduct survey studies on the ionic charge states of five elements (Mg, Fe, Si, C, and O) and the relative abundances of six elements (Mg/O, Fe/O, Si/O, C/O, Ne/O, and He/O) within ICMEs from 1998 February to 2011 August through the data of advanced composition explorer. The results show that ICMEs from active regions have higher ionic charge states and relative abundances than those from quiet-Sun regions. For the active-region ICMEs, we further analyze the relations between their composition and flare class, and find a positive relationship between them, i.e., the higher classes of the associated flares, the larger means of ionic charge states and

relative abundances (except the C/O) within ICMEs. As more (less) fractions of ICMEs originate from active regions around solar maximum (minimum), and active-region ICMEs usually are associated with higher-class flares, our studies might answer why ICME composition measured near 1 au exhibits the solar cycle dependence.

Table 1. The information of 96 ICMEs (CMEs) with identified source regions 1998-2011

Galactic Cosmic-Ray Propagation in the Inner Heliosphere: Improved Force-Field Model

Jung-Tsung Li, [John F. Beacom](#), [Annika H. G. Peter](#)

ApJ **937** 27 **2022**

<https://arxiv.org/pdf/2206.14815.pdf>

<https://iopscience.iop.org/article/10.3847/1538-4357/ac8cf3/pdf>

A key goal of heliophysics is to understand how cosmic rays propagate in the solar system's complex, dynamic environment. One observable is solar modulation, i.e., how the flux and spectrum of cosmic rays changes as they propagate inward. We construct an improved force-field model, taking advantage of new measurements of magnetic power spectral density by Parker Solar Probe to predict solar modulation within the Earth's orbit. We find that modulation of cosmic rays between the Earth and Sun is modest, at least at solar minimum and in the ecliptic plane. Our results agree much better with the limited data on cosmic-ray radial gradients within Earth's orbit than past treatments of the force-field model. Our predictions can be tested with forthcoming direct cosmic-ray measurements in the inner heliosphere by Parker Solar Probe and Solar Orbiter. They are also important for interpreting the gamma-ray emission from the Sun due to scattering of cosmic rays with solar matter and photons.

Radial velocity map of solar wind transients in the field of view of STEREO/HI1 on 3 and 4 April 2010

Xiaolei Li, [Yuming Wang](#), [Jingnan Guo](#), [Rui Liu](#)¹, [Bin Zhuang](#)

A&A **649**, A58 **2021**

<https://arxiv.org/pdf/2103.04740.pdf>

<https://www.aanda.org/articles/aa/pdf/2021/05/aa39766-20.pdf>

<https://doi.org/10.1051/0004-6361/202039766>

The solar wind transients propagating out in the inner heliosphere can be observed in white-light images from Heliospheric Imager-1 (HI1), an instrument of the Sun Earth Connection Coronal and Heliospheric Investigation (SECCHI) on board the Solar Terrestrial Relations Observatory (STEREO), from two perspectives. The spatial velocity distribution inside solar wind transients is key to understanding their dynamic evolution processes. We generated a velocity map of transients in 3D space based on 2D white-light images and used it to estimate the expansion rate as well as some kinematic properties of solar wind transients. Based on the recently developed correlation-aided reconstruction (CORAR) method in our previous work, which can recognize and locate 3D solar wind transients from STEREO/HI1 image data, we further developed a new technique for deriving the spatial distribution of the radial velocities of the most pronounced features inside solar wind transients. The technique was applied to events including a coronal mass ejection (CME) and three small-scale transients, so-called blobs, observed by HI1 on 3-4 April 2010 to reconstruct their radial velocity maps. The results match the forward-modeling results, simulations, and in situ observations at 1 AU fairly well. According to the obtained spatial distributions of height and radial velocity of the CME, we analyzed the self-similarity of the radial expansion of the CME ejecta. The dimensionless radial expansion rate of the northern and middle parts of the CME ejecta varies in the range of 0.7 - 1.0 at heliocentric distance between 25 Rs and 55Rs and the rate of the southern part in the range of 0.3 - 0.5, suggesting that the CME structure was distorted and shaped by the ambient solar wind. The technique we developed is expected to be applied to more events.

Simulation of the Interplanetary B z Using a Data-driven Heliospheric Solar Wind Model

Huichao Li^{1,2}, Xueshang Feng^{1,2}, Pingbing Zuo¹, and Fengsi Wei^{1,2}

2020 ApJ **900** 76

<https://doi.org/10.3847/1538-4357/aba61f>

Aimed to be ready for the transition from research to operation, we have developed a solar wind model by coupling a data-driven empirical coronal model with a magnetohydrodynamics heliospheric model. We performed a data-driven simulation of the solar wind for a two-year period during the declining and minimum phases of solar cycle 23. Comparisons with OMNI and Ulysses spacecraft data show that the model can reproduce the large-scale variations of the solar wind plasma parameters. The evolution of geocentric solar magnetospheric (GSM) B x and B z components are also reasonably duplicated by the model in terms of polarity and strength. Apparent signatures of the Russell–McPherron (R-M) effect are found from both observed data and simulated results, indicating that during the investigated

interval the R-M effect is the dominant mechanism that controls the large-scale evolution of the north–south component of the interplanetary magnetic field in the GSM frame. The results demonstrate that the established model can provide valuable space weather information about the solar wind.

Reconstructing solar wind inhomogeneous structures from stereoscopic observations in white-light: Solar wind transients in 3D

Xiaolei Li, [Yuming Wang](#), [Rui Liu](#), [Chenglong Shen](#), [Quanhao Zhang](#), [Shaoyu Lyu](#), [Bin Zhuang](#), [Fang Shen](#), [Jiajia Liu](#), [Yutian Chi](#)

JGR **Volume125, Issue7** e2019JA027513 2020

<https://arxiv.org/ftp/arxiv/papers/2005/2005.01238.pdf>

<https://agupubs.onlinelibrary.wiley.com/doi/pdf/10.1029/2019JA027513>

White-light images from Heliospheric Imager-1 (HI1) onboard the Solar Terrestrial Relations Observatory (STEREO) provide 2-dimensional (2D) global views of solar wind transients traveling in the inner heliosphere from two perspectives. How to retrieve the hidden three-dimensional (3D) features of the transients from these 2D images is intriguing but challenging. In our previous work (Li et al., 2018), a 'correlation-aided' method is developed to recognize the solar wind transients propagating along the Sun-Earth line based on simultaneous HI1 images from two STEREO spacecraft. Here the method is extended from the Sun-Earth line to the whole 3D space to reconstruct the solar wind transients in the common field of view of STEREO HI1 cameras. We demonstrate the capability of the method by showing the 3D shapes and propagation directions of a coronal mass ejection (CME) and three small-scale blobs during **3-4 April 2010**. Comparing with some forward modeling methods, we found our method reliable in terms of the position, angular width and propagation direction. Based on our 3D reconstruction result, an angular distorted, nearly North-South oriented CME on 3 April 2010 is revealed, manifesting the complexity of a CME's 3D structure.

Spatial Distribution of Electromagnetic Waves near the Proton Cyclotron Frequency in ICME Sheath Regions Associated with Quasi-perpendicular Shocks: Wind Observations

Q. H. Li^{1,2}, L. Yang^{1,3}, L. Xiang⁴, and D. J. Wu¹

2020 ApJ 892 98

<https://doi.org/10.3847/1538-4357/ab7cde>

Electromagnetic waves (EMWs) near the proton cyclotron frequency f_{cp} are transverse left-handed (LH) or right-handed (RH) polarized waves, and are ubiquitous in the solar wind. However, the characteristics of these waves in the sheath regions of interplanetary coronal mass ejections (ICMEs) are poorly understood. Through a comprehensive survey of Wind magnetic field and plasma data using dynamic spectra and repeated filtering analyses, 700 EMW events (7.1% of the analysis time) are identified in the 62 ICME sheath regions associated with quasi-perpendicular shocks involved with a low shock Mach number M_f and low upstream β_1 . In the ICME sheath regions, outward (inward)-propagating LH (RH) EMWs have relatively higher counts and longer duration than inward (outward)-propagating LH (RH) EMWs in the plasma frame, consistent with previous STEREO observations. The spatial distributions of the magnetic field, plasma, and frequency parameters of EMWs are also presented in both spacecraft and plasma frames, especially the proton (alpha) temperature anisotropy, α abundance N_α/N_p , and normalized differential alpha-proton speed V_d/V_A . After removing the Doppler shift, 81.1% (59%) of all outward (inward)-propagating LH EMWs have a frequency below (above) $0.5f_{cp}$, while 68.3% (64%) of all outward (inward)-propagating RH EMWs have a frequency smaller (greater) than $0.5f_{cp}$. Further investigations of local plasma parameters reveal that different excitation mechanisms for EMWs are in different subregions of the ICME sheath regions. These results are helpful in understanding the important role of EMWs in the solar wind–ICME coupling process with different sheath regions.

Stronger Southward Magnetic Field and Geoeffectiveness of ICMEs Containing Prominence Materials Measured from 1998 to 2011

Dongni Li and Shuo Yao¹

2020 ApJ 891 79

<https://iopscience.iop.org/article/10.3847/1538-4357/ab7197/pdf>

Interplanetary coronal mass ejections (ICMEs) could be classified into magnetic clouds (MCs) and non-MCs according to their magnetic field signatures, and into prominence-inside ICMEs (PIs) and non-PIs based on whether they contain colder and higher helium abundance plasmas than the solar wind. It is known that the MCs often lead to magnetic storms. However, whether or not the PIs have significant geoeffectiveness is unclear. This statistical work studies the southward interplanetary magnetic field (IMF) magnitude of the PIs, and the related magnetic storms' level. The data include the IMF and plasma moments measured by ACE and WIND, and the Dst index from 1998 to 2011. The

hypothesis test based on the proportions of two groups is used to analyze 95 ICMEs related to single storms (SSs). The results show that the magnetic storms caused by the PIs mostly distribute at a strong level, while that caused by the non-PIs and by all the 95 ICMEs mostly distribute at a moderate level. The PIs have a significantly higher probability of generating SSs than the non-PIs. Moreover, the MCs containing carbon-cold and helium-enhanced materials (MC&PIs) have the highest fraction of minimum B_z , less than -11 nT. Since the MC&PIs have large-scale magnetic flux rope and prominence material, the stronger southward IMF is probably provided by the prominence. It is in accordance with the observed injection of enhanced twisted flux ropes to prominence. Therefore, the detailed eruption and propagation processes of the three-part coronal mass ejections deserve more concern from a space weather perspective. **2000.07.27-29, 2000-10-29, 2001.06.26-27, 2005-09-11**

Table 2. 95 Single Storms and the Related ICMEs Selected from Feng et al. (2018)

Characteristics of solar wind rotation

Kejun Li, W. Feng

MNRAS Volume 489, Issue 3, Pages 3427–3435, 2019

<https://arxiv.org/pdf/1908.11021.pdf>

<https://doi.org/10.1093/mnras/stz2407>

Over 54 years of hourly mean value of solar wind velocity from 27 Nov. 1963 to 31 Dec. 2017 are used to investigate characteristics of the rotation period of solar wind through auto-correlation analysis. Solar wind of high velocity is found to rotate faster than low-velocity wind, while its rotation rate increases with velocity increasing, but in contrast for solar wind of low velocity, its rotation rate decreases with velocity increasing. Our analysis shows that solar wind of a higher velocity statistically possesses a faster rotation rate for the entire solar wind. The yearly rotation rate of solar wind velocity does not follow the Schwabe cycle, but it is significantly negatively correlated to yearly sunspot number when it leads by 3 years. Physical explanations are proposed to these findings.

Electromagnetic Waves around the Proton Cyclotron Frequency in the Sheath Regions of Interplanetary Magnetic Clouds: STEREO Observations

Q. H. Li^{1,2}, L. Yang^{1,3}, D. J. Wu¹, and T. Y. Wang⁴

2019 ApJ 874 55

sci-hub.se/10.3847/1538-4357/ab06f7

The compressed and turbulent sheath regions of interplanetary magnetic clouds (IMCs) provide a natural laboratory to study electromagnetic waves (EMWs) around the proton cyclotron frequency f_{cp} . Based on the Morlet wavelet spectral analysis, the repeated filtering analysis and the minimum variance analysis of high-resolution magnetic field data from the STEREO spacecraft, 81 EMW events are identified in the sheath regions of six IMCs. These EMWs are all transverse, almost circularly polarized, and quasi-parallel propagating along the background magnetic field. They can be left-handed (LH) or right-handed (RH) polarized in the spacecraft frame, where the occurrence rate of the LH-polarized EMWs is higher than that of RH-polarized ones, consistent with previous observations in the solar wind. Also, a comparative analysis of polarization sense of these EMWs has been made in the spacecraft and plasma frames. Our results show that more than half of EMW events suffer a polarization reversal from the spacecraft to plasma frames, which are deduced to propagate inward relative to the solar wind flow. Others are outward-propagating waves. In the plasma frame, the outward-propagating LH-EMWs and inward-propagating RH-EMWs have relatively higher occurrence rates than the inward-propagating LH-EMWs and outward-propagating RH-EMWs, respectively. Furthermore, in the plasma frame all the frequencies of LH-EMWs are below f_{cp} , but the RH-EMW frequencies can exceed f_{cp} . These results are helpful in understanding the physical properties of EMWs and their roles in the sheath regions of IMCs.

Magnetic Clouds: Solar Cycle Dependence, Sources, and Geomagnetic Impacts

Magnetic clouds (MCs) are transient magnetic structures giving the strongest southward magnetic field (B_z south) in the solar wind. The sheath regions of MCs may also carry a southward magnetic field. The southward magnetic field is responsible for space-weather disturbances. We report a comprehensive analysis of MCs and B_z components in their sheath regions for 1995 to 2017. 85% of 303 MCs contain a south B_z up to 50 nT. Sheath B_z during the 23 years may reach as high as 40 nT. MCs of the strongest magnetic magnitude and B_z south occur in the declining phase of the solar cycle. Bipolar MCs depend on the solar cycle in their polarity, but not in the occurrence frequency. Unipolar MCs show solar-cycle dependence in their occurrence frequency, but not in their polarity. MCs with the highest speeds, the largest

total-BB magnitudes, and sheath Bz south originate from source regions closer to the solar disk center. About 80% of large Dst storms are caused by MC events. Combinations of a south Bz in the sheath and south-first MCs in close succession have caused the largest storms. The solar-cycle dependence of bipolar MCs is extended to 2017 and now spans 42 years. We find that the bipolar MC Bz polarity solar-cycle dependence is given by MCs that originated from quiescent filaments in decayed active regions and a group of weak MCs of unclear sources, while the polarity of bipolar MCs with active-region flares always has a mixed Bz polarity without solar-cycle dependence and is therefore the least predictable for Bz forecasting. **17 March 2015, 20 Dec 2015**

Reconstructing solar wind inhomogeneous structures from stereoscopic observations in white-light: Small transients along the Sun-Earth line

The Heliospheric Imagers (HI) on board the two spacecraft of the Solar Terrestrial Relations Observatory (STEREO) provided white-light images of transients in the solar wind from dual perspectives from 2007 to 2014. In this paper, we develop a new method to identify and locate the transients automatically from simultaneous images from the two inner telescopes, known as HI-1, based on a correlation analysis. Correlation coefficient (cc) maps along the Sun-Earth line are constructed for the period from 1 Jan 2010 to 28 Feb 2011. From the maps, transients propagating along the Sun-Earth line are identified, and a 27-day periodic pattern is revealed, especially for small-scale transients. Such a periodicity in the transient pattern is consistent with the rotation of the Sun's global magnetic structure and the periodic crossing of the streamer structures and slow solar wind across the Sun-Earth line, and this substantiates the reliability of our method and the high degree of association between the small-scale transients of the slow solar wind and the coronal streamers. Besides, it is suggested by the cc map that small-scale transients along the Sun-Earth line are more frequent than large-scale transients by a factor of at least 2, and that they quickly diffused into background solar wind within about 40 Rs in terms of the signal-to-noise ratio of white-light emissions. The method provides a new tool to reconstruct inhomogeneous structures in the heliosphere from multiple perspectives.

Magnetic Clouds: Solar Cycle Dependence, Sources, and Geomagnetic Impacts

PLASMA HEATING INSIDE INTERPLANETARY CORONAL MASS EJECTIONS BY ALFVÉNIC FLUCTUATIONS DISSIPATION

Hui Li¹, Chi Wang¹, Jiansen He², Lingqian Zhang¹, John D. Richardson³, John W. Belcher³, and Cui Tu⁴
2016 ApJL 831 L13

Nonlinear cascade of low-frequency Alfvénic fluctuations (AFs) is regarded as one of the candidate energy sources that heat plasma during the non-adiabatic expansion of interplanetary coronal mass ejections (ICMEs). However, AFs inside ICMEs were seldom reported in the literature. In this study, we investigate AFs inside ICMEs using observations from Voyager 2 between 1 and 6 au. It has been found that AFs with a high degree of Alfvénicity frequently occurred

inside ICMEs for almost all of the identified ICMEs (30 out of 33 ICMEs) and for 12.6% of the ICME time interval. As ICMEs expand and move outward, the percentage of AF duration decays linearly in general. The occurrence rate of AFs inside ICMEs is much less than that in ambient solar wind, especially within 4.75 au. AFs inside ICMEs are more frequently presented in the center and at the boundaries of ICMEs. In addition, the proton temperature inside ICME has a similar "W"-shaped distribution. These findings suggest significant contribution of AFs on local plasma heating inside ICMEs.

Mapping magnetic field lines between the Sun and Earth†

JGR 2016

Magnetic field topologies between the Sun and Earth are important for the connectivity to Earth of solar suprathermal particles, e.g., solar energetic particles and beam electrons in type III solar radio bursts. An approach is developed for mapping large-scale magnetic field lines near the solar equatorial plane, using near-Earth observations and a solar wind model with nonzero azimuthal magnetic field at the source surface. Unlike Parker's spiral model, which restricts the in-ecliptic angle Φ_B in the Geocentric Solar Ecliptic coordinates to $(90^\circ - 180^\circ, 270^\circ - 360^\circ)$, and so is unable to predict field configurations for the other Φ_B values frequently observed in the solar wind, our approach can account for all the observed Φ_B values. A set of predicted maps show that near both minimal and maximal solar activity the field lines are typically open and that loops with both ends either connected to or disconnected from the Sun are relatively rare. The open field lines, nonetheless, often do not closely follow the Parker spiral, being less or more tightly wound, or strongly azimuthally or radially oriented, or inverted. The time-varying classes, e.g., bidirectional electrons, of suprathermal electron pitch angle distributions (PADs) at 1 AU are predicted from the mapped field line configurations and compared with Wind observations for two solar rotations, one each near solar minimum and solar maximum. PAD predictions by our approach agree quantitatively ($\approx 90\%$) with the PAD observations and outperform (by $\approx 20\%$) PAD predictions using Parker's model.

Magnetic Clouds and Origins in STEREO Era†

JGR, Volume 119, Issue 5, pages 3237–3246, May 2014; File

When a CME encounters the Earth, the Earth's electromagnetic environment is disturbed, especially when it is a Magnetic Cloud (MC) with enhanced, steady and long lasting southward field. The speed and the magnetic field of an MC are the two important properties for its geoeffectiveness. The correspondence between a CME and its resulting MC is not straight forward, partly due to the CME velocity and the complications during propagation through corona and the solar wind. From 2007 to 2012, we have three observing points at 1 AU near the ecliptic plane (ACE, STEREO A and B). We search for MC events encountered at one of the three observers and study the statistics independently and in comparison. We found that the annual number of MCs at each receiver vary significantly, and the temporal variation at each receiver does not always follow the solar activity level. The speed and the magnetic field strength of the MCs do vary with the solar activity level. The polarity of MC magnetic field at ACE and STEREO also shows large fluctuations. We have also identified the CME and solar activity sources for the L1 MC events. STEREO SECCHI images served critical roles in the determination of the CMEs both in solar quiet times and active times. We found that halo CMEs are not necessarily good indicators for receiving MCs. Further studies of CME initial velocity and the propagation through the heliosphere are needed in order to improve our space weather forecasting capability.

New approach for solving the inverse boundary value problem of Laplace's equation on a circle: Technique renovation of the Grad-Shafranov (GS) reconstruction

H. J. Li^{1,2}, X. S. Feng, ^{2,*}, J. Xiang, ¹, P. B. Zuo

JGR, Volume 118, Issue 6, pages 2876–2881, June 2013

In this paper, the essential technique of Grad-Shafranov (GS) reconstruction is reformulated into an inverse boundary value problems (IBVPs) for Laplace's equation on a circle by introducing a Hilbert transform between the normal and tangent component of the boundary gradients. It is proved that the specified IBVPs have unique solution, given the known Dirichlet and Neumann conditions on certain arc. Even when the arc is reduced to only one point on the circle, it can be inferred logically that the unique solution still exists there on the remaining circle. New solution approach for the specified IBVP is suggested with the help of the introduced Hilbert transform. An iterated Tikhonov regularization scheme is applied to deal with the ill-posed linear operators appearing in the discretization of the new approach.

Numerical experiments highlight the efficiency and robustness of the proposed method. According to linearity of the elliptic operator in GS equation, its solution can be divided into two parts. One is solved from a semilinear elliptic equation with an homogeneous Dirichlet boundary condition. The other is solved from the IBVP of Laplace's equation. It is concluded that there exists a unique solution for the so-called elliptic Cauchy problem for the essential technique of GS reconstruction.

Cyclic Reversal of Magnetic Cloud Poloidal Field
